Waste Product Accumulation. The kidneys are the primary excretory organs for urea (an end product of protein metabolism) and creatinine (an end product of endogenous muscle metabolism). BUN and serum creatinine levels are elevated in kidney failure. An elevated BUN level must be interpreted with caution because it can also be caused by dehydration; corticosteroids; or catabolism resulting from infections, fever, severe injury, or GI bleeding. The best serum indicator of AKI is creatinine because it is not significantly altered by other factors.

Neurologic Disorders. Neurologic changes can occur as the nitrogenous waste products accumulate in the brain and other nervous tissue. The manifestations can be as mild as fatigue and difficulty concentrating, and then escalate to seizures, stupor, and coma. *Asterixis* (flapping tremor when the wrist is extended) is most common with liver failure, but has been known to occur with advanced and severe kidney dysfunction. The flapping resembles a bird flapping its wings when the hands and wrists are extended outward.

Diuretic Phase. During the diuretic phase of AKI, daily urine output is usually around 1 to 3 L, but may reach 5 L or more. Although urine output is increasing, the nephrons are still not fully functional. The high urine volume is caused by osmotic diuresis from the high urea concentration in the glomerular filtrate and the inability of the tubules to concentrate the urine. In this phase the kidneys have recovered their ability to excrete wastes, but not to concentrate the urine. Hypovolemia and hypotension can occur from massive fluid losses. Patients who develop an oliguric phase will have greater diuresis than patients without oliguria.

Because of the large losses of fluid and electrolytes, the patient must be monitored for hyponatremia, hypokalemia, and dehydration. The diuretic phase may last 1 to 3 weeks. Near the end of this phase, the patient's acid-base, electrolyte, and waste product (BUN, creatinine) values begin to normalize.

Recovery Phase. The recovery phase begins when the GFR increases, allowing the BUN and serum creatinine levels to plateau and then decrease. Although the major improvements occur in the first 1 to 2 weeks of this phase, kidney function may take up to 12 months to stabilize.

The outcome of AKI is influenced by the patient's overall health, the severity of kidney failure, and the number and type of complications. Some individuals do not recover and progress to end-stage kidney disease. The older adult is less likely to have a complete recovery of kidney function. Most patients who recover achieve clinically normal kidney function with no complications (e.g., hypertension). Some scar tissue remains, but loss of function is not clinically significant.

Diagnostic Studies

A thorough history is essential for diagnosing the etiology of AKI. Consider prerenal causes when there is a history of dehydration, blood loss, or severe heart disease. Suspect intrarenal causes if the patient has been exposed to potentially nephrotoxic drugs or has a recent history of a blood transfusion or radiologic study using contrast media. Postrenal causes are suggested by a history of changes in the urinary stream, stones, benign prostatic hyperplasia, or cancer of the bladder or prostate.

Although changes in urine output and serum creatinine occur relatively late in the course of AKI, there are no better criteria for a diagnosis of AKI. An increase in serum creatinine may not be evident until there is a loss of more than 50% of kidney function. The rate of increase in serum creatinine is also important as a diagnostic indicator and in determining the severity of injury.

Urinalysis is an important diagnostic test. Urine sediment containing abundant cells, casts, or proteins suggests intrarenal

disorders. The urine osmolality, sodium content, and specific gravity help in differentiating the causes of AKI. Urine sediment may be normal in both prerenal and postrenal AKI. In intrarenal problems, hematuria, pyuria, and crystals may be seen.

To establish a diagnosis of AKI, other testing may be required. A kidney ultrasound is often the first test done, since it provides imaging without exposure to potentially nephrotoxic contrast agents. It is useful for evaluating for possible kidney disease and obstruction of the urinary collection system. A renal scan can assess abnormalities in kidney blood flow, tubular function, and the collecting system. A computed tomography (CT) scan can identify lesions, masses, obstructions, and vascular anomalies. A renal biopsy is considered the best method for confirming intrarenal causes of AKI.

Obtaining a magnetic resonance imaging (MRI) or magnetic resonance angiography (MRA) study with the contrast media gadolinium is not advised in patients with kidney failure unless there is a significant reason to do these tests or unless the ultrasound or CT will not provide the information needed. Administration of gadolinium has been associated with the development of a devastating and potentially lethal disorder, *nephrogenic systemic fibrosis,* in patients with kidney failure. The disease is characterized by skin hyperpigmentation and induration and joint contractures. However, the fibrosis can also develop in other organs.

In patients with normal kidney function, administration of contrast media poses minimal risk. In patients with kidney failure, *contrast-induced nephropathy* (CIN) can occur when contrast media for diagnostic studies causes nephrotoxic injury. The best way to avoid CIN is to avoid exposure to contrast media by using other diagnostic tests such as ultrasound. If contrast media must be administered to a high-risk patient, the patient needs to have optimal hydration and a low dose of the contrast agent. Treatment to prevent CIN remains controversial. Optimal hydration is the goal, but debate continues on whether a bicarbonate or sodium chloride solution with or without the prophylactic administration of *N*-acetylcysteine (Mucomyst) is beneficial.

Collaborative Care

Because AKI is potentially reversible, the primary goals of treatment are to eliminate the cause, manage the signs and symptoms, and prevent complications while the kidneys recover[2] (Table 47-4). The first step is to determine if there is adequate intravascular volume and cardiac output to ensure adequate perfusion of the kidneys. Diuretic therapy is often administered but not recommended in high doses. Diuretic therapy usually includes loop diuretics (e.g., furosemide [Lasix], bumetanide [Bumex]) or an osmotic diuretic (e.g., mannitol). If AKI is already established, forcing fluids and diuretics will not be effective and may, in fact, be harmful.

Closely monitor fluid intake during the oliguric phase of AKI. The general rule for calculating the fluid restriction is to add all losses for the previous 24 hours (e.g., urine, diarrhea, emesis, blood) plus 600 mL for insensible losses (e.g., respiration, diaphoresis). For example, if a patient excreted 300 mL of urine on Tuesday with no other losses, the fluid allocation on Wednesday would be 900 mL.

Hyperkalemia is one of the most serious complications in AKI because it can cause life-threatening cardiac dysrhythmias. The various therapies used to treat elevated potassium levels are listed in Table 47-5. Both insulin and sodium bicarbonate serve as a temporary measure for treatment of hyperkalemia by promoting a shift of potassium into the cells, but potassium will eventually be released. Calcium gluconate raises the threshold at which dysrhythmias occur, temporarily stabilizing the myocardium. Only sodium polystyrene sulfonate (Kayexalate) and

TABLE 47-4 COLLABORATIVE CARE

Acute Kidney Injury

Diagnostic
- History and physical examination
- Identification of precipitating cause
- Serum creatinine and BUN levels
- Serum electrolytes
- Urinalysis
- Renal ultrasound
- Renal scan
- CT scan

Collaborative Therapy
- Treatment of precipitating cause
- Fluid restriction (600 mL plus previous 24-hr fluid loss)
- Nutritional therapy
  - Adequate protein intake (0.6-2 g/kg/day) depending on degree of catabolism
  - Potassium restriction
  - Phosphate restriction
  - Sodium restriction
- Measures to lower potassium (if elevated) (see Table 47-5)
- Calcium supplements or phosphate-binding agents
- Enteral nutrition
- Parenteral nutrition
- Initiation of dialysis (if necessary)
- Continuous renal replacement therapy (if necessary)

TABLE 47-5 THERAPIES FOR ELEVATED POTASSIUM LEVELS

Regular Insulin IV
- Potassium moves into cells when insulin is given.
- IV glucose is given concurrently to prevent hypoglycemia.
- When effects of insulin diminish, potassium shifts back out of cells.

Sodium Bicarbonate
- Therapy can correct acidosis and cause a shift of potassium into cells.

Calcium Gluconate IV
- Generally used in advanced cardiac toxicity (with evidence of hyperkalemic ECG changes).
- Calcium raises the threshold for excitation, resulting in dysrhythmias.

Hemodialysis
- Most effective therapy to remove potassium.
- Works within a short time.

Sodium Polystyrene Sulfonate (Kayexalate)
- Cation-exchange resin is administered by mouth or retention enema.
- When resin is in the bowel, potassium is exchanged for sodium.
- Therapy removes 1 mEq of potassium per gram of drug.
- It is mixed in water with sorbitol to produce osmotic diarrhea, allowing for evacuation of potassium-rich stool from body.

Dietary Restriction
- Potassium intake is limited to 40 mEq/day.
- Primarily used to prevent recurrent elevation; not used for acute elevation.

dialysis actually remove potassium from the body. Never give this drug to a patient with a paralytic ileus because bowel necrosis can occur.

Conservative therapy may be all that is necessary until kidney function improves. Controversy exists about the timing of renal replacement therapy (RRT) in AKI.[10] The most common indications for RRT in AKI are (1) volume overload, resulting in compromised cardiac and/or pulmonary status; (2) elevated serum potassium level; (3) metabolic acidosis (serum bicarbonate level less than 15 mEq/L [15 mmol/L]); (4) BUN level greater than 120 mg/dL (43 mmol/L); (5) significant change in mental status; and (6) pericarditis, pericardial effusion, or cardiac tamponade. Although laboratory values provide rough parameters, the best guide to treatment is good clinical assessment.

If RRT is required, many options are available, but there is no consensus regarding the best approach.[10] Even though peritoneal dialysis (PD) is considered a viable option for RRT, it is not frequently used. Intermittent hemodialysis (HD) (e.g., at intervals of 4 hours either daily, every other day, or 3 or 4 times per week) and *continuous renal replacement therapy* (CRRT) have both been used effectively.

CRRT is provided continuously over approximately 24 hours through cannulation of an artery and vein or cannulation of two veins. CRRT has much slower blood flow rates compared with intermittent HD.

HD is the method of choice when rapid changes are required in a short time. It is technically more complicated because specialized staff and equipment and a vascular access are required. It also requires anticoagulation therapy to prevent the patient's blood from clotting when the blood contacts the foreign material in the extracorporeal dialysis circuit. Rapid fluid shifts during HD may cause hypotension.

RRT and CRRT are discussed later in this chapter on pp. 1123-1124.

Nutritional Therapy. The challenge of nutritional management in AKI is to provide adequate calories to prevent catabolism despite the restrictions required to prevent electrolyte and fluid disorders and azotemia. A primary nutritional goal in AKI is to maintain adequate caloric intake (providing 30 to 35 kcal/kg and 0.8 to 1.0 g of protein per kilogram of desired body weight) to prevent the further breakdown of body protein for energy purposes. Adequate energy should be primarily from carbohydrate and fat sources to prevent ketosis from endogenous fat breakdown and gluconeogenesis from muscle protein breakdown. Supplementation of essential amino acids can be given.

Potassium and sodium are regulated in accordance with plasma levels. Sodium is restricted as needed to prevent edema, hypertension, and HF. Dietary fat intake is increased so that the patient receives at least 30% to 40% of total calories from fat. Fat emulsion IV infusions given as a nutritional supplement provide a good source of nonprotein calories (see Chapter 40).

If a patient cannot maintain adequate oral intake, enteral nutrition is the preferred route for nutritional support (see Chapter 40). When the gastrointestinal (GI) tract is not functional, parenteral nutrition is necessary to provide adequate nutrition. The patient treated with parenteral nutrition may need daily HD or CRRT to remove the excess fluid. Concentrated formulas of parenteral nutrition are available to minimize fluid volume.

NURSING MANAGEMENT
ACUTE KIDNEY INJURY

NURSING ASSESSMENT

Monitor vital signs and fluid intake and output. Daily monitoring of a patient's urine output has prognostic implications and is crucial for determining therapy and daily fluid volume replacement. Examine the urine for color, specific gravity, glucose, protein, blood, and sediment. Assess the patient's general appearance, including skin color, edema, neck vein distention, and bruises.

If a patient is receiving dialysis, observe the access site for inflammation and exudate. Evaluate the patient's mental status and level of consciousness. Examine the oral mucosa for dryness and inflammation. Auscultate the lungs for crackles and rhonchi or diminished breath sounds. Monitor the heart for an S_3 gallop, murmurs, or a pericardial friction rub. Assess ECG readings for dysrhythmias. Review laboratory values and diagnostic test results. All of the previous data are essential for developing a collaborative plan of care.

NURSING DIAGNOSES

Nursing diagnoses and a potential complication for the patient with AKI include, but are not limited to, the following:

- Excess fluid volume *related to* kidney failure and fluid retention
- Risk for infection *related to* invasive lines, uremic toxins, and altered immune responses secondary to kidney failure
- Fatigue *related to* anemia, metabolic acidosis, and uremic toxins
- Anxiety *related to* disease processes, therapeutic interventions, and uncertainty of prognosis
- Potential complication: dysrhythmias *related to* electrolyte imbalances

PLANNING

The overall goals are that the patient with AKI will (1) completely recover without any loss of kidney function, (2) maintain normal fluid and electrolyte balance, (3) have decreased anxiety, and (4) adhere to and understand the need for careful follow-up care.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Prevention and early recognition of AKI are the most important components of care.[11] Prevention is primarily directed toward identifying and monitoring high-risk populations, controlling exposure to nephrotoxic drugs and industrial chemicals, and preventing prolonged episodes of hypotension and hypovolemia. In the hospital the factors that increase the risk for developing AKI are preexisting CKD, older age, massive trauma, major surgical procedures, extensive burns, cardiac failure, sepsis, or obstetric complications.

Careful monitoring of intake and output and fluid and electrolyte balance is essential. Assess and record extrarenal losses of fluid from vomiting, diarrhea, hemorrhage, and increased insensible losses. Prompt replacement of significant fluid losses helps prevent ischemic tubular damage associated with trauma, burns, and extensive surgery. Intake and output records and the patient's weight provide valuable indicators of fluid volume status. Aggressive diuretic therapy for the patient with fluid overload from any cause can lead to a reduction in renal blood flow.[12]

The individual who is taking drugs that are potentially nephrotoxic (see Table 45-3) must have his or her kidney function monitored. Nephrotoxic drugs should be used sparingly in the high-risk patient. When these drugs must be used, they should be given in the smallest effective doses for the shortest possible periods. Caution the patient about abuse of over-the-counter analgesics (especially nonsteroidal antiinflammatory drugs [NSAIDs]) because some of these may worsen kidney function in the patient with mild CKD.

Angiotensin-converting enzyme (ACE) inhibitors can also decrease perfusion pressure and cause hyperkalemia. If other measures such as diet modification, diuretics, and sodium bicarbonate cannot control the hyperkalemia, ACE inhibitors may need to be reduced or eliminated. However, ACE inhibitors are frequently used to prevent proteinuria and progression of kidney disease, especially in diabetic patients.[13]

ACUTE INTERVENTION. The patient with AKI is critically ill and suffers from the effects of not only kidney disease but also co-morbid diseases or conditions (e.g., diabetes, CV disease). Focus on the patient holistically, since he or she will have many physical and emotional needs. Usually the changes caused by AKI arise suddenly. Both the patient and caregiver need assistance in understanding that the whole body's functioning can be disrupted by kidney failure.

You have an important role in managing fluid and electrolyte balance during the oliguric and diuretic phases. Observe and record accurate intake and output. Take daily weights with the same scale at the same time each day to detect excessive gains or losses of body fluid (1 kg is equivalent to 1000 mL of fluid). Assess for the common signs and symptoms of hypervolemia (in the oliguric phase) or hypovolemia (in the diuretic phase), potassium and sodium disturbances, and other electrolyte imbalances that may occur in AKI (see Chapter 17).

Because infection is the leading cause of death in AKI, meticulous aseptic technique is critical. Protect the patient from other individuals with infectious diseases. Be alert for local manifestations of infection (e.g., swelling, redness, pain), as well as systemic manifestations (e.g., fever, malaise, leukocytosis), but realize that the temperature may not always be elevated. Patients with kidney failure have a blunted febrile response to an infection (e.g., pneumonia). If antibiotics are used to treat an infection, the type, frequency, and dosage must be carefully considered because the kidneys are the primary route of excretion for many antibiotics. Dosages need to be considered in light of the patient's level of kidney function if the drug is primarily eliminated by the kidneys. Nephrotoxic drugs (see Table 45-3) should be used judiciously.

Perform skin care and take measures to prevent pressure ulcers because the patient usually develops edema and decreased muscle tone. Mouth care is important to prevent stomatitis, which develops when ammonia (produced by bacterial breakdown of urea) in saliva irritates the mucous membranes.

INFORMATICS IN PRACTICE

Computer Monitoring of Antibiotic Safety

- Many patients receiving antibiotic therapy are at risk for kidney failure.
- Set the computer to alert you about elevated creatinine levels and, if possible, send you a text message.
- With earlier notification of the health care provider, medications can be stopped or doses adjusted and the patient's kidney function preserved.

AMBULATORY AND HOME CARE. Recovery from AKI is highly variable and depends on other organ system failures, the patient's general condition and age, the length of the oliguric phase, and the severity of nephron damage. Protein and potassium intake should be regulated in accordance with kidney function. Follow-up care and regular evaluation of kidney function are necessary. Teach the patient the signs and symptoms of recurrent kidney disease. Emphasize measures to prevent the recurrence of AKI.

The long-term convalescence of 3 to 12 months may cause psychosocial and financial hardships for both the patient and the family. Make appropriate referrals for counseling. If the kidneys do not recover, the patient will need to transition to life on chronic dialysis or possible future transplantation.

EVALUATION

The expected outcomes are that the patient with AKI will

- Regain and maintain normal fluid and electrolyte balance
- Adhere to the treatment regimen
- Experience no complications
- Have a complete recovery

GERONTOLOGIC CONSIDERATIONS

ACUTE KIDNEY INJURY

Older adults are at risk for the same causes of AKI as younger adults. However, they are more susceptible to AKI. Dehydration is a predisposing factor and tends to occur much more frequently in older adults. Dehydration is associated with polypharmacy (diuretics, laxatives, and drugs that suppress appetite or consciousness), acute febrile illnesses, and immobility from being bedridden.

In addition to dehydration, other common causes of AKI in the older adult include hypotension, diuretic therapy, aminoglycoside therapy, obstructive disorders (e.g., prostatic hyperplasia), surgery, infection, and contrast media.

In older adults, impaired function of other organ systems from CV disease or diabetes mellitus can increase the risk of developing AKI. The aging kidney is less able to compensate for changes in fluid volume, solute load, and cardiac output. Mortality rates are similar for older patients and younger patients. However, patients over 65 years of age are less likely to recover from AKI. Despite this, a patient's chronologic age should not be factored into the decision about whether to institute RRT.[9,10]

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) involves progressive, irreversible loss of kidney function. The Kidney Disease Outcomes Quality Initiative (KDOQI) of the National Kidney Foundation defines CKD as either the presence of kidney damage or a decreased GFR less than 60 mL/min/1.73 m^2 for longer than 3 months. The classification of CKD is presented in Table 47-6. The last stage of kidney failure, **end-stage kidney (renal) disease (ESKD),** occurs when the GFR is less than 15 mL/min. At this point, RRT (dialysis or transplantation) is required to maintain life.

Although CKD has many different causes, the leading causes are diabetes (about 50%) and hypertension (about 25%). Less common etiologies include glomerulonephritis, cystic diseases, and urologic diseases.[14] (Diseases of the renal system that affect the kidney are discussed in Chapter 46.) CKD is much more

TABLE 47-6 STAGES OF CHRONIC KIDNEY DISEASE

Description	GFR (mL/min/1.73 m²)	Clinical Action Plan
Stage 1 Kidney damage with normal or ↑ GFR	≥90	Diagnosis and treatment CVD risk reduction Slow progression
Stage 2 Kidney damage with mild ↓ GFR	60-89	Estimation of progression
Stage 3 Moderate ↓ GFR	30-59	Evaluation and treatment of complications
Stage 4 Severe ↓ GFR	15-29	Preparation for renal replacement therapy (dialysis, kidney transplant)
Stage 5 Kidney failure	<15 (or dialysis)	Renal replacement therapy (if uremia present and patient desires treatment)

Source: National Kidney Foundation. *www.kidney.org/kidneydisease/aboutckd.cfm.*

common than AKI (see Table 47-1). The increasing prevalence of CKD has been partially attributed to the increase in risk factors, including an aging population, rise in rates of obesity, and increased incidence of diabetes and hypertension.[14,15]

More than 26 million American adults have CKD, and a million more are at increased risk. One of every nine Americans has CKD. Over half a million Americans are receiving treatment (dialysis, transplant) for ESKD. Despite all the technologic advances in life-sustaining treatment with dialysis, patients with ESKD have a high mortality rate. As the stage of kidney disease progresses, the mortality rate also increases. Mortality rates are as high as 19% to 24% for individuals with stage 5 CKD on dialysis. About 20% of patients with ESKD receiving dialysis die each year.[14]

Because the kidneys are highly adaptive, kidney disease is often not recognized until there has been considerable loss of nephrons. Because patients with CKD are frequently asymptomatic, CKD is underdiagnosed and undertreated. It has been estimated that about 70% of people with CKD are unaware that they have the disease.[14]

The prognosis and course of CKD are highly variable depending on the etiology, patient's condition and age, and adequacy of health care follow-up. Some individuals live normal, active lives with compensated kidney failure, whereas others may rapidly progress to ESKD (stage 5). Since 1972, the United States has covered the majority of the costs of providing dialysis for those eligible for Medicare benefits. Under Title XVIII of the Social Security Act, ESKD was recognized as a disability. As such, more than 90% of individuals of any age who have ESKD are eligible for financial assistance for treatment through Medicare. Medicare pays for 80% of eligible charges, with the remaining being paid for by state or private insurance or out of pocket.[14]

Clinical Manifestations

As kidney function deteriorates, every body system becomes affected. The clinical manifestations are a result of retained substances, including urea, creatinine, phenols, hormones, electrolytes, and water. **Uremia** is a syndrome in which kidney function declines to the point that symptoms may develop in multiple body systems (Fig. 47-2). It often occurs when the GFR is 10 mL/min or less.

The manifestations of uremia vary among patients according to the cause of the kidney disease, co-morbid conditions, age, and degree of adherence to the prescribed medical regimen. Many patients are tolerant of the changes because they occur gradually.

Urinary System. In the early stages of CKD, patients usually do not report any change in urine output. Since diabetes is the primary cause of CKD, polyuria may be present, but not necessarily as a consequence of kidney disease. Because most people continue to have sufficient urine output, it is often difficult to convince them that they have kidney disease. As CKD progresses, patients have increasing difficulty with fluid retention and require diuretic therapy. After a period on dialysis, patients may develop anuria.

Metabolic Disturbances

Waste Product Accumulation. As the GFR decreases, the BUN and serum creatinine levels increase. The BUN is increased not only by kidney failure, but also by protein intake, fever, corticosteroids, and catabolism. For this reason, serum creatinine clearance determinations (calculated GFR) are considered more accurate indicators of kidney function than BUN or creatinine. Significant elevations in BUN contribute to development of nausea, vomiting, lethargy, fatigue, impaired thought processes, and headaches.

Altered Carbohydrate Metabolism. Defective carbohydrate metabolism is caused by impaired glucose metabolism, resulting from cellular insensitivity to the normal action of insulin. Mild to moderate hyperglycemia and hyperinsulinemia may occur. Insulin and glucose metabolism may improve (but not to normal values) after the initiation of dialysis.

Patients with diabetes who develop uremia may require less insulin than before the onset of CKD. This is because insulin, which depends on the kidneys for excretion, remains in circulation longer. As a result, a number of patients who required insulin before starting dialysis will be able to discontinue insulin therapy when they start dialysis and their kidney disease pro-

CULTURAL & ETHNIC HEALTH DISPARITIES

Chronic Kidney Disease

- Chronic kidney disease (CKD) has a high incidence in minority populations, especially African Americans and Native Americans.
- Hypertension and diabetes mellitus are also more common in African Americans and Native Americans.

African Americans

- The risk of CKD as a complication of hypertension is significantly increased in African Americans.
- African Americans have the highest rate of CKD, nearly four times that of whites.

Native Americans

- Native Americans have a rate of CKD twice that of whites.
- The rate of CKD is six times higher among Native Americans with diabetes than among other ethnic groups with diabetes.

Hispanics

- The rate of CKD in Hispanics is 1.5 times higher than in non-Hispanic whites.

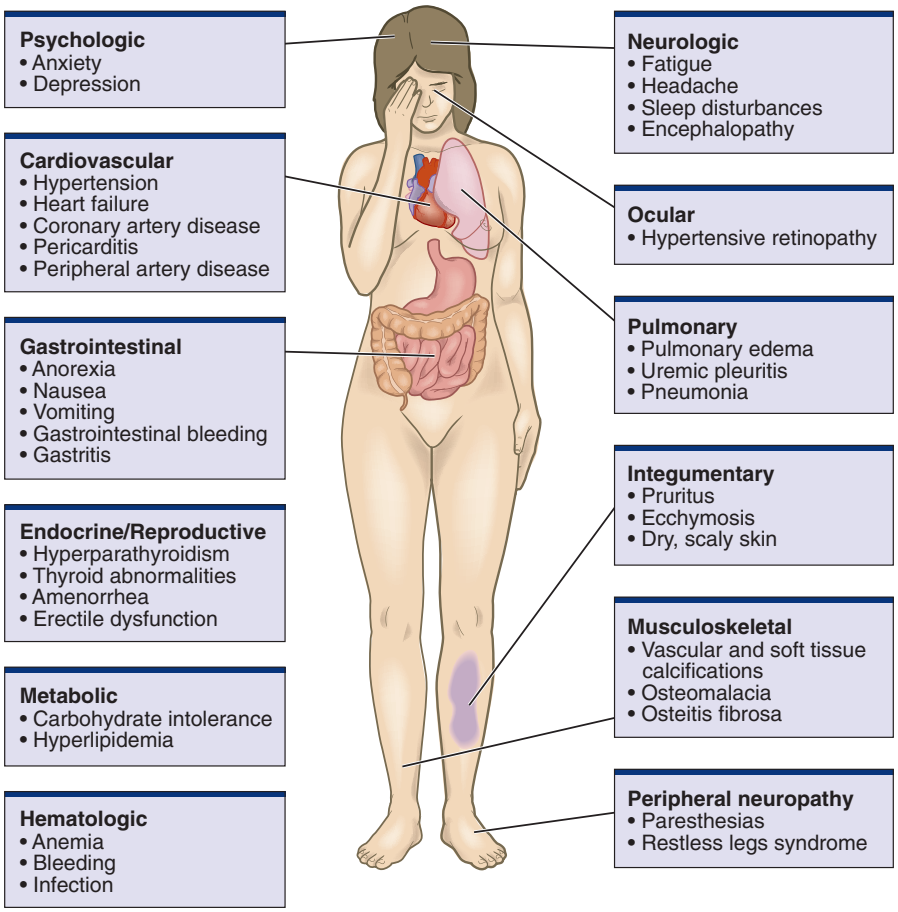

FIG. 47-2 Possible clinical manifestations of chronic kidney disease.

gresses. The insulin dosing must be individualized and glucose levels monitored carefully.

Elevated Triglycerides. Hyperinsulinemia stimulates hepatic production of triglycerides. Almost all patients with uremia develop dyslipidemia, with increased very-low-density lipoproteins (VLDLs), increased low-density lipoproteins (LDLs), and decreased high-density lipoproteins (HDLs). The altered lipid metabolism is related to decreased levels of the enzyme lipoprotein lipase, which is important in the breakdown of lipoproteins. Most patients with CKD die from CV disease.[15]

Electrolyte and Acid-Base Imbalances

Potassium. Hyperkalemia is a serious electrolyte disorder associated with kidney disease. Fatal dysrhythmias have been reported when the serum potassium level reaches 7 to 8 mEq/L (7 to 8 mmol/L). Hyperkalemia results from the decreased excretion of potassium by the kidneys, the breakdown of cellular protein, bleeding, and metabolic acidosis. Potassium may also come from the food consumed, dietary supplements, drugs, and IV infusions.

Sodium. Sodium may be elevated, normal, or low in kidney failure. Because of impaired sodium excretion, sodium along with water is retained. If large quantities of water are retained, dilutional hyponatremia occurs. Sodium retention can contribute to edema, hypertension, and HF. Sodium intake must be individually determined but is generally restricted to 2 g/day.

Calcium and Phosphate. Calcium and phosphate alterations are discussed in the section on the musculoskeletal system on p. 1110.

Magnesium. Magnesium is primarily excreted by the kidneys. Hypermagnesemia is generally not a problem unless the patient is ingesting magnesium (e.g., milk of magnesia, magnesium citrate, antacids containing magnesium). Clinical manifestations of hypermagnesemia can include absence of reflexes, decreased mental status, cardiac dysrhythmias, hypotension, and respiratory failure.

Metabolic Acidosis. Metabolic acidosis results from the kidneys' impaired ability to excrete the acid load (primarily ammonia) and from defective reabsorption and regeneration of bicarbonate. The average adult produces 80 to 90 mEq of acid per day. This acid is normally buffered by bicarbonate. In kidney failure, plasma bicarbonate, which is an indirect measure of acidosis, usually falls to a new steady state at around 16 to 20 mEq/L (16 to 20 mmol/L). The decrease in plasma bicarbonate reflects its use in buffering metabolic acids. The bicarbonate level generally does not progress below this level because hydrogen ion production is usually balanced by buffering from demineralization of the bone (the phosphate buffering system).

Hematologic System

Anemia. A normocytic, normochromic anemia is associated with CKD. The anemia is due to decreased production of the hormone erythropoietin by the kidneys. Erythropoietin normally stimulates precursor cells in the bone marrow to produce RBCs (erythropoiesis). Other factors contributing to anemia are nutritional deficiencies, decreased RBC life span, increased hemolysis of RBCs, frequent blood samplings, and bleeding from the GI tract. For patients receiving maintenance hemodialysis (HD), blood loss in the dialyzer may also contribute to the anemic state. Elevated levels of parathyroid hormone (PTH) (produced to compensate for low serum calcium levels) can

inhibit erythropoiesis, shorten survival of RBCs, and cause bone marrow fibrosis, which can result in decreased numbers of hematopoietic cells.

Sufficient iron stores are needed for erythropoiesis. Many patients with kidney failure are iron deficient and require oral iron supplements. Folic acid, which is essential for RBC maturation, is dialyzable because it is water soluble. It needs to be supplemented in the diet (folic acid 1 mg/day).

Bleeding Tendencies. The most common cause of bleeding in uremia is a qualitative defect in platelet function. This dysfunction is caused by impaired platelet aggregation and impaired release of platelet factor III. In addition, alterations in the coagulation system with increased concentrations of both factor VIII and fibrinogen occur. The altered platelet function, hemorrhagic tendencies, and GI bleeding susceptibility can usually be corrected with regular HD or PD.

Infection. Patients with advanced CKD have an increased susceptibility to infection. Infectious complications are caused by changes in leukocyte function and altered immune response and function. Both cellular and humoral immune responses are suppressed. Other factors contributing to the increased risk of infection include hyperglycemia and external trauma (e.g., catheters, needle insertions into vascular access sites).

Cardiovascular System. The most common cause of death in patients with CKD is CV disease. Myocardial infarction, ischemic heart disease, peripheral arterial disease, HF, cardiomyopathy, and stroke are leading causes of death. Even a slight reduction in GFR has been associated with a higher risk for coronary artery disease.[15] CV disease and CKD are so closely linked that if patients develop cardiac events (e.g., myocardial infarction, HF), evaluation of kidney function is recommended.

Traditional CV risk factors such as hypertension and elevated lipids are common in CKD patients. However, CV disease may also be related to nontraditional CV risk factors such as vascular calcification and arterial stiffness, which are major contributors to CV disease in patients with CKD. The calcium deposits in the vascular medial layer are associated with stiffening of the blood vessels. The mechanisms involved are multifactorial. They include (1) vascular smooth muscle cells changing into chondrocytes or osteoblast-like cells, (2) high total body amount of calcium and phosphate resulting from abnormal bone metabolism, (3) impaired renal excretion, and (4) drug therapies to treat the bone disease (e.g., calcium phosphate binders).[16]

Hypertension is highly prevalent in patients with CKD because hypertension is both a cause and a consequence of CKD. Hypertension is aggravated by sodium retention and increased extracellular fluid volume.[17] In some individuals, increased renin production contributes to hypertension (see Fig. 45-4).

Hypertension and diabetes mellitus are contributing risk factors for vascular complications. The vascular changes from long-standing hypertension and the accelerated atherosclerosis contribute to the higher rate of CV disease in CKD. Left ventricular hypertrophy (LVH) is present in about 75% of patients receiving dialysis. Long-standing hypertension, extracellular fluid volume overload, and anemia contribute to development of LVH that may eventually lead to cardiomyopathy and HF.

Patients with CKD are susceptible to cardiac dysrhythmias that result from hyperkalemia and decreased coronary artery perfusion. Uremic pericarditis can develop and occasionally progresses to pericardial effusion and cardiac tamponade. Pericarditis is typically manifested by a friction rub, chest pain, and low-grade fever.

Hypertension can cause retinopathy, encephalopathy, and nephropathy. Because of the many effects of hypertension, blood pressure (BP) control is one of the most important therapeutic goals in the management of CKD.

Respiratory System. With severe acidosis, the respiratory system may attempt to compensate with Kussmaul breathing, which results in increased carbon dioxide removal by exhalation (see Chapter 17). Dyspnea may occur as a manifestation of fluid overload, pulmonary edema, uremic pleuritis (pleurisy), pleural effusions, and respiratory infections (e.g., pneumonia).

Gastrointestinal System. Stomatitis with exudates and ulcerations, a metallic taste in the mouth, and *uremic fetor* (a urinous odor of the breath) are commonly found in CKD. Anorexia, nausea, and vomiting may develop if CKD progresses to ESKD and is not treated with dialysis. Weight loss and malnutrition may also occur. Diabetic *gastroparesis* (delayed gastric emptying) can compound the effects of malnutrition for patients with diabetes. GI bleeding is also a risk because of mucosal irritation and the platelet defect. Constipation may be due to the ingestion of iron salts or calcium-containing phosphate binders. Constipation can be made worse by limitations on fluid intake and physical inactivity.

Neurologic System. Neurologic changes are expected as kidney failure progresses. They are the result of increased nitrogenous waste products, electrolyte imbalances, metabolic acidosis, and atrophy and demyelination of nerve fibers.

The central nervous system (CNS) becomes depressed, resulting in lethargy, apathy, decreased ability to concentrate, fatigue, irritability, and altered mental ability. Seizures and coma may result from a rapidly increasing BUN and hypertensive encephalopathy.

Peripheral neuropathy is initially manifested by a slowing of nerve conduction to the extremities. Individuals with advanced stage 5 CKD may complain of restless legs syndrome (see Chapter 59), described as "bugs crawling inside the leg." Paresthesias are most often experienced in the feet and legs and may be described by the patient as a burning sensation. Eventually, motor involvement may lead to bilateral footdrop, muscular weakness and atrophy, and loss of deep tendon reflexes. Muscle twitching, jerking, *asterixis* (hand-flapping tremor), and nocturnal leg cramps also occur. In patients with diabetes, uremic neuropathy is compounded by the neuropathy associated with diabetes mellitus.

Dialysis should improve general CNS manifestations and may slow or halt the progression of neuropathies. However, motor neuropathy may not be reversible. The treatment for neurologic problems is dialysis or transplantation. Altered mental status, a late manifestation of CKD stage 5, is rarely seen unless the patient has chosen to forgo RRT.

Musculoskeletal System. **CKD mineral and bone disorder (CKD-MBD)** develops as a systemic disorder of mineral and bone metabolism caused by progressive deterioration in kidney function (Fig. 47-3). As kidney function deteriorates, less vitamin D is converted to its active form, resulting in decreased serum levels. Activated vitamin D is necessary to optimize absorption of calcium from the GI tract; thus low levels of active vitamin D result in decreased serum calcium levels.[18]

Normally serum calcium levels are tightly regulated. PTH is the primary regulator of serum calcium levels. When hypocalcemia occurs, the parathyroid gland secretes PTH, which stimulates bone demineralization, thereby releasing calcium from the bones. Phosphate is released as well, leading to elevated

PATHOPHYSIOLOGY MAP

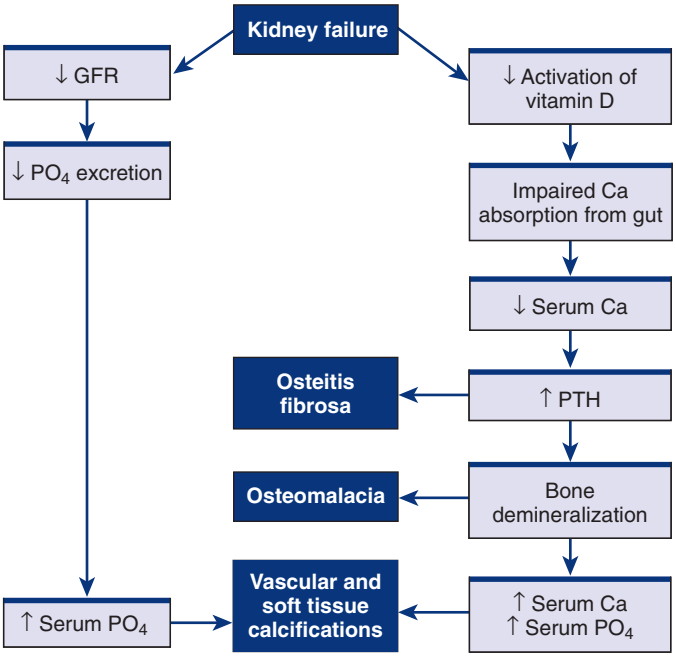

FIG. 47-3 Mechanisms of chronic kidney disease mineral and bone disorder (CKD-MBD). *GFR,* Glomerular filtration rate; *PTH,* parathyroid hormone.

serum phosphate levels. Hyperphosphatemia also results from decreased phosphate excretion by the kidneys. Hyperphosphatemia decreases serum calcium levels and further reduces the kidneys' ability to activate vitamin D.

Low serum calcium, elevated phosphate, and decreased vitamin D contribute to the stimulation of the parathyroid gland and excretion of PTH. The PTH acts on the bone to increase remodeling and increase serum calcium levels. The accelerated rate of bone remodeling causes a weakened bone matrix and places the patient at a higher risk for fractures.

Normally plasma calcium is found ionized or free (physiologically active form) or bound to protein. In kidney failure, it is unusual for hypocalcemia to be symptomatic. The reason for this is that, in the acidotic state associated with renal failure, more calcium is in the ionized form than is bound to protein. However, a low ionized calcium level can lead to tetany (see Chapter 17).

CKD-MBD is a common complication of CKD and results in both skeletal complications and extraskeletal complications (vascular and soft tissue complications). Skeletal complications include *osteomalacia,* which results from demineralization from slow bone turnover and defective mineralization of newly formed bone, and *osteitis fibrosa,* a decalcification of the bone and replacement of bone tissue with fibrous tissue.

Extraskeletal complications result from vascular calcifications. As previously mentioned, vascular calcifications are a significant contributing factor to CV disease. "Uremic red eye" is caused by the irritation from calcium deposits in the eye. Intracardiac calcifications can disrupt the conduction system and cause cardiac arrest. CKD-MBD contributes significantly to a patient's increased morbidity and mortality risks.[18]

Integumentary System. Pruritus is more prevalent in patients receiving dialysis than in the earlier stages of CKD. A small percentage of patients develop refractory pruritus that can have a devastating impact on their well-being and quality of life. Pruritus has multiple causes, including dry skin, calcium-phosphate deposition in the skin, and sensory neuropathy. The itching may be so intense that it can lead to bleeding or infection secondary to scratching. Uremic frost is an extremely rare condition in which urea crystallizes on the skin; this is usually seen only when BUN levels are extremely elevated (e.g., over 200 mg/dL).

Reproductive System. Both men and women can experience infertility and a decreased libido. Women usually have decreased levels of estrogen, progesterone, and luteinizing hormone, causing anovulation and menstrual changes (usually amenorrhea). Menses and ovulation may return after dialysis is started. Men experience loss of testicular consistency, decreased testosterone levels, and low sperm counts.

Sexual dysfunction may also be caused by anemia, which causes fatigue and decreased libido. In addition, peripheral neuropathy can cause impotence in men and anorgasmy in women. Additional factors that may cause changes in sexual function are psychologic problems (e.g., anxiety, depression), physical stress, and side effects of drugs.

Sexual function may improve with maintenance dialysis and may become normal with successful transplantation. Patients that become pregnant while receiving dialysis have been able to carry a fetus to term, but there is significant risk to the mother and infant. Pregnancy in patients with a kidney transplant is more common, but there is still considerable risk to both the mother and fetus.

Psychologic Changes. Personality and behavioral changes, emotional lability, withdrawal, and depression are commonly observed in patients with CKD. Fatigue and lethargy contribute to the feeling of illness. The changes in body image caused by edema, integumentary disturbances, and access devices (e.g., fistulas, catheters) may lead to anxiety and depression. Decreased ability to concentrate and slowed mental activity can give the appearance of dullness and disinterest in the environment. The patient must also deal with significant changes in lifestyle, occupation, family responsibilities, and financial status. Long-term survival depends on medications, dietary restrictions, dialysis, and possibly transplantation. The patient also grieves the loss of kidney function. This can be a prolonged process for some individuals.

Diagnostic Studies

Because persistent proteinuria is usually the first indication of kidney damage, screening for CKD involves a dipstick evaluation of protein in the urine or evaluation for microalbuminuria, which is not detected with routine urinalysis. Patients with diabetes need to have examination of their urine for microalbuminuria if none is detected on routine urinalysis.

A person with persistent proteinuria (1+ protein on standard dipstick testing two or more times over a 3-month period) should have further assessment of risk factors and a diagnostic workup with blood and urine tests to evaluate for CKD. A urine test for albumin-to-creatinine ratio provides an accurate estimate of the protein and albumin excretion rate. A ratio greater than 300 mg albumin per 1 g creatinine signals CKD.

A urinalysis can detect RBCs, WBCs, protein, casts, and glucose. An ultrasound of the kidneys is usually done to detect any obstructions and to determine the size of the kidneys. Other diagnostic studies (Table 47-7) help establish the diagnosis and

TABLE 47-7 COLLABORATIVE CARE

Chronic Kidney Disease

Diagnostic

- History and physical examination
- Identification of reversible kidney disease
- Renal ultrasound
- Renal scan
- CT scan
- Renal biopsy
- BUN, serum creatinine, and creatinine clearance levels
- Serum electrolytes
- Lipid profile
- Protein-to-creatinine ratio in first morning voided specimen
- Urinalysis
- Hematocrit and hemoglobin levels

Collaborative Therapy

- Correction of extracellular fluid volume overload or deficit
- Nutritional therapy*
- Erythropoietin therapy
- Calcium supplementation, phosphate binders, or both
- Antihypertensive therapy
- Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs)
- Measures to treat hyperlipidemia
- Measures to lower potassium†
- Adjustment of drug dosages to degree of renal function
- Renal replacement therapy (dialysis, kidney transplant)

*See Tables 47-10 and 47-11.
†See Table 47-5.

cause of CKD. A kidney biopsy may be necessary to provide a definitive diagnosis.

Many consider serum creatinine the best indicator of kidney function, but in reality serum creatinine alone poorly reflects kidney function. GFR is the preferred measure to determine kidney function. Several GFR calculators are available. The two equations used most frequently to estimate GFR are the Cockcroft-Gault formula and the Modification of Diet in Renal Disease (MDRD) Study equation (Table 47-8). The National Kidney Foundation KDOQI guidelines recommend the MDRD Study equation to estimate GFR.[19]

Collaborative Care

The overall goals of CKD therapy are to preserve existing kidney function, reduce the risks of CV disease, prevent complications, and provide for the patient's comfort (Table 47-9). For many, early recognition, diagnosis, and treatment can deter the progression of kidney disease. It is important that patients with CKD receive appropriate follow-up and referral to a nephrologist early in the course of the disease. Every effort is made to detect and treat potentially reversible causes of kidney failure (e.g., HF, dehydration, infections, nephrotoxins, urinary tract obstruction, glomerulonephritis, renal artery stenosis).

Patients with CKD have a high incidence of CV complications. A higher percentage of patients will die from CV disease than live to need dialysis. When a patient is diagnosed as having CKD, therapy is aimed at treating the CV disease in addition to slowing the progression of kidney disease (see Table 47-7).

A focus on stages 1 through 4 (see Table 47-6) before the need for dialysis (stage 5) includes the control of hypertension, hyperparathyroid disease, anemia, hyperglycemia, and dyslipidemia. The following section focuses primarily on the drug and nutritional aspects of care.

TABLE 47-8 INDICATORS OF KIDNEY FUNCTION

This example shows why serum creatinine is a poor indicator of kidney function. Calculation of GFR is considered the best index to estimate kidney function as indicated by the following example.

	Type of Patient	
Estimation of GFR	**76-Yr-Old African American Woman (Weight 56 kg)**	**28-Yr-Old African American Man (Weight 74 kg)**
Serum creatinine	1.4 mg/dL	1.4 mg/dL
GFR, estimated by the Cockcroft-Gault formula*	30.2 mL/min	82.2 mL/min
GFR, estimated by MDRD equation†	47 mL/min/1.73 m^2	64 mL/min/1.73 m^2

*Cockcroft-Gault GFR = (140 – Age) × (Weight in kilograms) × (0.85 if female)/(72 × Cr).
†GFR as estimated by MDRD equation calculator can be accessed at www.mdrd.com.
Cr, Creatinine; *GFR,* glomerular filtration rate; *MDRD,* modification of diet in renal disease.

TABLE 47-9 RISK FACTORS FOR CHRONIC KIDNEY DISEASE

Risk Factors	Prevention and Management
Diabetes	Achieve optimal glycemic control.
Hypertension	Maintain BP in normal range with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs).
Age >60 yr	Prevent insult or kidney injury.
Cardiovascular disease	Institute aggressive risk factor reduction.
Family history of CKD	Teach about increased risk and assist with appropriate screening (BP measurement, urinalysis).
Exposure to nephrotoxic drugs	Limit exposure and give sodium bicarbonate as treatment.
Ethnic minority (e.g., African American, Native American)	Teach about increased risk and assist with appropriate screening (BP measurement, urinalysis).

Drug Therapy

Hyperkalemia. Multiple strategies are used to manage hyperkalemia (see Table 47-5). Every effort is made to control hyperkalemia with the restriction of high-potassium foods and drugs. Acute hyperkalemia may require treatment with IV glucose and insulin or IV 10% calcium gluconate. Sodium polystyrene sulfonate, a cation-exchange resin, is commonly used to lower potassium levels in stage 4 and can be administered on an outpatient basis.

Tell the patient to expect some diarrhea because this preparation contains sorbitol, a sugar alcohol that has an osmotic laxative action and ensures evacuation of the potassium from the bowel. Never give sodium polystyrene sulfonate to a patient with a hypoactive bowel (paralytic ileus) because fluid shifts could lead to bowel necrosis. As sodium polystyrene sulfonate exchanges sodium ions for potassium ions, observe the patient for sodium and water retention. If changes appear in the ECG such as peaked T waves and widened QRS complexes, dialysis may be required to remove excess potassium.

Hypertension. For some, the progression of CKD can be delayed by controlling hypertension. (Control and treatment of

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Can Exercise Improve Physical Fitness in Chronic Kidney Disease?

Clinical Question

For adults with chronic kidney disease (P), what is the effect of exercise (I) on physical fitness and functioning (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Forty-five RCTs ($n = 1863$) of adults with chronic kidney disease (CKD) or kidney transplant. Physical exercise interventions lasted at least 8 wk. Most common intervention was aerobic exercise.
- Fitness and cardiovascular parameters were measured.
- Regular exercise improved muscle strength, walking ability, blood pressure and heart rate, and quality of life.
- Exercise did not significantly affect total cholesterol or triglyceride levels.

Conclusion

- Exercise significantly improved physical fitness (aerobic capacity).

Implications for Nursing Practice

- Encourage regular aerobic exercise to counter muscle strength loss in patients with CKD.
- Maintain contact with patient to promote and encourage adherence to recommended exercise.

Reference for Evidence

Heiwe S, Jacobson SH: Exercise training for adults with chronic kidney disease, *Cochrane Database Syst Rev* 10:CD003236, 2011.

hypertension are discussed in Chapter 33.) It is recommended that the target BP be less than 130/80 mm Hg for patients with CKD and 125/75 mm Hg for patients with significant proteinuria.[17] Treatment of hypertension includes (1) weight loss (if obese), (2) therapeutic lifestyle changes (e.g., exercise, avoidance of alcohol, smoking cessation), (3) diet recommendations (DASH Diet; see eTable 33-1), and (4) administration of antihypertensive drugs. Most patients require two or more drugs to reach target BP.

The antihypertensive drugs most commonly used are diuretics, calcium channel blockers, ACE inhibitors, and angiotensin receptor blocker (ARB) agents. Prescribed medications depend on whether the patient with CKD has diabetes or not. The ACE inhibitors and ARBs are used with diabetics and those with nondiabetic proteinuria because they decrease proteinuria and possibly delay the progression of CKD. However, they must be used cautiously in patients with ESKD because they can further decrease the GFR and increase serum potassium levels.

Periodically measure the BP with the patient in the supine, sitting, and standing positions to monitor the effect of antihypertensive drugs. Teach the patient and caregiver how to monitor the BP at home and what readings require immediate intervention. BP control is essential to slow atherosclerotic changes that could further impair kidney function.

CKD-MBD. Interventions for CKD-MBD include limiting dietary phosphorus, administering phosphate binders, supplementing vitamin D, and controlling hyperparathyroidism.[18] Phosphate intake is not usually restricted until the patient requires RRT. At that time, phosphate is usually limited to about 1 g/day, but dietary control alone is usually inadequate.

Phosphate binders include calcium-based binders: calcium acetate (PhosLo) and calcium carbonate (Caltrate). They bind phosphate in the bowel and are then excreted in the stool. The administration of calcium may increase the calcium load and place the patient at increased risk for vascular calcifications. Therefore, when calcium levels are increased or there is evidence of existing vascular or soft tissue calcifications, consider changing to noncalcium-based phosphate binders, such as lanthanum carbonate (Fosrenol) and sevelamer carbonate (Renvela).

To be most effective, administer phosphate binders with each meal. Constipation is a frequent side effect of phosphate binders and may necessitate the use of stool softeners.

Because bone disease (osteomalacia) is associated with excessive aluminum, aluminum preparations should be used with caution in patients with kidney failure. Do not use magnesium-containing antacids (e.g., Maalox, Mylanta) because magnesium depends on the kidneys for excretion.

Hypocalcemia is a problem in the later stages of CKD because of the inability of the GI tract to absorb calcium in the absence of active vitamin D. If hypocalcemia persists even if the serum phosphate levels are normal, then supplemental calcium and vitamin D should be given. Assess vitamin D levels to determine the need for supplementation. If the levels are low (serum values less than 30 ng/mL), vitamin D supplementation is recommended in the form of cholecalciferol.

Treatment of secondary hyperparathyroidism in ESKD patients requires the activated form of vitamin D because the kidneys no longer possess the ability to activate vitamin D. Active vitamin D is available as oral or IV calcitriol (Rocaltrol, Calcijex), IV paricalcitol (Zemplar), or oral or IV doxercalciferol (Hectorol), and can reduce the elevated levels of PTH.

Hypercalcemia may occur with calcium and vitamin D supplementation. If hypercalcemia occurs, then reduce or discontinue vitamin D and calcium-based phosphate binders. Noncalcium-based phosphate binders can be substituted.

Cinacalcet (Sensipar), a calcimimetic agent, is used to control secondary hyperparathyroidism. Calcimimetics mimic calcium and increase the sensitivity of the calcium receptors in the parathyroid glands. As a result, the parathyroid glands detect calcium at lower serum levels and decrease PTH secretion.

If hyperparathyroid disease becomes severe despite medical management, a subtotal or total parathyroidectomy may be performed to decrease the synthesis and secretion of PTH. In most cases, a total parathyroidectomy is performed, and some parathyroid tissue is transplanted into the forearm. The transplanted cells produce PTH as needed. If production of PTH becomes excessive, some of the cells can be removed from the forearm.

It is difficult to determine what type of bone disease a patient might have by just looking at the serum levels of calcium, phosphorus, PTH, and alkaline phosphatase. The gold standard for diagnosis is a bone biopsy.

Anemia. The most important cause of anemia is a decreased production of erythropoietin. Exogenous erythropoietin (EPO) is used in the treatment. It is available as epoetin alfa (Epogen, Procrit), which can be administered IV or subcutaneously, usually two or three times per week. Darbepoetin alfa (Aranesp) is longer acting and can be administered weekly or biweekly.

A significant increase in hemoglobin and hematocrit levels is usually not seen for 2 to 3 weeks. Higher hemoglobin levels

(more than 12 g/dL) and higher doses of EPO are associated with a higher rate of thromboembolic events and increased risk of death from serious CV events (heart attack, HF, stroke). The recommendation is to use the lowest possible dose of EPO to treat anemia. Furthermore, treatment of CKD-related anemia should be individualized with the goal being to reduce the need for blood transfusions. There is no target hemoglobin or widely accepted EPO dosing strategy.[20] Teach people who are prescribed EPO about the risks and benefits and allow them to make an informed decision regarding their individual treatment.

If EPO is used in the management of anemia, recognize that uncontrolled hypertension is a contraindication and that EPO may exacerbate an individual's hypertension. The underlying mechanism is related to the hemodynamic changes (e.g., increased whole blood viscosity) that occur as the anemia is corrected.

Another side effect of EPO therapy is the development of iron deficiency from the increased demand for iron to support erythropoiesis. Iron supplementation is recommended if the plasma ferritin concentrations fall below 100 ng/mL. Some studies have supported the use of parenteral iron with a much higher ferritin value (e.g., 800 ng/mL) in order to optimize treatment. Most CKD patients receive iron supplementation either by mouth or parenterally. Nonadherence may be an issue with oral supplementation because iron has GI side effects such as gastric irritation and constipation. Orally administered iron should not be taken at the same time as phosphate binders because calcium binds the iron, preventing its absorption. Tell the patient that iron may make the stool dark in color.

Most patients receiving HD are prescribed IV iron sucrose injection (Venofer) or sodium ferric gluconate complex in sucrose injection (Ferrlecit). Supplemental folic acid (1 mg/day) is usually given because it is needed for RBC formation and is removed by dialysis.

Blood transfusions should be avoided in treating anemia unless the patient experiences an acute blood loss or has symptomatic anemia (i.e., dyspnea, excess fatigue, tachycardia, palpitations, chest pain). Undesirable effects of transfusions are the increased sensitization and development of antibodies, thus making it more difficult to find a compatible donor for transplantation. Multiple blood transfusions may lead to iron overload because each unit of blood contains about 250 mg of iron.

Dyslipidemia. Dyslipidemia, a known traditional risk factor for CV disease, is a common problem in CKD. Statins (HMG-CoA reductase inhibitors), such as atorvastatin (Lipitor), are used to lower LDL cholesterol levels (see Table 34-5). Evidence supports the use of statins in patients with CKD (especially patients with diabetes) not yet on dialysis. However, simvastatin has been associated with a higher rate of myopathy. It is recommended that patients who develop myopathy on simvastatin be switched to atorvastatin, which has minimal renal clearance and less chance of causing myopathy. The effectiveness of statins in patients on dialysis is still being studied. Fibrates (fibric acid derivatives), such as gemfibrozil (Lopid), are used to lower triglyceride levels (see Table 34-5) and can also increase HDLs. Specific drugs of these classes that are used depend on the individual patient response and physician recommendation.

Complications of Drug Therapy. Many drugs are partially or totally excreted by the kidneys. Delayed and decreased elimination leads to an accumulation of drugs and the potential for drug toxicity. Drug doses and frequency of administration must be adjusted based on the severity of the kidney disease. Increased sensitivity may result as drug levels increase in the blood and tissues. Drugs of particular concern include digoxin, diabetic agents (metformin, glyburide), antibiotics (e.g., vancomycin, gentamicin), and opioid medications.

Nutritional Therapy

Protein Restriction. The current diet is designed to be as normal as possible to maintain good nutrition (Table 47-10). Calorie-protein malnutrition is a potential and serious problem that results from altered metabolism, anemia, proteinuria, anorexia, and nausea. Additional factors leading to malnutrition include depression and complex diets that restrict protein, phosphorus, potassium, and sodium. Frequent monitoring of laboratory parameters, especially serum albumin, prealbumin (may be a better indicator of recent or current nutritional status than albumin), and ferritin, and anthropometric measurements are necessary to evaluate nutritional status. All patients with CKD should be referred to a dietitian for nutritional education and guidance.

For the patient who is undergoing dialysis, protein is not routinely restricted (see Table 47-10). The beneficial role of protein restriction in CKD stages 1 through 4 as a means to reduce the decline in kidney function is being studied.

Historically, dietary counseling often encouraged a restriction of protein for individuals with CKD. Despite some evidence that protein restriction has benefits, many patients find it difficult to adhere to these diets. For CKD stages 1 through 4, many clinicians just encourage a diet with normal protein

TABLE 47-10 NUTRITIONAL THERAPY

Chronic Kidney Disease*

	Pre–End-Stage Kidney Disease	Hemodialysis	Peritoneal Dialysis
Fluid allowance	As desired or depends on urine output	Urine output plus 600-1000 mL	Unrestricted if weight and blood pressure controlled and residual renal function
Calories	30-35 kcal/kg/day	30-35 kcal/kg/day	25-35 kcal/kg/day (includes calories from dialysate glucose absorption)
Protein	Individualized or 0.6-1.0 g/kg/day (low protein)	1.2 g/kg/day	1.2-1.3 g/kg/day

*Diets must be individualized in accordance with needs.

intake. However, teach patients to avoid high-protein diets and supplements because they may overstress the diseased kidneys.

Dietary protein guidelines for PD differ from those for HD because of protein loss in the dialysate. During PD, protein intake must be high enough to compensate for the losses so that the nitrogen balance is maintained. The recommended protein intake is at least 1.2 g/kg of ideal body weight (IBW) per day; this can be increased depending on the patient's individual needs.

For patients with malnutrition or inadequate caloric or protein intake, commercially prepared products that are high in protein but low in sodium and potassium are available (e.g., Nepro, Amin-Aid).[21] As an alternative, liquid or powder breakfast drinks may be purchased at the grocery store.

Water Restriction. Water and any other fluids are not routinely restricted in patients with CKD stages 1 to 5 who are not receiving HD. In an effort to reduce fluid retention, diuretics are often used. Patients on HD have a more restricted fluid intake than patients receiving PD. For those receiving HD, as their urine output diminishes, fluids are restricted. Recommended fluid intake depends on the daily urine output. Generally, 600 mL (from insensible loss) plus an amount equal to the previous day's urine output is allowed for a patient receiving HD.

Foods that are liquid at room temperature (e.g., gelatin, ice cream) should be counted as fluid intake. The fluid allotment should be spaced throughout the day so that the patient does not become thirsty. Patients are advised to limit fluid intake so that weight gains are no more than 1 to 3 kg between dialyses (termed *interdialytic weight gain*).

Sodium and Potassium Restriction. Patients with CKD are advised to restrict sodium. Sodium-restricted diets may vary from 2 to 4 g/day. Do not equate sodium and salt because the sodium content in 1 g of sodium chloride is equivalent to 400 mg of sodium. Instruct the patient to avoid high-sodium foods such as cured meats, pickled foods, canned soups and stews, frankfurters, cold cuts, soy sauce, and salad dressings (see Chapter 35, Table 35-8). Potassium restriction depends on the kidneys' ability to excrete potassium. Most salt substitutes should be avoided if patients have been instructed to restrict potassium because they contain potassium chloride.

Dietary restrictions for potassium range from about 2 to 3 g (39 mg = 1 mEq). Teach patients receiving HD which foods are high in potassium and to avoid them (Table 47-11).

Patients using PD do not usually need potassium restrictions and may even be prescribed oral potassium supplementation because of the loss of potassium with dialysis exchanges.

Phosphate Restriction. As kidney function deteriorates, phosphate elimination by the kidneys is diminished and the patient begins to develop hyperphosphatemia. By the time a patient reaches ESKD, phosphate should be limited to approximately 1 g/day. Foods that are high in phosphate include meat, dairy products (e.g., milk, ice cream, cheese, yogurt), and foods containing dairy products (e.g., pudding). Many foods that are high in phosphate are also high in protein. Since patients on dialysis are encouraged to eat a diet containing protein, phosphate binders are essential to control phosphate.

NURSING MANAGEMENT CHRONIC KIDNEY DISEASE

NURSING ASSESSMENT

Obtain a complete history of any existing kidney disease or family history of kidney disease. Some kidney disorders, including Alport syndrome and polycystic kidney disease, have a genetic basis. Other disorders that can lead to CKD are diabetes mellitus, hypertension, and systemic lupus erythematosus.

Because many drugs are potentially nephrotoxic, ask the patient about both current and past use of prescription and over-the-counter drugs and herbal preparations. Decongestants and antihistamines that contain pseudoephedrine and phenylephrine cause vasoconstriction and lead to an increase in BP. Also assess the use of antacids. Magnesium and aluminum from antacids can accumulate in the body because they cannot be excreted. Some antacids contain high levels of salt, contributing to hypertension. In addition, antacids may interfere with absorption of other medications.

NSAIDs (aspirin, acetaminophen, ibuprofen, naproxen) can contribute to the development of AKI and progression of CKD, especially when taken in higher doses than recommended. Analgesics in combination and in large quantities have been associated with the development of kidney failure. If taken as prescribed for short periods, these analgesics are usually considered safe.

Assess the patient's dietary habits and discuss any problems regarding intake. Measure the height and weight, and evaluate any recent weight changes.

Recognize that CKD is a lifelong illness. The chronicity of kidney disease and the long-term treatment affect virtually every area of a person's life, including family relationships, social and work activities, self-image, and emotional state. Assess the patient's support systems. The choice of treatment modality may be related to support systems available.

NURSING DIAGNOSES

Nursing diagnoses for CKD may include, but are not limited to, the following:

- Excess fluid volume *related to* impaired kidney function
- Risk for electrolyte imbalance *related to* impaired kidney function resulting in hyperkalemia, hypocalcemia, hyperphosphatemia, and altered vitamin D metabolism
- Imbalanced nutrition: less than body requirements *related to* restricted intake of nutrients (especially protein), nausea, vomiting, anorexia, and stomatitis

Additional information on nursing diagnoses is presented in eNursing Care Plan 47-1 (available on the website for this chapter).

PLANNING

The overall goals are that a patient with CKD will (1) demonstrate knowledge of and ability to comply with the therapeutic regimen, (2) participate in decision making for the plan of care and future treatment modality, (3) demonstrate effective coping strategies, and (4) continue with activities of daily living within physiologic limitations.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Identify individuals at risk for CKD. These include people who have been diagnosed with diabetes or hypertension and people with a history (or a family history) of kidney disease and repeated urinary tract infections. These individuals should have regular checkups along with calculation of the estimated GFR and a routine urinalysis.

People with diabetes need to have their urine checked for microalbuminuria if routine urinalysis is negative for protein. Advise patients with diabetes to report any changes in urine appearance (color, odor), frequency, or volume to the health care provider. If a patient needs a potentially nephrotoxic drug, it is important to monitor kidney function with serum creatinine and BUN.

Individuals identified as at risk need to take measures to prevent or delay the progression of CKD. Most important are measures to reduce the risk or progression of CV disease. These include glycemic control for patients with diabetes (see Chapter 49); BP control; and lifestyle modifications, including smoking cessation.

ACUTE INTERVENTION. Most of the care of the patient with CKD occurs on an outpatient basis. In-hospital care is required for management of complications and for kidney transplantation (if applicable).

AMBULATORY AND HOME CARE. Teach the patient and caregiver about the diet, drugs, and follow-up medical care (Table 47-12). The patient needs to understand the drugs and the common side effects. Because patients with CKD take many medications, a pillbox organizer or a list of the drugs and the times of administration that can be posted in the home may be helpful. Instruct the patient to avoid certain over-the-counter drugs such as NSAIDs and aluminum- and magnesium-based laxatives and antacids. Any over-the-counter medications need to be considered as a risk, since even acetaminophen taken in large doses can be toxic to the kidneys.

Teach the patient to take daily BPs and identify signs and symptoms of fluid overload, hyperkalemia, and other electrolyte imbalances. The dietitian should meet with the patient and caregiver on a regular basis for diet planning. A diet history and consideration of cultural variations facilitate diet planning and adherence.

Motivate patients to the highest level of self-management that is possible for them to achieve. The length of time that a patient can receive conservative medical management for CKD is highly variable. It depends on the rate of progression to kidney failure and the presence of other co-morbid conditions. Specific nursing management of the patient with CKD is presented in eNursing Care Plan 47-1.

Preferably, if the patient is considered a candidate for kidney transplantation, the evaluation can be accomplished before initiation of dialysis. In the best of circumstances, patients can receive a transplant before ever having to start dialysis. Even though transplantation offers the best therapeutic management for patients with kidney failure, the critical shortage of donor organs has limited this treatment option.

Most patients require dialysis, either peritoneal dialysis (PD) or hemodialysis (HD). The majority of patients in the United States choose HD. Clearly explain to the patient and caregiver what is involved in dialysis, transplantation, and even the option for palliative care. Discuss the opportunity for home HD.

Provide information about the treatment options so the patient can be involved in the decision-making process and be given a sense of control over life-altering decisions. Inform the patient that if dialysis is chosen, the option of transplantation still remains. Let the patient know that if a transplanted organ fails, the patient can return to dialysis. Counsel the patient that retransplantation may also be an option.

It is important to respect the patient's choice to not receive treatment.[22] Many times, patients themselves initiate the

HEALTHY PEOPLE

Prevention and Detection of Chronic Kidney Disease

- Early detection and treatment are the primary methods for reducing chronic kidney disease.
- Monitor blood pressure to detect elevations so treatment can be started early.
- Treat hypertension appropriately and aggressively, since it is the second leading cause of chronic kidney disease.
- Ensure proper diagnosis and treatment of diabetes mellitus, since it is the leading cause of chronic kidney disease.

TABLE 47-12 PATIENT & CAREGIVER TEACHING GUIDE

Chronic Kidney Disease

Include the following information in the teaching plan for the patient and caregiver.

1. Necessary dietary (protein, sodium, potassium, phosphate) and fluid restrictions.
2. Difficulties in modifying diet and fluid intake.
3. Signs and symptoms of electrolyte imbalance, especially high potassium.
4. Alternative ways of reducing thirst, such as sucking on ice cubes, lemon, or hard candy.
5. Rationales for prescribed drugs and common side effects.
   Examples:
   - Phosphate binders (including calcium supplements used as phosphate barriers) should be taken with meals.
   - Calcium supplements prescribed to treat hypocalcemia directly should be taken on an empty stomach (but not at the same time as iron supplements).
   - Iron supplements should be taken between meals.
6. The importance of reporting any of the following:
   - Weight gain >4 lb (2 kg)
   - Increasing BP
   - Shortness of breath
   - Edema
   - Increasing fatigue or weakness
   - Confusion or lethargy
7. Need for support and encouragement. Share concerns about lifestyle changes, living with a chronic illness, and decisions about type of dialysis or transplantation.

conversation about palliative care. Focus the discussion on moving from the curative approach to promotion of comfort care and consideration of hospice care. Listen to the patient and caregiver, allowing them to do most of the talking, and pay special attention to their hopes and fears. (Palliative and end-of-life care is discussed in Chapter 10.)

EVALUATION

The expected outcomes are that the patient with CKD will maintain

- Fluid and electrolyte levels within normal ranges
- An acceptable weight with no more than a 10% weight loss

Additional information on expected outcomes is presented in eNursing Care Plan 47-1 (available on the website).

DIALYSIS

Dialysis is the movement of fluid and molecules across a semipermeable membrane from one compartment to another. Clinically, dialysis is a technique in which substances move from the blood through a semipermeable membrane and into a dialysis solution *(dialysate)*. It is used to correct fluid and electrolyte imbalances and to remove waste products in kidney failure. It can also be used to treat drug overdoses.

The two methods of dialysis available are **peritoneal dialysis (PD)** and **hemodialysis (HD)** (Table 47-13). In PD the peritoneal membrane acts as the semipermeable membrane. In HD an artificial membrane (usually made of cellulose-based or synthetic materials) is used as the semipermeable membrane and is in contact with the patient's blood.

TABLE 47-13 COMPARISON OF PERITONEAL DIALYSIS AND HEMODIALYSIS

Advantages	Disadvantages
Peritoneal Dialysis (PD)	
• Immediate initiation in almost any hospital • Less complicated than hemodialysis • Portable system with CAPD • Fewer dietary restrictions • Relatively short training time • Usable in patient with vascular access problems • Less cardiovascular stress • Home dialysis possible • Preferable for diabetic patient	• Bacterial or chemical peritonitis • Protein loss into dialysate • Exit site and tunnel infections • Self-image problems with catheter placement • Hyperglycemia • Surgery for catheter placement • Contraindicated in patient with multiple abdominal surgeries, trauma, unrepaired hernia • Requires completion of education program • Catheter can migrate • Best instituted with willing partner
Hemodialysis (HD)	
• Rapid fluid removal • Rapid removal of urea and creatinine • Effective potassium removal • Less protein loss • Lowering of serum triglycerides • Home dialysis possible • Temporary access can be placed at bedside	• Vascular access problems • Dietary and fluid restrictions • Heparinization may be necessary • Extensive equipment necessary • Hypotension during dialysis • Added blood loss that contributes to anemia • Specially trained personnel necessary • Surgery for permanent access placement • Self-image problems with permanent access

CAPD, Continuous ambulatory peritoneal dialysis.

Dialysis is begun when the patient's uremia can no longer be adequately treated with conservative medical management. Generally dialysis is initiated when the GFR is less than 15 mL/min/1.73 m^2. This criterion can vary widely in different clinical situations, and the physician determines when to start dialysis based on the patient's clinical status. Certain uremic complications, including encephalopathy, neuropathies, uncontrolled hyperkalemia, pericarditis, and accelerated hypertension, indicate a need for immediate dialysis.

Most patients with ESKD are treated with dialysis because (1) there is a lack of donated organs, (2) some patients are physically or mentally unsuitable for transplantation, or (3) some patients do not want transplants. An increasing number of individuals, including older adults and those with complex medical problems, are receiving maintenance dialysis. A patient's chronologic age is not a factor in determining candidacy for dialysis. Factors that are important are the patient's ability to cope and the existing support system.

General Principles of Dialysis

Solutes and water move across the semipermeable membrane from the blood to the dialysate or from the dialysate to the blood in accordance with concentration gradients. The principles of diffusion, osmosis, and ultrafiltration are involved in dialysis (Fig. 47-4). *Diffusion* is the movement of solutes from an area of greater concentration to an area of lesser concentration. In kidney failure, urea, creatinine, uric acid, and electrolytes (potassium, phosphate) move from the blood to the dialysate with the net effect of lowering their concentration in the blood. RBCs, WBCs, and plasma proteins are too large to diffuse through the pores of the membrane. Small-molecular-weight substances can pass from the dialysate into a patient's blood, so the purity of the water used for dialysis is monitored and controlled.

Osmosis is the movement of fluid from an area of lesser concentration to an area of greater concentration of solutes. Glucose is added to the dialysate and creates an osmotic gradient across the membrane, pulling excess fluid from the blood.

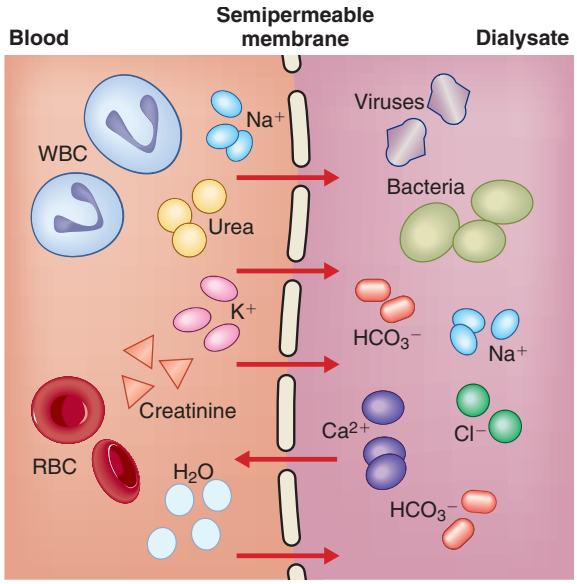

FIG. 47-4 Osmosis and diffusion across a semipermeable membrane.

Excess fluid is removed by creating a pressure differential between the blood and the dialysate solution. *Ultrafiltration* (water and fluid removal) results when there is an osmotic gradient or pressure gradient across the membrane. In PD, excess fluid is removed by increasing the osmolality of the dialysate (osmotic gradient) with the addition of glucose. In HD, the gradient is created by increasing pressure in the blood compartment (positive pressure) or decreasing pressure in the dialysate compartment (negative pressure). Extracellular fluid moves into the dialysate because of the pressure gradient. The excess fluid is removed by creating a pressure differential between the blood and the dialysate solution with a combination of positive pressure in the blood compartment or negative pressure in the dialysate compartment.

PERITONEAL DIALYSIS

Although PD was first used in 1923, it did not come into widespread use for chronic treatment until the 1970s with the development of soft, pliable peritoneal solution bags and the introduction of the concept of continuous PD. In the United States, approximately 12% of patients receiving dialysis treatments are on PD.

Catheter Placement

Peritoneal access is obtained by inserting a catheter through the anterior abdominal wall (Fig. 47-5). The catheter is about 60 cm long and has one or two Dacron cuffs on its subcutaneous and peritoneal portions. The cuffs act as anchors and prevent the migration of microorganisms down the shaft from the skin. Within a few weeks, fibrous tissue grows into the Dacron cuff, holding the catheter in place and preventing bacterial penetration into the peritoneal cavity. The tip of the catheter rests in the peritoneal cavity and has many perforations spaced along the distal end of the tubing to allow fluid to flow in and out of the catheter.

The technique for catheter placement varies. Although it is possible to place a permanent catheter in the peritoneal cavity at the bedside with a trocar, it is usually done via surgery so that its placement can be directly visualized, minimizing potential complications. Preparation of the patient for catheter insertion includes emptying the bladder and bowel, weighing the patient, and obtaining a signed consent form. After placement, PD may be initiated immediately with low volume exchanges, or delayed for 2 weeks pending healing and sealing of the exit site. Once the catheter incision site is healed, the patient may shower and then pat the catheter and exit site dry.

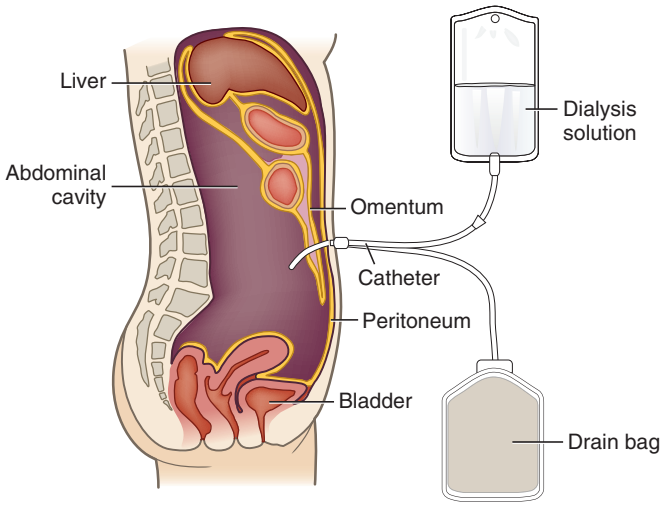

FIG. 47-5 Peritoneal dialysis showing peritoneal catheter inserted into peritoneal cavity.

Daily catheter care varies. Some patients just wash with soap and water and go without a dressing (Fig. 47-6), whereas others require daily dressing changes. Teach all patients to examine their catheter site for signs of infection. Showering is preferred to bathing.[23]

Dialysis Solutions and Cycles

PD is accomplished by putting dialysis solution into the peritoneal space. The three phases of the PD cycle are inflow (fill), dwell (equilibration), and drain. The three phases are called an *exchange*. During *inflow,* a prescribed amount of solution, usually 2 L, is infused through an established catheter over about 10 minutes. The flow rate may be decreased if the patient has pain. After the solution has been infused, the inflow clamp is closed before air enters the tubing.

The next part of the cycle is the *dwell* phase, or equilibration, during which diffusion and osmosis occur between the patient's blood and the peritoneal cavity. The duration of the dwell time can last from 20 or 30 minutes to 8 or more hours, depending on the method of PD.

Drain time takes 15 to 30 minutes and may be facilitated by gently massaging the abdomen or changing position. The cycle starts again with the infusion of another 2 L of solution. For manual PD, a period of about 30 to 50 minutes is required to complete an exchange.

Dialysis solutions vary, and the choice of the exchange volume is primarily determined by the size of the peritoneal cavity. A larger person may tolerate a 3-L exchange volume without any difficulty, whereas an average-size person usually tolerates a 2-L exchange. Smaller exchange volumes are used for patients with a smaller body, pulmonary compromise (the added pressure of the large volume may precipitate respiratory difficulty), or inguinal hernias.

Ultrafiltration (fluid removal) during PD depends on osmotic forces, with glucose being the most effective osmotic agent currently available. Dextrose remains the most commonly used osmotic agent in PD solutions. It is relatively safe and inexpensive, but has been associated with high rates of peritoneal glucose absorption leading to problems with hypertriglyceridemia, hyperglycemia, and long-term peritoneal membrane dysfunction.

Alternatives to dextrose PD solution include icodextrin and amino acid solutions. Icodextrin is a commercially available

FIG. 47-6 Peritoneal catheter exit site.

isoosmolar preparation and induces ultrafiltration by its oncotic effect. Amino acid PD solutions are also available and primarily used for patients requiring nutritional supplementation.

Peritoneal Dialysis Systems

Automated Peritoneal Dialysis. **Automated peritoneal dialysis (APD)** is the most popular form of PD because it allows patients to do dialysis while they sleep. An automated device called a cycler is used to deliver the dialysate for APD (Fig. 47-7). The automated cycler times and controls the fill, dwell, and drain phases. The machine cycles four or more exchanges per night with 1 to 2 hours per exchange. Alarms and monitors are built into the system to make it safe for the patient to sleep while dialyzing. The patient disconnects from the machine in the morning and usually leaves fluid in the abdomen during the day.

It is difficult to achieve the required solute and fluid clearance solely with nighttime APD. Therefore one or two daytime manual exchanges may also be prescribed to ensure adequate dialysis. Cyclers are about the size of a DVD player and have longer tubing to allow greater mobility.

Continuous Ambulatory Peritoneal Dialysis. **Continuous ambulatory peritoneal dialysis (CAPD)** is done while the patient is awake during the day. Exchanges are carried out manually by exchanging 1.5 to 3 L of peritoneal dialysate at least four times daily, with dwell times averaging 4 hours. For example, one schedule exchanges at 7 AM, 12 noon, 5 PM, and 10 PM. In this procedure, the person instills 2 to 3 L of dialysate from a collapsible plastic bag into the peritoneal cavity through a disposable plastic tube.

In CAPD the bag and line can be disconnected after the instillation of the fluid. After the equilibration period, the line is reconnected to the catheter, the dialysate (effluent) is drained from the peritoneal cavity, and a new 2- to 3-L bag of dialysate solution is infused. In PD it is critical to maintain aseptic technique to avoid peritonitis. Several tubing connections and devices are commercially available to help in maintaining an aseptic system.

Complications of Peritoneal Dialysis

Exit Site Infection. Infection of the peritoneal catheter exit site is most commonly caused by *Staphylococcus aureus* or *Staphylococcus epidermidis* (from skin flora). Clinical manifestations of an exit site infection include redness at the site, tenderness, and drainage. Superficial exit site infections caused by these organisms are generally resolved with antibiotic therapy. If not treated immediately, subcutaneous tunnel infections usually progress to abscess formation and may cause peritonitis, necessitating catheter removal.

FIG. 47-7 Automated peritoneal dialysis that can be used while the patient is sleeping.

Peritonitis. Peritonitis results from contamination or from progression of an exit site or tunnel infection. Most frequently peritonitis occurs because of improper technique in making or breaking connections for exchanges. Less commonly, peritonitis results from bacteria in the intestine crossing over into the peritoneal cavity. Peritonitis is usually caused by *S. aureus* or *S. epidermidis.*

The primary clinical manifestations of peritonitis are abdominal pain and cloudy peritoneal effluent with a WBC count greater than 100 cells/μL (more than 50% neutrophils) or demonstration of bacteria in the peritoneal effluent by Gram stain or culture. GI manifestations of peritonitis may include diarrhea, vomiting, abdominal distention, and hyperactive bowel sounds. Fever may or may not be present.

Cultures, Gram stain, and a WBC differential of the peritoneal effluent are used to confirm the diagnosis of peritonitis. Antibiotics can be given orally, IV, or intraperitoneally. In most cases, the patient is treated on an outpatient basis. The formation of adhesions in the peritoneum can result from repeated infections and interferes with the peritoneal membrane's ability to act as a dialyzing surface. Repeated infections may require the removal of the peritoneal catheter and termination of PD.

Hernias. Because of increased intraabdominal pressure secondary to the dialysate infusion, hernias can develop in predisposed individuals such as multiparous women and older men. However, in most situations after hernia repair, PD can be resumed after several days using small dialysate volumes and keeping the patient supine.

Lower Back Problems. Increased intraabdominal pressure can cause or aggravate lower back pain. The lumbosacral curvature is increased by intraperitoneal infusion of dialysate. Orthopedic binders and a regular exercise program for strengthening the back muscles have been beneficial for some patients.

Bleeding. After Tenckhoff catheter placement, it is not uncommon for the PD effluent drained after the first few exchanges to be pink or slightly bloody secondary to the trauma associated with catheter insertion. However, bloody effluent over several days or the new appearance of blood in the effluent can indicate active intraperitoneal bleeding. If this occurs, check the BP and hematocrit. Blood may also be present in the effluent of women who are menstruating or ovulating, and this requires no intervention.

Pulmonary Complications. Atelectasis, pneumonia, and bronchitis may occur from repeated upward displacement of the diaphragm, resulting in decreased lung expansion. The longer the dwell time, the greater the likelihood of pulmonary problems. Frequent repositioning and deep-breathing exercises can help. When the patient is lying in bed, elevate the head of the bed to prevent these problems.

Protein Loss. The peritoneal membrane is permeable to plasma proteins, amino acids, and polypeptides. These substances are lost in the dialysate fluid. The amount of loss is usually about 0.5 g/L of dialysate drainage, but it can be as high as 10 to 20 g/day. This loss may increase to as much as 40 g/day during episodes of peritonitis as the peritoneal membrane becomes more permeable. Unresolved peritonitis is associated with exaggerated protein loss that can result in malnutrition and

may indicate the need to terminate PD temporarily or sometimes permanently.

Effectiveness of Chronic Peritoneal Dialysis

Learning the self-management skills required to do PD is usually accomplished in a 3- to 7-day training program. Mortality rates are about equal between in-center HD patients and PD patients for the first few years or possibly even a little lower for patients receiving PD. However, after about 2 years, mortality rates for patients receiving PD are higher, especially for the older person with diabetes and patients with a prior history of CV disease.

The primary advantage of PD is its simplicity and that it is a home-based program, allowing the patient to be in control. There is no need for special water systems, and equipment setup is relatively simple. PD is especially indicated for the individual who has vascular access problems or responds poorly to the hemodynamic stresses of HD.[23]

HEMODIALYSIS

Vascular Access

Obtaining vascular access is one of the most difficult problems associated with HD. To perform HD, a very rapid blood flow is required, and access to a large blood vessel is essential. The types of vascular access include arteriovenous fistulas (AVFs), arteriovenous grafts (AVGs), and temporary vascular access.[24]

Arteriovenous Fistulas and Grafts. A subcutaneous **arteriovenous fistula (AVF)** is usually created in the forearm or upper arm with an anastomosis between an artery and a vein (usually cephalic or basilic) (Figs. 47-8, *A*, and 47-9). The fistula allows arterial blood to flow through the vein. The vein becomes "arterialized" with a larger caliber and thicker walls. The arterial blood flow is essential to provide the rapid blood flow required for HD. As the arterialized vein matures, it is more amenable to repeated venipunctures. Maturation may take 6 weeks to months. AVF should be placed at least 3 months before the need to initiate HD.

Normally, a *thrill* can be felt by palpating the area of anastomosis, and a *bruit* (rushing sound) can be heard with a stethoscope. The bruit and thrill are created by arterial blood moving at a high velocity through the vein. AVFs are more difficult to create in patients with a history of severe peripheral vascular disease, those with prolonged IV drug use, and obese women. For these individuals, a synthetic graft may be required.

Arteriovenous grafts (AVGs) are made of synthetic materials (polytetrafluoroethylene [PTFE, Teflon]) and form a "bridge" between the arterial and venous blood supplies. Grafts are placed under the skin and are surgically anastomosed between an artery (usually brachial) and a vein (usually antecubital) (Fig. 47-8, *B*). An interval of 2 to 4 weeks is usually necessary to allow the graft to heal, but some centers may use it earlier. Because grafts are made of artificial materials, they are more likely than AVFs to become infected, and they also have a tendency to be thrombogenic. When AVG infections occur, they may require surgical removal, since it is difficult to completely resolve the infection from the synthetic material.

Surgical creation of an arteriovenous access for HD has several risks, including development of distal ischemia *(steal syndrome)* and pain because too much of the arterial blood is being shunted or "stolen" from the distal extremity. Classic manifestations of steal syndrome are pain distal to the access site, numbness or tingling of fingers that may worsen during dialysis, and poor capillary refill. Aneurysms can also develop in the arteriovenous access and can rupture if left untreated.

Never perform BP measurements, insertion of IV lines, and venipuncture in the extremity with the vascular access. These special precautions are taken to prevent infection and clotting of the vascular access.

Temporary Vascular Access. In some situations, when immediate vascular access is required, catheterization of the internal jugular or femoral vein is performed. A flexible Teflon, silicone rubber, or polyurethane catheter is inserted at the bedside into one of these large veins and provides access to the circulation without surgery (Fig. 47-10). The catheters usually have a double external lumen with an internal septum separating the two internal segments. One lumen is used for blood removal and the other for blood return (Fig. 47-11, *A* and *B*). It is now recommended that patients not be discharged from the hospital with a temporary catheter. These catheters have high rates of infection, dislodgment, and malfunction.

Long-term cuffed HD catheters are often used for temporary vascular access. These catheters provide temporary access while the patient is waiting for fistula placement or as long-term access when other forms of access have failed. This type of catheter exits on the upper chest wall and is tunneled subcutaneously to the internal or external jugular vein (Fig. 47-11, *C*). The catheter tip rests in the right atrium. It has one or two

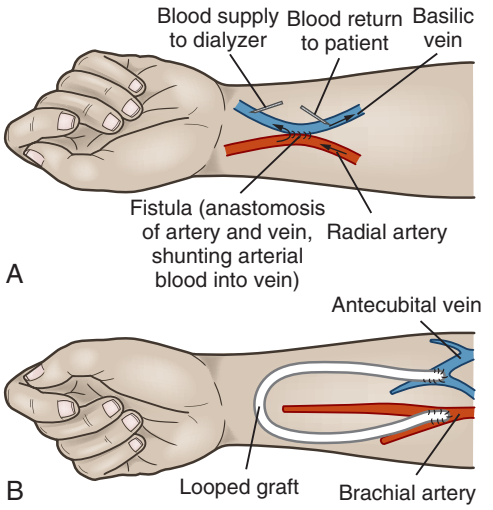

FIG. 47-8 Vascular access for hemodialysis. **A,** Arteriovenous fistula. **B,** Arteriovenous graft.

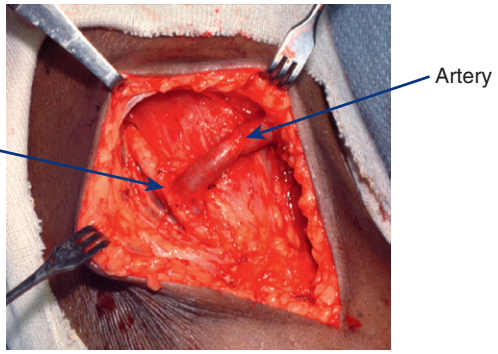

FIG. 47-9 Arteriovenous fistula created by anastomosing an artery and a vein.

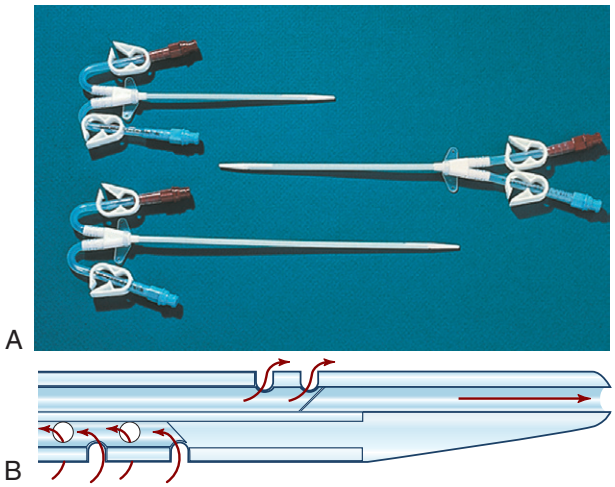

FIG. 47-10 Temporary double-lumen vascular access catheter for acute hemodialysis. **A,** Soft, flexible double-lumen tube is attached to a Y hub. **B,** The distance between the arterial intake lumen and the venous return lumen typically provides recirculation rates of 5% or less.

subcutaneous Dacron cuffs that prevent infection from tracking along the catheter and anchor the catheter, thus eliminating the need for sutures.

Advance planning is essential for management of the patient with kidney failure who is approaching end-stage disease and the need for dialysis. Enough time is needed for evaluation and consideration of the best arteriovenous access for HD and preparation for PD.

Dialyzers. The HD dialyzer is a long plastic cartridge that contains thousands of parallel hollow tubes or fibers. The fibers are semipermeable membranes made of cellulose-based or other synthetic materials. The blood is pumped into the top of the cartridge and is dispersed into all of the fibers. Dialysis fluid *(dialysate)* is pumped into the bottom of the cartridge and bathes the outside of the fibers. Ultrafiltration, diffusion, and osmosis occur across the pores of this semipermeable membrane. When the dialyzed blood reaches the end of the thousands of semipermeable fibers, it converges into a single tube that returns it to the patient. Dialyzers differ in regard to surface area, membrane composition and thickness, clearance of waste products, and removal of fluid.

Procedure for Hemodialysis

The needles used for HD are large bore, usually 14 to 16 gauge, and are inserted into the fistula or graft to obtain vascular access. One needle is placed to pull blood from the circulation to the HD machine, and the other needle is used to return the dialyzed blood to the patient. The needles are attached via tubing to dialysis lines.

If a patient has a catheter, the two blood lines are attached to the two catheter lumens. The needle closer to the fistula (red catheter lumen) is used to pull blood from the patient and send it to the dialyzer with the assistance of a blood pump. Heparin is added to the blood as it flows into the dialyzer because any time blood contacts a foreign substance, it has a tendency to clot. Blood is returned from the dialyzer to the patient through the second needle (blue catheter lumen).

In addition to the dialyzer, a dialysate delivery and monitoring system is used (Fig. 47-12). This system pumps the dialysate through the dialyzer, countercurrent to the blood flow. Dialysis is terminated by flushing the dialyzer with saline solution to

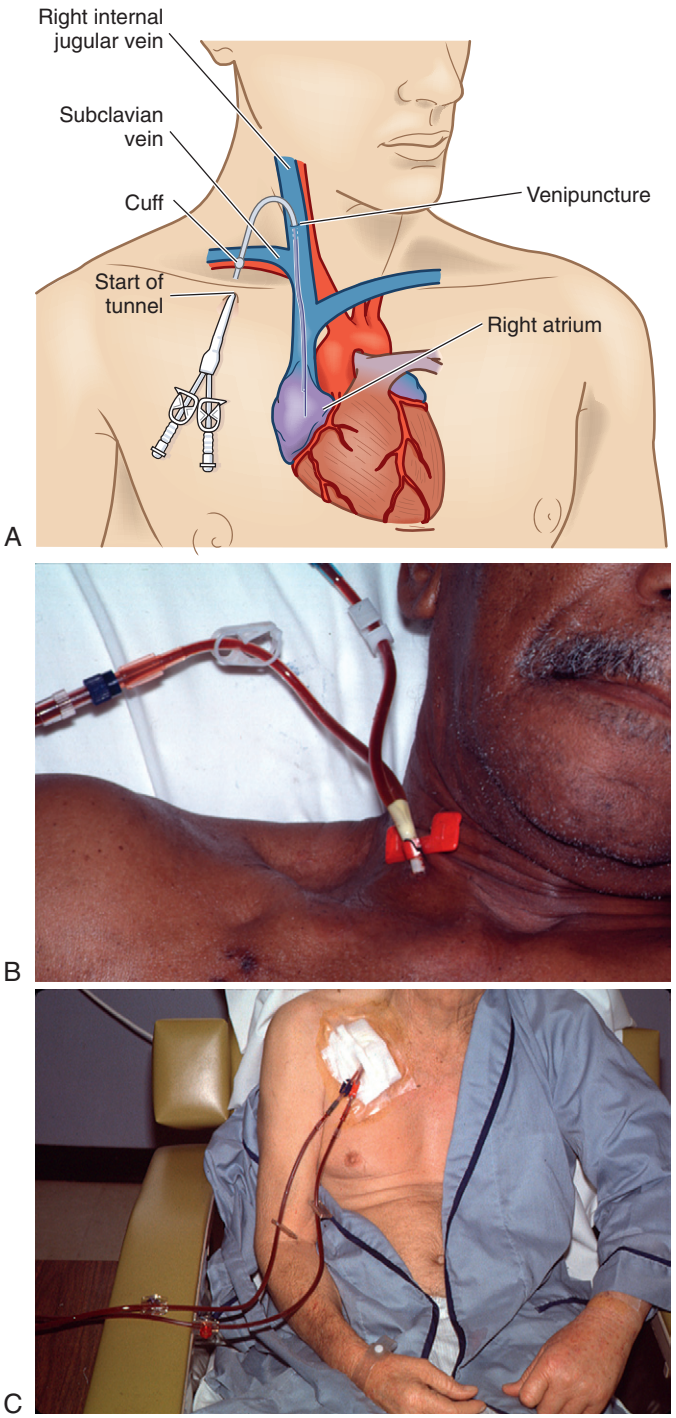

FIG. 47-11 **A,** Right internal jugular placement for a tunneled, cuffed semipermanent catheter. **B,** Temporary hemodialysis catheter in place. **C,** Long-term cuffed hemodialysis catheter.

return the blood in the extracorporeal circuit back to the patient through the vascular access. Then the needles are removed from the patient, and firm pressure is applied to the venipuncture sites until the bleeding stops.

Before beginning treatment, complete an assessment that includes fluid status (weight, BP, peripheral edema, lung and heart sounds), condition of vascular access, temperature, and general skin condition. The difference between the last postdialysis weight and the present predialysis weight determines the ultrafiltration or the amount of weight (from fluid)

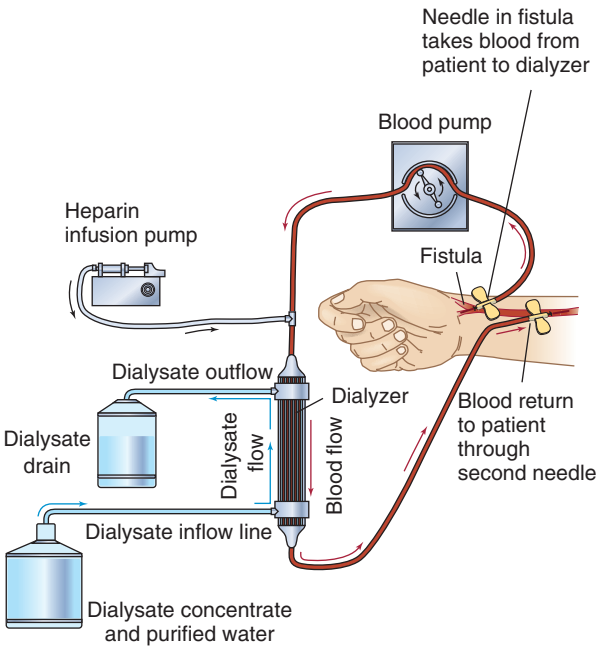

FIG. 47-12 Components of a hemodialysis system. Blood is removed via a needle inserted in a fistula or via catheter lumen. It is propelled to the dialyzer by a blood pump. Heparin is infused either as a bolus predialysis or through a heparin pump continuously to prevent clotting. Dialysate is pumped in and flows in the opposite direction of the blood. The dialyzed blood is returned to the patient through a second needle or catheter lumen. Old dialysate and ultrafiltrate are drained and discarded.

to be removed. While the patient is on dialysis, take vital signs at least every 30 to 60 minutes because rapid BP changes may occur.

Most maintenance dialysis facilities use reclining chairs that allow for elevation of the feet if hypotension develops. Most people sleep, read, talk, or watch television during dialysis.

Settings and Schedules for Hemodialysis. The majority of HD patients are treated in a community-based center and dialyze for 3 to 4 hours 3 days per week. Other schedule options for HD are short daily HD and long nocturnal HD. In short daily HD, the patient dialyzes for 2½ to 3 hours per session 5 to 6 days per week. Short daily HD is usually done at home.

In-center HD programs have adapted their dialysis schedules so patients can be free during the day. The patient receiving long nocturnal HD has the advantage of sleeping while dialyzing. Each nocturnal treatment lasts 6 to 8 hours, and the patient dialyzes up to six times per week. Patients who choose daily dialysis or nocturnal dialysis tend to feel better, are more in control of their lives, tend to require fewer medications, and have fewer dialysis-related side effects (e.g., hypotension, cramps).

In addition to in-center HD, home HD is available (Fig. 47-13). The option for home HD often depends on a patient's family support. One of the main advantages of home HD is that it allows greater freedom in choosing dialysis times. Daily home HD also offers the potential of significant health benefits. Currently only about 2% of HD patients dialyze at home.

Complications of Hemodialysis

Hypotension. Hypotension that occurs during HD primarily results from rapid removal of vascular volume (hypovolemia), decreased cardiac output, and decreased systemic vascular resistance. The drop in BP during dialysis may precipitate lightheadedness, nausea, vomiting, seizures, vision changes, and chest pain from cardiac ischemia. The usual treatment for hypotension includes decreasing the volume of fluid being removed and infusion of 0.9% saline solution.

FIG. 47-13 Home hemodialysis is growing in popularity, and machines are more compact.

Muscle Cramps. The pathogenesis of muscle cramps in HD is poorly understood. Factors associated with the development of muscle cramps include hypotension, hypovolemia, high ultrafiltration rate (large interdialytic weight gain), and low-sodium dialysis solution. Cramps are more frequently seen in the first month after initiation of dialysis than in the subsequent period. Treatment includes reducing the ultrafiltration rate and administering fluids (saline, glucose, mannitol). Hypertonic saline is not recommended, since the sodium load can be problematic. Hypertonic glucose administration is preferred.

Loss of Blood. Blood loss may result from blood not being completely rinsed from the dialyzer, accidental separation of blood tubing, dialysis membrane rupture, or bleeding after the removal of needles at the end of dialysis. If a patient has received too much heparin or has clotting problems, postdialysis bleeding can be significant. It is essential to rinse back all blood, to closely monitor heparinization to avoid excess anticoagulation, and to hold firm but nonocclusive pressure on access sites until the risk of bleeding has passed.

Hepatitis. At one time, hepatitis B had an unusually high prevalence in dialysis patients, but the incidence today is low. Lower transfusion requirements, screening, and recommendations for vaccinations have lowered the incidence. However, outbreaks of hepatitis B still occur, since transmission is attributed to breaks in infection control practices. To prevent transmission, the Centers for Disease Control and Prevention (CDC) has recommended that all patients and personnel in dialysis units receive hepatitis B vaccine.

Currently, hepatitis C virus (HCV) is responsible for the majority of cases of hepatitis in dialysis patients. (Hepatitis is discussed in more detail in Chapter 44.) Approximately 8% to 10% of patients undergoing dialysis in the United States are positive for anti-HCV, which indicates a previous infection. Infection control precautions are mandated in care of the patient with hepatitis C to protect the patient and staff. (Infection

control precautions are discussed in Chapter 15.) Currently, no vaccine is available for hepatitis C.[25]

Effectiveness of Hemodialysis

HD is still an imperfect therapy for management of ESKD. It cannot fully replace the normal functions of the kidneys. It can ease many of the symptoms of CKD and, if started early, can prevent certain complications. However, it does not alter the accelerated rate of development of CV disease and the related high mortality rate.

The yearly death rate of patients receiving maintenance dialysis remains high at an estimated 19% to 24%. The majority of deaths are caused by CV disease (stroke or myocardial infarction). Infectious complications are the second leading cause of death.

Individual adaptation to maintenance HD varies considerably. Initially many patients feel positive about the dialysis because it makes them feel better and keeps them alive, but there is often great ambivalence about whether it is worthwhile. Dependence on a machine is a reality. In response to their illness, dialysis patients may be nonadherent or depressed and exhibit suicidal tendencies. The primary nursing goals are to assist the patient in maintaining a healthy self-image and, if possible, rehabilitate with the hopes of returning to work.

CONTINUOUS RENAL REPLACEMENT THERAPY

Continuous renal replacement therapy (CRRT) is an alternative or adjunctive method for treating AKI. It provides a means by which uremic toxins and fluids are removed, while acid-base status and electrolytes are adjusted slowly and continuously in a hemodynamically unstable patient. The patients selected are usually those who do not respond to dietary interventions and drug therapy. The principle of CRRT is to dialyze patients in a more physiologic way over 24 hours, just like the kidneys.

CRRT is contraindicated if a patient has life-threatening manifestations of uremia (hyperkalemia, pericarditis) that require rapid resolution. CRRT can be used in conjunction with HD.

Various types of CRRT are available (Table 47-14). CRRT most commonly uses the venovenous approaches of continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF).

Vascular access for CVVH or CVVHD is achieved through the use of a double-lumen catheter (as used in HD [see Fig. 47-10]) placed in the jugular or femoral vein. A blood pump is used to propel the blood through the circuit. A highly permeable, hollow-fiber hemofilter removes plasma water and nonprotein solutes, which are collectively termed *ultrafiltrate*. The ultrafiltration rate (UFR) may range from 0 to 500 mL/hr. Under the influence of hydrostatic pressure and osmotic pressure, water and nonprotein solutes pass out of the filter into the extracapillary space and drain through the ultrafiltrate port into a collection device (drainage bag) (Fig. 47-14). The remaining fluid continues through the filter and returns to the patient via the return port of the double-lumen catheter.

While the ultrafiltrate drains out of the hemofilter, fluid and electrolyte replacements can be infused into the infusion port located after the filter as the blood returns to the patient. This fluid is designed to replace volume and solutes such as sodium, chloride, bicarbonate, and glucose. It also further dilutes intravascular fluid, decreasing the concentration of unwanted solutes such as BUN, creatinine, and potassium. The infusion rate of replacement fluid is determined by the degree of fluid and electrolyte imbalance. Replacement fluid may also be infused into the infusion port before the hemofilter. This method allows for greater clearance of urea and can decrease filter clotting.

Anticoagulation is needed to prevent blood clotting during CRRT. Heparin may be infused as a bolus at the initiation of CRRT or through the heparin infusion port before the hemofilter.

Several features of CRRT differ from HD:

- It is continuous rather than intermittent. Large volumes of fluid can be removed over days (24 hours to more than 2 weeks) versus hours (3 to 4 hours).
- Solute removal can occur by *convection* (no dialysate required) in addition to osmosis and diffusion.

TABLE 47-14 CONTINUOUS RENAL REPLACEMENT THERAPIES

Therapy	Abbreviation	Purpose
Continuous venovenous hemofiltration	CVVH	Removes both fluid and solutes. Replacement fluid required.
Slow continuous ultrafiltration	SCUF	Simplified version of CVVH. Removes fluid. No fluid replacement required.
Continuous venovenous hemodialysis	CVVHD	Removes both fluids and solutes. Requires both dialysate and replacement fluid.
Continuous venovenous hemodiafiltration	CVVHDF	Removes both fluids and solutes. Requires both dialysate and replacement fluid.

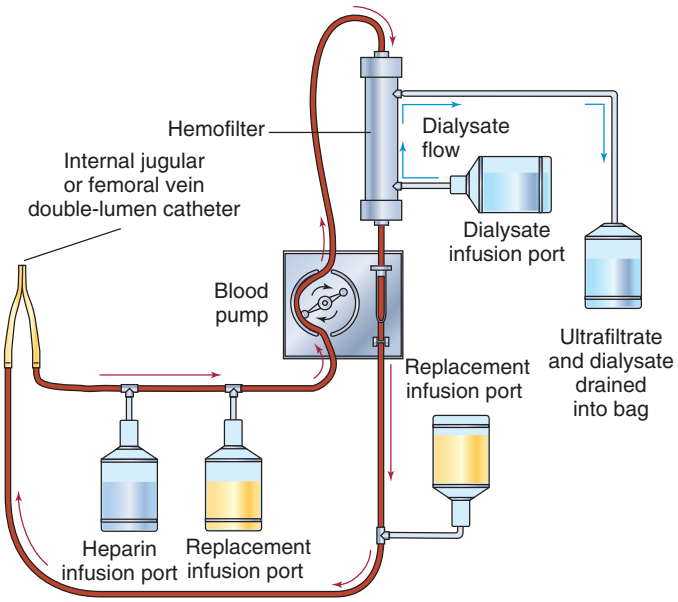

FIG. 47-14 Basic schematic of continuous venovenous therapies. Blood pump is required to pump blood through the circuit. Replacement ports are used for instilling replacement fluids and can be given prefilter or postfilter. Dialysate port is used for infusing dialysis solution. Regardless of modality, ultrafiltrate is drained via the ultrafiltration drain port.

- It causes less hemodynamic instability (e.g., hypotension).
- It does not require constant monitoring by a specialized HD nurse but does require a trained ICU nurse.
- It does not require complicated HD equipment, but a blood pump is needed for venovenous therapies.

The type of CRRT can be customized to the patient's needs. Some types involve the introduction of replacement fluids. Large volumes of fluid may be removed hourly (200 to 800 mL), and then a portion of this fluid is replaced. The type of fluid replacement depends on the patient's stability and individual needs. Ultrafiltration and convective losses occur, and solute concentrations in the blood are diluted with the replacement fluid.

The *hemodialysis therapies* (CVVHD and CVVHDF) use dialysate. Dialysis fluid is attached to the distal end of the hemofilter, and the fluid is pumped countercurrent to the blood flow (see Fig. 47-14). As in dialysis, diffusion of solutes and ultrafiltration via hydrostatic pressure and osmosis occur. This is an ideal treatment for a patient who needs both fluid and solute control but cannot tolerate the rapid fluid shifts associated with HD.

CRRT can be continued as long as 30 to 40 days, but the hemofilter should be changed every 24 to 48 hours because of loss of filtration efficiency or potential for clotting. The ultrafiltrate should be clear yellow, and specimens may be obtained for evaluation of serum chemistries. If the ultrafiltrate becomes bloody or blood tinged, a possible rupture in the filter membrane should be suspected, and treatment is suspended immediately to prevent blood loss and infection.

Specific nursing interventions include obtaining weights and monitoring and documenting laboratory values daily to ensure adequate fluid and electrolyte balance. Assessment of hourly intake and output, vital signs, and hemodynamic status is essential. Although reductions in central venous pressure and pulmonary artery pressure are expected, there should be little change in mean arterial pressure or cardiac output. Patency of the CRRT system is assessed and maintained, and the patient's vascular access site is cared for to prevent infection. Treatment is discontinued and the needle(s) removed once the patient's AKI is resolved or there is a decision to withdraw treatment because of patient deterioration.

KIDNEY TRANSPLANTATION

Major progress has been made in kidney transplantation since the first live donor kidney transplant was performed in 1954 in Boston between identical twins. The advances made in organ procurement and preservation, surgical techniques, tissue typing and matching, immunosuppressant therapy, and prevention and treatment of graft rejection have dramatically increased the success of kidney transplantation. (A general discussion of organ transplantation is in Chapter 14, pp. 219-223).

Even though kidney transplantation is by far the best treatment option available to patients with ESKD, fewer than 4% ever receive a transplant. This is because of the high disparity between the supply and demand for kidneys. Every year thousands are waiting for kidney transplantation (more than 93,000 are currently on the list), yet less than one fourth ever receive a kidney. Most die while waiting. Transplantation from a deceased donor usually requires a prolonged waiting period with differences in waiting time depending on age, gender, and race. Average wait times in the United States for a cadaveric kidney to become available usually ranges from 2 to 5 years.[26]

Kidney transplantation is very successful, with 1-year graft survival rates over 90% for deceased donor transplants and 95% for live donor transplants.[26] An advantage of kidney transplantation when compared with dialysis is that it reverses many of the pathophysiologic changes associated with renal failure. It also eliminates the dependence on dialysis and the accompanying dietary and lifestyle restrictions. Transplantation is also less expensive than dialysis after the first year.

Recipient Selection

Appropriate recipient selection is important for a successful outcome. Candidacy is determined by a variety of medical and psychosocial factors that vary among transplant centers. Some transplant programs exclude patients who are morbidly obese or who continue to smoke (despite smoking cessation interventions). A careful evaluation is completed in an attempt to identify and minimize potential complications after transplantation. Certain patients, particularly those with CV disease and diabetes mellitus, are considered high risk and must be carefully evaluated and then monitored closely after the transplantation. For a small number of patients who are approaching ESKD, a *preemptive transplant* (before dialysis is required) is possible if they have a living donor. This approach is most advantageous for patients with diabetes, who have a much higher mortality rate on dialysis than nondiabetics.

Contraindications to transplantation include disseminated malignancies, refractory or untreated cardiac disease, chronic respiratory failure, extensive vascular disease, chronic infection, and unresolved psychosocial disorders (e.g., nonadherence to medical regimens, alcoholism, drug addiction). At one time, patients diagnosed with human immunodeficiency virus (HIV) infection were denied the opportunity for kidney transplantation. However, centers that have included HIV patients demonstrate graft and patient survival rates for patients with HIV that are comparable to those in the HIV-negative population. The presence of hepatitis B or C is not a contraindication to transplantation.[25]

Surgical procedures may be required before transplantation based on the results of the recipient evaluation. Coronary artery bypass or coronary angioplasty may be indicated for advanced coronary artery disease. Cholecystectomy may be necessary for patients with a history of gallstones, biliary obstruction, or cholecystitis. On rare occasions, bilateral nephrectomies are necessary for patients with refractory hypertension, recurrent urinary tract infections, or grossly enlarged kidneys from polycystic kidney disease. In general, the recipient's own kidneys do not need to be removed before he or she receives a kidney transplant.

Histocompatibility Studies

Histocompatibility studies, including human leukocyte antigen (HLA) testing and crossmatching, are discussed in Chapter 14 on pp. 220-221.

Donor Sources

Kidneys for transplantation may be obtained from compatible blood-type deceased donors, blood relatives, emotionally related (close and distant) living donors (e.g., spouses, distant cousins, etc.), and altruistic living donors who are known (friends) or unknown to the recipient.

ETHICAL/LEGAL DILEMMAS

Allocation of Resources

Situation

T.H., a transplant nurse coordinator, is considering her feelings about two patients who are being evaluated for placement on the deceased (cadaveric) kidney transplant waiting list. One patient is a 40-yr-old African American schoolteacher. She is married and has two children. The other patient is a 22-yr-old unemployed white man. He misses three or four dialysis treatments per month and does not take his antihypertensive medications consistently.

Ethical/Legal Points for Consideration

- The foundation of this conflict resides in the Constitution where the founders made education a free public resource and ignored health care as a right. Health care then became a privilege, a resource to be obtained by persons with the funds to pay for it.
- It took almost 200 yr for health entitlement programs to be developed. Medicare is a federally administrated program. Individuals covered by Medicare are protected by Constitutional laws prohibiting discrimination based on race, gender, religion, and ethnic background.
- Medicaid is a federally sponsored program jointly administered by the various states. The states have the right to set coverage eligibility and limits, but may not violate an individual's constitutionally protected rights against discrimination.
- It is highly unlikely that the standard prohibitions against discrimination will change, but it is possible that definitions of unhealthy behavior such as substance abuse, alcoholism, smoking, and obesity might be used to screen out candidates.
- Nurses are concerned about social justice because of their health advocacy role. Today the situation is immensely more complex because of the cost and availability of care.

Discussion Questions

1. What does the 2001 American Nurses Association (ANA) Code of Ethics say about how you as a nurse should view patients?
2. What are your thoughts about which of the patients should receive the next available kidney transplant?

Another option is *paired organ donation* where one donor/recipient pair who are incompatible or poorly matched with each other find another donor/recipient pair with whom they can exchange kidneys. Thus a spouse (person A) who wants to donate a kidney to his wife (person B) but is incompatible is paired with another donor/recipient pair involving a son with ESKD (person C) and his mother (person D). In this example, person A would donate his kidney to person C, and person D would donate her kidney to person B. Paired organ donation is the practice of matching biologically incompatible donor/recipient pairs to permit transplantation of both candidates with a well-matched organ. Expanding the living donor pool is one of the best possibilities for decreasing the size of the waiting list and reducing wait times for people needing a deceased donor.

Live Donors. Live donors undergo an extensive multidisciplinary evaluation to be certain that they are in good health and have no history of disease that would place them at risk for developing kidney failure or operative complications. Psychosocial and financial evaluations are also done. Crossmatches are done at the time of the evaluation and about a week before the transplant to ensure that no antibodies to the donor are present or that the antibody titer is below the allowed level. Advantages of a live donor kidney include better patient and graft survival rates regardless of histocompatibility match, immediate organ availability, immediate function because of minimal *cold time* (kidney out of body and not getting blood supply), and the opportunity to have the recipient in the best possible medical condition because the surgery is elective.

The potential donor sees a nephrologist for a complete history and physical examination and laboratory and diagnostic studies. Laboratory studies include a 24-hour urine study for creatinine clearance and total protein, complete blood count, and chemistry and electrolyte profiles. Hepatitis B and C, HIV, and cytomegalovirus (CMV) testing is done to assess for any transmitted diseases. An ECG and chest x-ray are also done. A renal ultrasound and a renal arteriogram or three-dimensional CT scan is performed to ensure that the blood vessels supplying each kidney are adequate and that there are no anomalies and to determine which kidney will be removed.

A transplant psychologist or social worker determines if the individual is emotionally stable and able to deal with the issues related to organ donation. All donors must be informed about the risks and benefits of donation, the potential short- and long-term complications, and what to expect during the hospitalization and recovery phases. Kidney donation is considered safe without any long-term health consequences. Although the costs of the evaluation and surgery are covered by the recipient's insurance, no compensation is available for lost wages during the posthospitalization recovery period. This period can last 6 weeks or longer.

When there is ABO incompatibility between a donor and recipient, paired donor exchange is a viable alternative. Another option for ABO incompatibility or a positive crossmatch between the donor and recipient is to use plasmapheresis to remove antibodies from the recipient. (Crossmatching is discussed in Chapter 14.) This allows transplant candidates to receive kidneys from live donors with blood types that have traditionally been considered incompatible. After the transplant, the patient undergoes additional plasmapheresis treatments.

Deceased Donors. Deceased (cadaver) kidney donors are relatively healthy individuals who have suffered an irreversible brain injury and are declared brain dead. The most common causes of injury are cerebral trauma from motor vehicle accidents or gunshot wounds, intracerebral or subarachnoid hemorrhage, and anoxic brain damage caused by cardiac arrest. The brain-dead donor must have effective CV function and be supported on a ventilator to preserve the organs. The donor must be free of active IV drug abuse; severe hypertension; long-standing diabetes mellitus; malignancies; sepsis; and communicable diseases, including HIV, hepatitis B and C, syphilis, and tuberculosis.

Even if the donor carried a signed donor card, permission from the donor's legal next of kin is still requested after brain death is determined. That is why it is important for you to talk with your family about your wishes before losing the capacity to convey your desires.

The kidneys are removed and preserved. They can be preserved for up to 72 hours, but most transplant surgeons prefer to transplant kidneys before the cold time (time outside of the body when being transported from the deceased donor to the recipient) reaches 24 hours. Prolonged cold time increases the likelihood that the kidney will not function immediately, and acute tubular necrosis (ATN) may develop.

The United Network for Organ Sharing (UNOS) distributes deceased donor kidneys using an objective computerized point system. The ABO group, HLA typing, age, antibody level, and length of time waiting are entered into the national computer

for each candidate. When a donor becomes available, the donor's key information is compared with the data of all patients awaiting transplantation locally and nationwide. Points are given for how close the HLA match is, how long the patient has been waiting, if the antibody level is unusually high, and if the recipient is younger than 19 years old. Extra points are given for high antibody levels because this can severely limit the number of donors with whom the patient will not have a positive crossmatch. The kidney is offered to the recipient with the most points in the local area. If no patients in the local area are suitable, the organ is then offered in the region and then in the nation. When a kidney arrives at the recipient's transplant center, a final crossmatch is done and must be negative for the deceased donor transplantation to proceed. (Crossmatching is discussed in Chapter 14.)

The only exception to the previous plan is if a patient needs an emergency transplant or if a donor and recipient match on all six HLA antigens (zero antigen mismatch). The patient meeting either one of these criteria goes to the top of the list. Emergency transplants are given priority because the patient is facing imminent death if not transplanted (e.g., a patient who had no vascular access sites left and can no longer dialyze). Zero antigen mismatches are given priority because statistically these grafts have better survival rates. If a zero antigen mismatch patient is identified nationally, one of the donor kidneys must be sent to that recipient's transplant center regardless of location.

Surgical Procedure

Live Donor. Living donation accounts for nearly 27% of all kidney transplants in the United States, and most transplant centers regard them as the preferred donation modality. The donor nephrectomy is performed by a urologist or transplant surgeon. The donor's surgery begins 1 to 2 hours before the recipient's surgery. The recipient is surgically prepared for the kidney transplant in a nearby operating room.

Laparoscopic donor nephrectomy is the most common technique for removing a kidney in a living donor. (Laparoscopic nephrectomy is discussed in Chapter 46.) After the kidney has been removed, it is flushed with a chilled, sterile electrolyte solution and prepared for immediate transplant into the recipient. The use of a laparoscopic donor nephrectomy procedure is minimally invasive with fewer risks and shorter recovery time than an open procedure. The laparoscopic approach significantly decreases hospital stay, pain, operative blood loss, debilitation, and length of time off work. For these reasons, the number of people willing to donate a kidney has increased significantly.

For an *open* (*conventional) nephrectomy,* the donor is placed in the lateral decubitus position on the operating table so that the flank is exposed laterally. An incision is made at the level of the eleventh rib. The rib may have to be removed to provide adequate visualization of the kidney.

Kidney Transplant Recipient. The transplanted kidney is usually placed extraperitoneally in the iliac fossa. The right iliac fossa is preferred to facilitate anastomoses of the blood vessels and ureter and minimize the occurrence of paralytic ileus.

Before any incisions are made, a urinary catheter is placed into the bladder. An antibiotic solution is instilled to distend the bladder and decrease the risk of infection. A crescent-shaped incision is made extending from the iliac crest to the symphysis pubis (Fig. 47-15).

Rapid revascularization is critical to prevent ischemic injury to the kidney. The donor artery is anastomosed to the recipient's internal iliac (hypogastric) or external iliac artery. The donor vein is anastomosed to the recipient's external iliac vein.

When the anastomoses are complete, the clamps are released, and blood flow to the kidney is reestablished. The kidney should become firm and pink. Urine may begin to flow from the ureter immediately.

The donor ureter in most cases is then tunneled through the bladder submucosa before entering the bladder cavity and being sutured in place. This approach is called *ureteroneocystostomy.* This allows the bladder wall to compress the ureter as it contracts for micturition, thereby preventing reflux of urine up the ureter into the transplanted kidney. The transplant surgery takes about 3 to 4 hours.

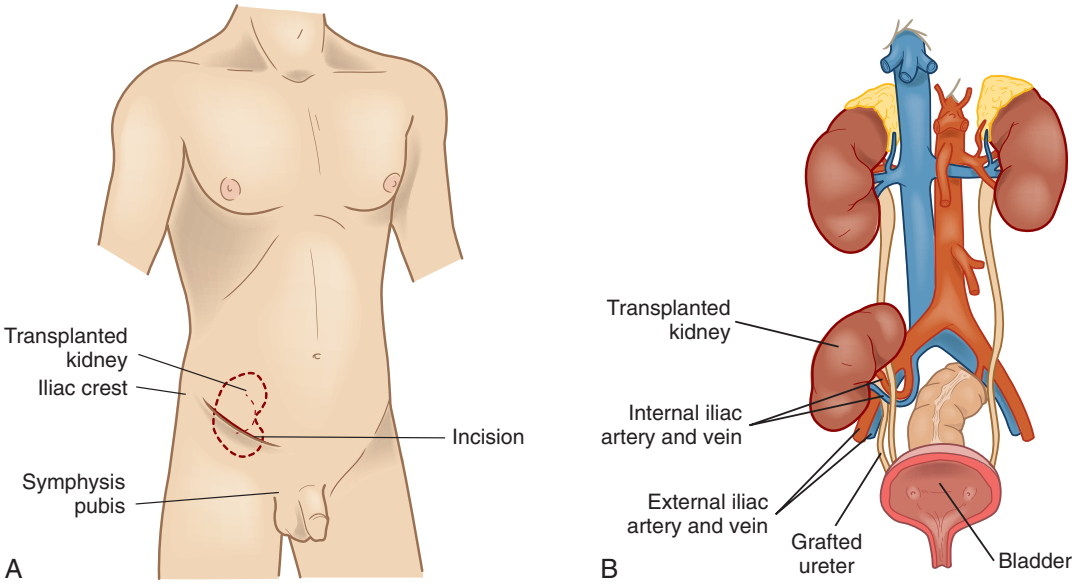

FIG. 47-15 **A,** Surgical incision for a renal transplant. **B,** Surgical placement of transplanted kidney.

NURSING MANAGEMENT
KIDNEY TRANSPLANT RECIPIENT

PREOPERATIVE CARE

Nursing care of the patient in the preoperative phase includes emotional and physical preparation for surgery. Because the patient and caregiver may have been waiting years for the kidney transplant, a review of the operative procedure and what can be expected in the immediate postoperative recovery period is necessary. Stress that there is a chance the kidney may not function immediately, and dialysis may be required for days to weeks. Review the need for immunosuppressive drugs and measures to prevent infection.

To ensure the patient is in optimal physical condition for surgery, an ECG, chest x-ray, and laboratory studies are ordered. Dialysis may be required before surgery for any significant problems such as fluid overload or hyperkalemia. A patient on PD must empty the peritoneal cavity of all dialysate solution before going to surgery. Because dialysis may be required after transplantation, the patency of the vascular access must be maintained. The vascular access extremity should be labeled "dialysis access, no procedures" to prevent use of the affected extremity for BP measurement, blood drawing, or IV infusions.

POSTOPERATIVE CARE

LIVE DONOR. The usual postoperative care for the donor is similar to that following open (conventional) or laparoscopic nephrectomy (see Chapter 46). Closely monitor renal function to assess for impairment, and monitor the hematocrit to assess for bleeding. Donors experience more pain after an open nephrectomy than a laparoscopic procedure. Generally, all donors have more pain than their recipients do. Donors who have had an open surgical approach are ready to be discharged from the hospital in 4 or 5 days and can usually return to work in 6 to 8 weeks. With a laparoscopic approach, donors are discharged from the hospital in 2 to 4 days and can return to work in 4 to 6 weeks. The donor is seen by the surgeon 1 to 2 weeks after discharge.

Nurses caring for the living donor need to acknowledge the precious gift that this person has given. The donor has taken physical, emotional, and financial risks to assist the recipient. It is vital that the donor not be forgotten postoperatively. The donor will need even more support if the donated organ does not work immediately or for some reason fails.

KIDNEY TRANSPLANT RECIPIENT. The first priority during this period is maintenance of fluid and electrolyte balance. Because close monitoring is required, kidney transplant recipients spend the first 12 to 24 hours in the ICU. Very large volumes of urine may be produced soon after the blood supply to the transplanted kidney is reestablished. This diuresis is due to (1) the new kidney's ability to filter BUN, which acts as an osmotic diuretic; (2) the abundance of fluids administered during the operation; and (3) initial renal tubular dysfunction, which inhibits the kidney from concentrating urine normally. Urine output during this phase may be as high as 1 L/hr and gradually decreases as the BUN and serum creatinine levels return toward normal.

Urine output is replaced with fluids milliliter for milliliter hourly for the first 12 to 24 hours. Central venous pressure readings are essential for monitoring postoperative fluid status. Dehydration must be avoided to prevent subsequent renal hypoperfusion and renal tubular damage. Electrolyte monitoring to assess for the hyponatremia and hypokalemia often associated with rapid diuresis is critical. Treatment with potassium supplements or infusion of 0.9% normal saline may be indicated. IV sodium bicarbonate may also be required if the patient develops metabolic acidosis from delayed kidney function.

Acute tubular necrosis (ATN) can occur because of prolonged cold times causing ischemic damage and the use of marginal cadaveric donors (those who are medically suboptimal). While the patient is in ATN, dialysis is required to maintain fluid and electrolyte balance. Some patients have high-output ATN with the ability to excrete fluid but not metabolic wastes or electrolytes. Other patients have oliguric or anuric ATN. These patients are at risk for fluid overload in the immediate postoperative period and must be assessed closely for the need for dialysis. The period of ATN can last anywhere from days to weeks, with gradually improving kidney function. Most patients with ATN are discharged from the hospital on dialysis. This is extremely discouraging for the patient, who needs reassurance that renal function usually improves. Dialysis is discontinued when urine output increases and serum creatinine and BUN begin to normalize.

A sudden decrease in urine output in the early postoperative period is a cause for concern. It may be due to dehydration, rejection, a urine leak, or obstruction. A common cause of early obstruction is a blood clot in the urinary catheter. Catheter patency must be maintained, since the catheter remains in the bladder for 3 to 5 days to allow the ureter-bladder anastomosis to heal. If blood clots are suspected, gentle catheter irrigation (if ordered by the health care provider) can reestablish patency.

With a hospital length of stay averaging 4 to 5 days, discharge planning and teaching needs must be identified and addressed early in the hospital course. Postoperative teaching includes how to recognize signs of rejection, infection, and any complications of surgery. Frequent blood tests and clinic visits help detect rejection early. Patient teaching to ensure a smooth transition from the hospital to the home is an integral part of the nursing care.

Immunosuppressive Therapy

The goal of immunosuppression is to adequately suppress the immune response to prevent rejection of the transplanted kidney while maintaining sufficient immunity to prevent overwhelming infection. Immunosuppressive therapy is discussed in Chapter 14 and in Table 14-16.

Complications of Transplantation

Complications of RRTs, including PD, HD, and kidney transplantation, are compared in Table 47-15.

Rejection. Rejection is one of the major problems following kidney transplantation. Rejection can be hyperacute, acute, or chronic. These types of rejection are discussed in Chapter 14 on p. 221. Patients with chronic rejection should be put on the transplant list in the hope that they can be retransplanted before dialysis is required.

Infection. Infection remains a significant cause of morbidity and mortality after transplantation. The transplant recipient is at risk for infection because of suppression of the body's normal defense mechanisms by surgery, immunosuppressive drugs, and the effects of ESKD. Underlying systemic illness such as diabetes mellitus or systemic lupus erythematosus, malnutrition, and older age can further compound the negative effects on the

TABLE 47-15 COMPLICATIONS OF DIALYSIS AND TRANSPLANTATION

Peritoneal Dialysis (PD)	Hemodialysis (HD)	Transplantation
• Exit site infection • Peritonitis • Abdominal pain • Catheter outflow • Hernias • Lower back pain • Cardiovascular disease • Pulmonary problems • Atelectasis • Pneumonia • Bronchitis • Protein loss • Carbohydrate abnormalities • Lipid abnormalities • Encapsulating sclerosing peritonitis	• Hypotension • Muscle cramps • Exsanguination • Hepatitis • Infection, including sepsis • Disequilibrium syndrome • Cardiovascular disease	• Rejection of transplant • Hyperacute • Acute • Chronic • Susceptibility to infection • Cardiovascular disease • Malignancies • Recurrence of kidney disease • Corticosteroid-related complications

immune response. At times the signs and symptoms of infection can be subtle. You need to be astute in your observation and assessment of kidney transplant recipients because prompt diagnosis and treatment of infections will improve patient outcomes.

The most common infections observed in the first month after transplantation are similar to those acquired by any postoperative patient, such as pneumonia, wound infections, IV line and drain infections, and urinary tract infections. Fungal and viral infections are not uncommon because of the patient's immunosuppressed state. Fungal infections include *Candida, Cryptococcus,* and *Aspergillus* organisms and *Pneumocystis jiroveci.* Fungal infections are difficult to treat, require prolonged treatment periods, and often involve the administration of nephrotoxic drugs. Transplant recipients usually receive prophylactic antifungal drugs to prevent these infections, such as clotrimazole (Mycelex), fluconazole (Diflucan), and trimethoprim/sulfamethoxazole (Bactrim).

Viral infections, including CMV, Epstein-Barr virus, herpes simplex virus (HSV), varicella-zoster virus, and polyomavirus (e.g., BK virus), can be primary infections or reactivations of existing disease. Primary infections occur as new infections after transplantation from an exogenous source such as the donated organ or a blood transfusion. Reactivation occurs when a virus exists in a patient and becomes reactivated after transplantation because of immunosuppression.

CMV is one of the most common viral infections. If a recipient has never had CMV and receives an organ from a donor with a history of CMV, antiviral prophylaxis will be administered (e.g., ganciclovir [Cytovene], valganciclovir [Valcyte]). If a primary active CMV infection is diagnosed or there is symptomatic reactivation of CMV, IV ganciclovir is given along with an immune globulin that contains CMV antibodies. To prevent HSV infections, oral acyclovir (Zovirax) is given for several months after the transplant.

Cardiovascular Disease. Transplant recipients have an increased incidence of atherosclerotic vascular disease. CV disease is the leading cause of death after renal transplantation. Hypertension, dyslipidemia, diabetes mellitus, smoking, rejection, infections, and increased homocysteine levels can all contribute to CV disease. Immunosuppressants can worsen hypertension and dyslipidemia. Teach the patient to control risk factors such as elevated cholesterol, triglycerides, and blood glucose and weight gain. Adherence to the prescribed antihypertensive regimen is essential not only to prevent CV events but also to prevent damage to the new kidney. (Hypertension is discussed in Chapter 33.)

Malignancies. The overall incidence of malignancies in kidney transplant recipients is greater than in the general population, primarily because of immunosuppressive therapy. Not only do immunosuppressants suppress the immune system to prevent rejection, but they also suppress the ability to fight infection and the production of abnormal cells such as cancer cells.[27]

The most common types of cancer after transplant are basal and squamous cell carcinoma of the skin, Hodgkin's and non-Hodgkin's lymphoma, and Kaposi sarcoma. Patients are also at risk for cancers of the liver, stomach, oropharynx, anus, vulva, and penis.

Regular screening for cancer is an important part of the transplant recipient's preventive care. Advise the patient to avoid sun exposure by using protective clothing and sunscreens to minimize the incidence of skin cancers.

Recurrence of Original Kidney Disease. Recurrence of the original disease that destroyed the native kidneys occurs in some kidney transplant recipients. It is most common with certain types of glomerulonephritis, immunoglobulin A (IgA) nephropathy, diabetic nephropathy, and focal segmental sclerosis. Disease recurrence can result in the loss of a functioning kidney transplant. Patients must be advised before transplantation if they have a disease known to recur.

Corticosteroid-Related Complications. Aseptic necrosis of the hips, knees, and other joints can result from chronic corticosteroid therapy and renal osteodystrophy. Other significant problems related to corticosteroids include peptic ulcer disease, glucose intolerance and diabetes, cataracts, dyslipidemia, infections, and malignancies. In the first year after transplantation, corticosteroid doses are usually decreased to 5 to 10 mg/day. The use of tacrolimus and cyclosporine has allowed the corticosteroid doses to be much lower than they were in the past.

Many transplant programs have initiated corticosteroid-free drug regimens because of the problems of long-term corticosteroid use. Other centers withdraw patients from corticosteroids over a short period after transplantation. For patients who remain on corticosteroids, vigilant monitoring for side effects and early treatment are essential.

GERONTOLOGIC CONSIDERATIONS

CHRONIC KIDNEY DISEASE

The incidence of CKD in the United States is increasing most rapidly in older patients. The most common diseases leading to renal failure in older people are hypertension and diabetes.

The care of this older population is particularly challenging, not only because of the normal physiologic changes of aging but also because of the disabilities, chronic diseases, and number of co-morbid conditions that develop.[28] Physiologic changes of clinical importance in the older CKD patient include diminished cardiopulmonary function, bone loss, immunodeficiency, altered protein synthesis, impaired cognition, and altered drug metabolism. Malnutrition is common in these patients for a

variety of reasons, including lack of mobility, lack of understanding of basic nutritional requirements, social isolation, physical disability, impaired cognitive function, and malabsorption problems.

When conservative therapy for CKD is no longer effective, the older patient needs to consider the best treatment modality based on his or her physical and emotional health, personal preferences, and availability of support. PD allows the patient to be more mobile and to enjoy an increased sense of control over the illness. PD causes less hemodynamic instability than HD but does require self-care or assistance from another person, which may not always be available.

Most individuals 65 years of age or older select treatment with HD, specifically in-center treatment, because of a lack of assistance in the home and reluctance to manage the technology of dialysis. Establishing vascular access for HD may be a concern for an older patient because of atherosclerotic changes. Although transplantation is an option, older patients are less likely to be considered as candidates. Older adults need to be carefully screened to ensure that the benefits of transplantation outweigh the risks.[29] A living donor is preferable so that there is not a prolonged waiting time.

The most common cause of death in older ESKD patients is CV disease (myocardial infarction, stroke), followed by withdrawal from dialysis. If a competent patient decides to withdraw from dialysis, it is essential to support the patient and family. Ethical issues (see the Ethical/Legal Dilemmas box on this page) to consider in this situation include patient competency, benefit versus burden of treatment, and futility of treatment. Withdrawal from treatment is not a failure if the patient is well informed and comfortable with the decision.[30]

The increasing number of older, debilitated ESKD patients receiving dialysis has raised a number of ethical concerns about the use of scarce resources in a population with a limited life expectancy. Dialysis (especially PD) has been successfully used in older adults. Quality of life is good in many older ESKD patients receiving dialysis. There appears to be no justification for excluding the older adult from dialysis programs. Rationing dialysis based on age alone is not supported based on current outcome and quality-of-life data.

ETHICAL/LEGAL DILEMMAS

Withdrawing Treatment

Situation

L.R., a 70-yr-old patient with diabetes mellitus and end-stage kidney disease, has been on dialysis for 10 yr. He tells you that he wants to discontinue his dialysis. His quality of life has diminished during the past 2 yr since his wife died. He is not a transplant candidate.

Ethical/Legal Points for Consideration

- Informed consent includes the legal right to refuse treatment. However, the right to refuse may be more difficult if (1) it is contrary to the wishes of family and friends, (2) the treatment still appears to have some effectiveness, and (3) the treatment has been in place for some time.
- Quality-of-life decisions often outweigh the benefit against the burden of treatment. When a treatment becomes too burdensome, the patient (if competent) may request to withdraw the treatment.
- It must be determined whether some other treatable problem such as depression may be clouding the patient's judgment.
- Some health care professionals become conflicted when they are asked to withdraw treatment, since they may think they are contributing to the patient's untimely death.
- If a decision is made to withdraw treatment, the health care team, patient, and family should develop an appropriate follow-up plan that includes palliative care and hospice support.

Discussion Questions

1. How should you respond to L.R.'s request?
2. What is the American Nurses Association's position on withdrawing or withholding treatment that no longer benefits the patient or causes suffering?

CASE STUDY

Chronic Kidney Disease

iStockphoto/Thinkstock

Patient Profile

M.B. is a 56-yr-old African American college professor. He is seen by his primary care provider for a routine physical examination. He has not been seen by a physician in a little over a year. He complains of generalized malaise, frequent urination, and "increasing thirst." His medical history is significant for borderline hypertension and dyslipidemia. He also smokes at least one pack of cigarettes per day, and his efforts to quit have been unsuccessful.

Subjective Data

- Family history: father died of a heart attack at age 62, brother had coronary artery bypass graft (CABG) at age 50, mother died from complications of diabetes
- Becomes "winded" when walking from his car to his office at the university
- Wakes up at night to urinate and has more frequent urination
- Increasing thirst

Objective Data

Laboratory Data

- Calculated creatinine clearance using the MDRD equation: 42 mL/min/1.73 m^2
- Serum creatinine 2.5 mg/dL
- BUN 35 mg/dL
- Serum glucose 264 mg/dL
- Hgb 13 g/dL
- Serum cholesterol 236 mg/dL

Physical Examination

- Weight 220 lb, height 5 ft, 11 in
- Blood pressure 168/104 mm Hg

Discussion Questions

1. What do you think caused M.B.'s kidney failure?
2. What stage of chronic kidney disease does he have?
3. What are the most important treatments for M.B.?
4. Identify the abnormal diagnostic study results and why each would occur.
5. ***Priority Decision:*** What are the priority nursing interventions that would help promote M.B.'s self-management of his disease process?
6. ***Priority Decision:*** Based on the assessment data provided, what are the priority nursing diagnoses? Are there any collaborative problems?
7. ***Evidence-Based Practice:*** M.B. tells you that he has not been taking his blood pressure medications regularly. When he asks you how important they are, what will you tell him?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg.*

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which descriptions characterize acute kidney injury *(select all that apply)?*
   - **a.** Primary cause of death is infection.
   - **b.** It almost always affects older people.
   - **c.** Disease course is potentially reversible.
   - **d.** Most common cause is diabetic nephropathy.
   - **e.** Cardiovascular disease is most common cause of death.
2. RIFLE defines three stages of AKI based on changes in
   - **a.** blood pressure and urine osmolality.
   - **b.** fractional excretion of urinary sodium.
   - **c.** estimation of GFR with the MDRD equation.
   - **d.** serum creatinine or urine output from baseline.
3. During the oliguric phase of AKI, the nurse monitors the patient for *(select all that apply)*
   - **a.** hypotension.
   - **b.** ECG changes.
   - **c.** hypernatremia.
   - **d.** pulmonary edema.
   - **e.** urine with high specific gravity.
4. If a patient is in the diuretic phase of AKI, the nurse must monitor for which serum electrolyte imbalances?
   - **a.** Hyperkalemia and hyponatremia
   - **b.** Hyperkalemia and hypernatremia
   - **c.** Hypokalemia and hyponatremia
   - **d.** Hypokalemia and hypernatremia
5. A patient is admitted to the hospital with chronic kidney disease. The nurse understands that this condition is characterized by
   - **a.** progressive irreversible destruction of the kidneys.
   - **b.** a rapid decrease in urine output with an elevated BUN.
   - **c.** an increasing creatinine clearance with a decrease in urine output.
   - **d.** prostration, somnolence, and confusion with coma and imminent death.
6. Nurses need to teach patients at risk for developing chronic kidney disease. Individuals considered to be at increased risk include *(select all that apply)*
   - **a.** older African Americans.
   - **b.** patients more than 60 years old.
   - **c.** those with a history of pancreatitis.
   - **d.** those with a history of hypertension.
   - **e.** those with a history of type 2 diabetes.
7. Patients with chronic kidney disease experience an increased incidence of cardiovascular disease related to *(select all that apply)*
   - **a.** hypertension.
   - **b.** vascular calcifications.
   - **c.** a genetic predisposition.
   - **d.** hyperinsulinemia causing dyslipidemia.
   - **e.** increased high-density lipoprotein levels.
8. Nutritional support and management are essential across the entire continuum of chronic kidney disease. Which statements would be considered true related to nutritional therapy *(select all that apply)?*
   - **a.** Fluid is not usually restricted for patients receiving peritoneal dialysis.
   - **b.** Sodium and potassium may be restricted in someone with advanced CKD.
   - **c.** Decreased fluid intake and a low potassium diet are hallmarks of the diet for a patient receiving hemodialysis.
   - **d.** Decreased fluid intake and a low potassium diet are hallmarks of the diet for a patient receiving peritoneal dialysis.
   - **e.** Increased fluid intake and a diet with potassium-rich foods are hallmarks of a diet for a patient receiving hemodialysis.
9. An ESKD patient receiving hemodialysis is considering asking a relative to donate a kidney for transplantation. In assisting the patient to make a decision about treatment, the nurse informs the patient that
   - **a.** successful transplantation usually provides better quality of life than that offered by dialysis.
   - **b.** if rejection of the transplanted kidney occurs, no further treatment for the renal failure is available.
   - **c.** hemodialysis replaces the normal functions of the kidneys, and patients do not have to live with the continual fear of rejection.
   - **d.** the immunosuppressive therapy following transplantation makes the person ineligible to receive other forms of treatment if the kidney fails.
10. To assess the patency of a newly placed arteriovenous graft for dialysis, the nurse should *(select all that apply)*
    - **a.** monitor the BP in the affected arm.
    - **b.** irrigate the graft daily with low-dose heparin.
    - **c.** palpate the area of the graft to feel a normal thrill.
    - **d.** listen with a stethoscope over the graft to detect a bruit.
    - **e.** frequently monitor the pulses and neurovascular status distal to the graft.
11. A major advantage of peritoneal dialysis is
    - **a.** the diet is less restricted and dialysis can be performed at home.
    - **b.** the dialysate is biocompatible and causes no long-term consequences.
    - **c.** high glucose concentrations of the dialysate cause a reduction in appetite, promoting weight loss.
    - **d.** no medications are required because of the enhanced efficiency of the peritoneal membrane in removing toxins.
12. A kidney transplant recipient complains of having fever, chills, and dysuria over the past 2 days. What is the first action that the nurse should take?
    - **a.** Assess temperature and initiate workup to rule out infection.
    - **b.** Reassure the patient that this is common after transplantation.
    - **c.** Provide warm cover for the patient and give 1 g acetaminophen orally.
    - **d.** Notify the nephrologist that the patient has developed symptoms of acute rejection.

1. a, c, 2. d, 3. b, d, 4. c, 5. a, 6. a, b, d, e, 7. a, b, d, 8. a, b, c, 9. a, 10. c, d, e, 11. a, 12. a

CASE STUDY

Managing Multiple Patients

Introduction

You are working on the medical-surgical unit and have been assigned to care for the following four patients. You are also assigned to receive a new admission to the clinical unit. You have one UAP on your team to help you.

Patients

iStockphoto/Thinkstock

A.K., a 28-year-old African American man, was admitted for observation after a renal ultrasound identified calculi in the left ureter. A.K. came to the ED with complaints of sharp, colicky left flank pain for which the health care provider prescribed IV opioids. His last pain medication was given 2 hours ago. His current pain level is 4 on a scale of 1-10. He is voiding dark, smoky colored urine. His vital signs are within normal limits. He has positive costovertebral tenderness.

iStockphoto/Thinkstock

S.U., a 38-year-old Hispanic woman, was admitted with acute pyelonephritis following a recent UTI. She complains of bilateral flank pain and has abdominal tenderness to palpation. Her temperature is 100.4° F (38° C). Her urinalysis indicates pyuria and hematuria. Her WBC is elevated at 12,000/µL. Blood culture results are pending. IV antibiotics have been started.

iStockphoto/Thinkstock

M.B., a 56-year-old African American college professor, was admitted with uncontrolled hypertension. He was recently diagnosed with CKD. He smokes at least one pack of cigarettes per day and is experiencing some nicotine withdrawal symptoms. His BP on admission was 224/102 mm Hg. He is receiving IV metoprolol (Lopressor) 5 mg q4hr prn for SBP >180 mm Hg. His most recent BP 3 hr ago was 174/86 mm Hg.

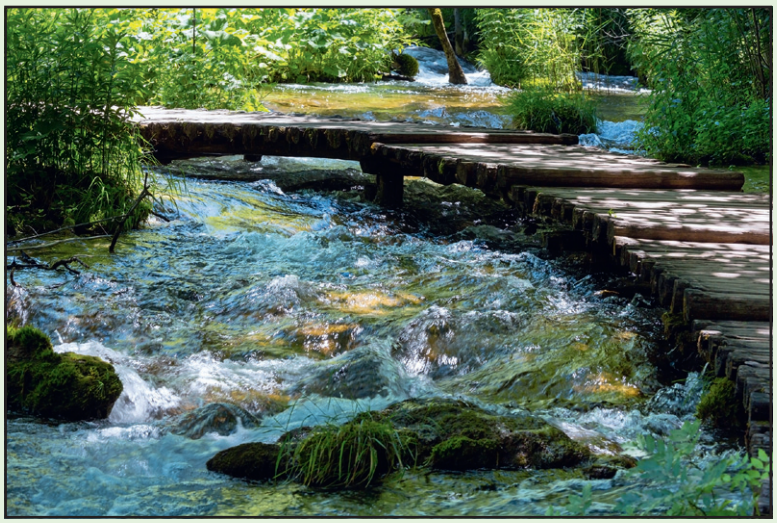
iStockphoto/Thinkstock

D.M., an 82-year-old woman, was admitted to the ED with severe dehydration, heart failure, and acute kidney injury. Her daughter found her unconscious and lying on the floor. She is confused. Her serum potassium level is 5.7 mEq/L. Her urine output for the past 8 hours was 90 mL.

Management Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Second? Provide a rationale for your decision.
2. ***Delegation Decision:*** Which tasks could you delegate to the UAP *(select all that apply)?*
   a. Obtain vital signs on M.B.
   b. Strain A.K.'s voided urine.
   c. Report D.M.'s potassium level to health care provider.
   d. Assess S.U. for potential side effects of the IV antibiotics.
   e. Measure D.M.'s urine output and report the results to the RN.
3. ***Priority and Delegation Decision:*** As you are assessing D.M., the UAP informs you that M.B.'s blood pressure is 190/86. He is asymptomatic. Additionally, the charge nurse informs you that you will be receiving a patient with heart failure from the ED within the next 10 minutes. Which action would be most appropriate?
   a. Ask the charge nurse to assign the new admission to someone else.
   b. Have the UAP admit the new patient while you administer M.B.'s IV metoprolol.
   c. Call the ED and have them hold the new admission until after you have assessed all your patients.
   d. Ask the charge nurse to administer M.B.'s IV metoprolol while you complete your assessment of D.M.

Case Study Progression



As you complete your assessment of D.M., you notice her apical pulse is irregular. She has +1 pitting edema in her lower extremities. Her blood pressure is 160/90 mmHg, heart rate 88 bpm, and respiratory rate 28/min. Her respirations are deep. You notify her health care provider.

4. Which interventions would you expect the health care provider to order for M.B. *(select all that apply)?*
   a. Administer IV Kayexalate.
   b. Obtain arterial blood gas levels.
   c. Place an indwelling urinary catheter.
   d. Perform continuous cardiac monitoring.
   e. Prepare M.B. for hemodialysis and notify her family.
5. ***Priority Decision:*** Which nursing diagnosis would be of highest priority when planning care for A.K.?
   a. Risk for injury
   b. Impaired comfort
   c. Risk for infection
   d. Ineffective self-health management
6. Which statement would be most appropriate when teaching S.U. about her kidney infection?
   a. "The damage to your kidneys will likely require dialysis."
   b. "Influenza is the most likely cause of your kidney infection."
   c. "You will need to be in the hospital for a 2-week course of IV antibiotics."
   d. "It is very important that you maintain adequate hydration to flush your kidneys."
7. ***Management Decision:*** As the UAP prepares the room for the patient being admitted from the ED, you overhear her telling a co-worker that she has to do all your work for you. What is your best initial action?
   a. Report the incident to the charge nurse for follow-up.
   b. Ask the UAP to discuss her concerns with you in private.
   c. Tell the UAP how much you appreciate and value her input on your team.
   d. Immediately clarify the situation by telling the UAP all the tasks you are completing.

LEARNING OUTCOMES

1. Describe the common characteristics and functions of hormones.
2. Identify the locations of the endocrine glands.
3. Describe the functions of hormones secreted by the pituitary, thyroid, parathyroid, and adrenal glands and the pancreas.
4. Describe the locations and roles of hormone receptors.
5. Select the significant subjective and objective assessment data related to the endocrine system that should be obtained from a patient.
6. Link age-related changes in the endocrine system to differences in assessment findings.
7. Differentiate normal from common abnormal findings of a physical assessment of the endocrine system.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the endocrine system.

STRUCTURES AND FUNCTIONS OF ENDOCRINE SYSTEM

Glands

Endocrine glands include the hypothalamus, pituitary, thyroid, parathyroids, adrenals, pancreas, ovaries, testes, and pineal gland (Fig. 48-1). *Exocrine glands* are not part of the endocrine system. They secrete their substances into ducts that then empty into a body cavity or onto a surface. For example, salivary glands produce saliva, which is secreted through salivary ducts into the mouth.

Hormones

Hormones are chemical substances produced in the body that control and regulate the activity of certain target cells or organs. Many are produced in one part of the body and control and regulate the activity of certain cells or organs in another part of the body.

Endocrine glands produce and secrete hormones that travel to affect their specific target tissues. For example, the thyroid gland synthesizes the hormone thyroxine, which affects all body tissues. Some hormones are released directly into the circulation, whereas others may act locally on cells

Reviewed by Saundra J. Hendricks, RN, MS, FNP, BC-ADM, Endocrine Nurses Society, Former President, The Methodist Hospital, Department of Medicine, Houston, Texas; Beth Lucasey, RN, MA, Endocrine Nurses Society Board Member, VP Marketing and Communication, TVAX Biomedical, Kansas City, Missouri; Barbara Lukert, MD, Endocrine Nurses Society Advisor, Endocrinologist, University of Kansas Medical Center, Kansas City, Kansas; and Teresa J. Seright, RN, PhD, CCRN, Assistant Professor of Nursing, Montana State University, Bozeman, Montana.

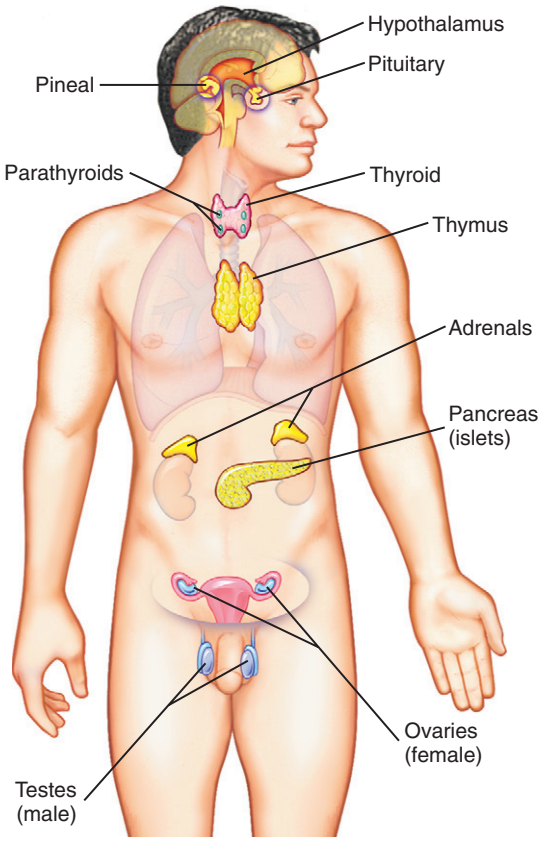

FIG. 48-1 Location of the major endocrine glands. The parathyroid glands lie on the posterior surface of the thyroid gland.

where they are released and never enter the bloodstream. This local effect is called *paracrine action*. The action of sex steroids on the ovary is an example of paracrine action.

Most hormones have common characteristics, including (1) secretion in small amounts at variable but predictable rates; (2) regulation by feedback systems; and (3) binding to specific target cell receptors. Table 48-1 summarizes the major hormones, glands or tissues from which they are synthesized, target organs or tissues, and functions.

In addition to important physiologic activities, hormones help regulate the nervous system. For example, catecholamines are hormones when they are secreted by the adrenal medulla, but act as neurotransmitters when secreted by nerve cells in the brain and peripheral nervous system. When epinephrine, a catecholamine, travels through the blood, it is a hormone and affects target tissues. When it travels across synaptic junctions, it acts as a neurotransmitter.[1]

In addition to the endocrine glands, other body organs may secrete hormones. For example, the kidneys secrete erythropoietin, the heart secretes atrial natriuretic peptide, and the gastrointestinal (GI) tract secretes numerous peptide hormones (e.g., gastrin). These hormones are discussed in their respective assessment chapters.

Hormone Receptors. Hormones exert their effects by recognizing their target tissues and attaching to receptor sites in a "lock-and-key" type of mechanism. Therefore a hormone will act only on cells that have a receptor specific for that hormone (Fig. 48-2).

Lipid-Soluble and Water-Soluble Hormones. Hormones are classified by their chemical structure as either lipid soluble or water soluble. The differences in solubility become important in understanding how the hormone interacts with the target cell.

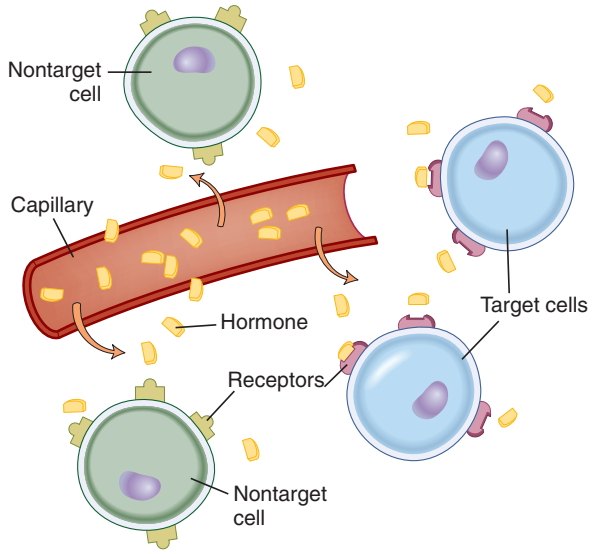

FIG. 48-2 The target cell concept. Hormones act only on cells that have receptors specific to that hormone, since the shape of the receptor determines which hormone can react with it. This is an example of the lock-and-key model of biochemical reactions.

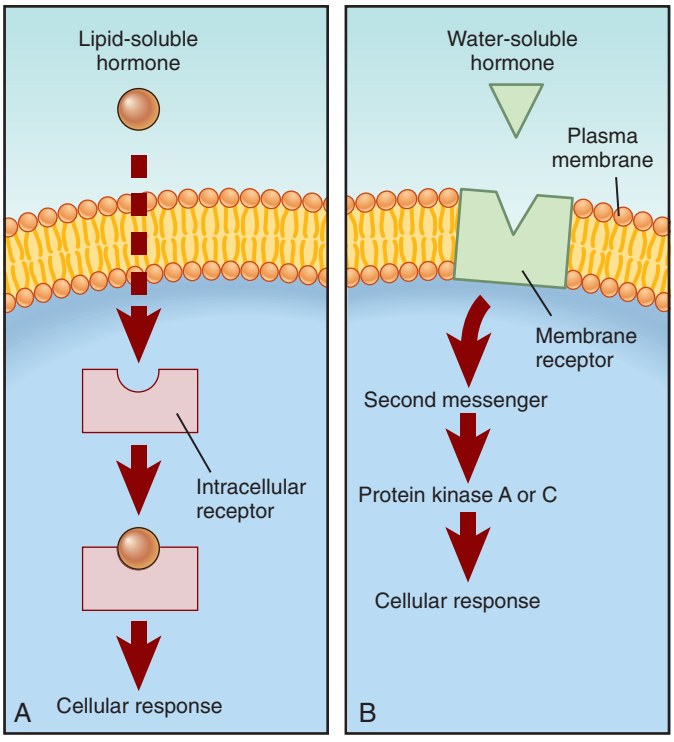

FIG. 48-3 **A,** Lipid-soluble hormones (e.g., steroid hormones) penetrate the cell membrane and interact with intracellular receptors. **B,** Water-soluble hormones (e.g., protein hormones) bind to receptors located in the cell membrane. The hormone-receptor interaction stimulates various cell responses.

Lipid-soluble hormones are synthesized from cholesterol and are produced by the adrenal cortex, sex glands, and thyroid.[2] Lipid-soluble hormones (steroids, thyroid) are relatively small molecules that cross the target cell membrane by simple diffusion. Steroid and thyroid hormone receptors are located inside the cell (Fig. 48-3). Lipid-soluble hormones are bound to plasma

TABLE 48-1 ENDOCRINE GLANDS AND HORMONES

Hormones	Target Tissue	Functions
Anterior Pituitary (Adenohypophysis)		
Growth hormone (GH), or somatotropin	All body cells	Promotes protein anabolism (growth, tissue repair) and lipid mobilization and catabolism.
Thyroid-stimulating hormone (TSH), or thyrotropin	Thyroid gland	Stimulates synthesis and release of thyroid hormones, growth and function of thyroid gland.
Adrenocorticotropic hormone (ACTH)	Adrenal cortex	Fosters growth of adrenal cortex. Stimulates secretion of corticosteroids.
Gonadotropic hormones • Follicle-stimulating hormone (FSH) • Luteinizing hormone (LH)*	Reproductive organs	Stimulate sex hormone secretion, reproductive organ growth, reproductive processes.
Melanocyte-stimulating hormone (MSH)	Melanocytes in skin	Increases melanin production in melanocytes to make skin darker.
Prolactin	Ovary and mammary glands in women Testes in men	Stimulates milk production in lactating women. Increases response of follicles to LH and FSH. Stimulates testicular function in men.
Posterior Pituitary (Neurohypophysis)		
Oxytocin	Uterus, mammary glands	Stimulates milk secretion, uterine contractility.
Antidiuretic hormone (ADH), or vasopressin	Renal tubules, vascular smooth muscle	Promotes reabsorption of water, vasoconstriction.
Thyroid		
Thyroxine (T_4)	All body tissues	Precursor to T_3.
Triiodothyronine (T_3)	All body tissues	Regulates metabolic rate of all cells and processes of cell growth and tissue differentiation.
Calcitonin	Bone tissue	Regulates calcium and phosphorus blood levels. Decreases serum Ca^{2+} levels.
Parathyroids		
Parathyroid hormone (PTH), or parathormone	Bone, intestine, kidneys	Regulates calcium and phosphorus blood levels. Promotes bone demineralization and increases intestinal absorption of Ca^{2+}. Increases serum Ca^{2+} levels.
Adrenal Medulla		
Epinephrine (adrenaline)	Sympathetic effectors	Increases in response to stress. Enhances and prolongs effects of sympathetic nervous system.
Norepinephrine (noradrenaline)	Sympathetic effectors	Increases in response to stress. Enhances and prolongs effects of sympathetic nervous system.
Adrenal Cortex		
Corticosteroids (e.g., cortisol, hydrocortisone)	All body tissues	Promote metabolism. Increased in response to stress. Antiinflammatory.
Androgens (e.g., DHEA, androsterone) and estradiol	Reproductive organs	Promote growth spurt in adolescence, secondary sex characteristics, and libido in both sexes.
Mineralocorticoids (e.g., aldosterone)	Kidney	Regulate sodium and potassium balance and thus water balance.
Pancreas (Islets of Langerhans)		
Insulin (from β cells)	General	Promotes movement of glucose out of blood and into cells.
Amylin (from β cells)	Liver, stomach	Decreases gastric motility, glucagon secretion, and endogenous glucose release from liver. Increases satiety.
Glucagon (from α-cells)	General	Stimulates glycogenolysis and gluconeogenesis.
Somatostatin	Pancreas	Inhibits insulin and glucagon secretion.
Pancreatic polypeptide	General	Influences regulation of pancreatic exocrine function and metabolism of absorbed nutrients.
Gonads		
Women: Ovaries		
Estrogen	Reproductive system, breasts	Stimulates development of secondary sex characteristics, preparation of uterus for fertilization and fetal development. Stimulates bone growth.
Progesterone	Reproductive system	Maintains lining of uterus necessary for successful pregnancy.
Men: Testes		
Testosterone	Reproductive system	Stimulates development of secondary sex characteristics, spermatogenesis.

*In men, sometimes referred to as interstitial cell–stimulating hormone (ICSH).
DHEA, Dehydroepiandrosterone.

proteins for transport in the blood. Although lipid-soluble hormones are inactive when bound to plasma proteins, they can be released when appropriate and immediately exert their action at the target tissue.

Water-soluble hormones (insulin, growth hormone [GH], and prolactin) have receptors on or in the cell membrane.[3] Water-soluble hormones circulate freely in the blood to their target tissues, where they act. Water-soluble hormones are not dependent on plasma proteins for transport (see Fig. 48-3).

Regulation of Hormonal Secretion. The regulation of endocrine activity is controlled by specific mechanisms of varying levels of complexity. These mechanisms stimulate or inhibit hormone synthesis and secretion and include feedback, nervous system control, and physiologic rhythms.

Simple Feedback. **Negative feedback** relies on the blood level of a hormone or other chemical compound regulated by the hormone (e.g., glucose). It is the most common type of endocrine feedback system and results in the gland increasing or decreasing the release of a hormone. Negative feedback is similar to the functioning of a thermostat in which cold air in a room activates the thermostat to release heat, and hot air signals the thermostat to prevent more warm air from entering the room.

The pattern of insulin secretion is a physiologic example of negative feedback between glucose and insulin. Elevated blood glucose levels stimulate the secretion of insulin from the pancreas (see eFig. 48-1 available on the website for this chapter). As blood glucose levels decrease, the stimulus for insulin secretion also decreases. The homeostatic mechanism is considered negative feedback because it reverses the change in blood glucose level. Another example of negative feedback is the relationship between calcium and parathyroid hormone (PTH). Low blood levels of calcium stimulate the parathyroid gland to release PTH, which acts on bone, the intestine, and the kidneys to increase blood calcium levels. The increased blood calcium level then inhibits further PTH release (Fig. 48-4).

Positive feedback is also used to regulate hormone synthesis and release. The female ovarian hormone estradiol operates by this type of feedback. Increased levels of estradiol produced by the follicle during the menstrual cycle result in increased production and release of follicle-stimulating hormone (FSH) by the anterior pituitary. FSH causes further increases in estradiol until the death of the follicle. This results in a drop of FSH serum levels. Thus with this type of feedback, rising hormone levels cause another gland to release a hormone that then stimulates further release of the first hormone. A mechanism for shutting off release of the first hormone (e.g., follicle death) is required or it will continue to be released.

Nervous System Control. In addition to chemical regulation, some endocrine glands are directly affected by the activity of the nervous system. Pain, emotion, sexual excitement, and stress can stimulate the nervous system to modulate hormone secretion. Neural involvement is initiated by the central nervous system (CNS) and implemented by the sympathetic nervous system (SNS). For example, stress is sensed or perceived by the CNS with subsequent stimulation of the SNS. The SNS secretes catecholamines that increase heart rate and blood pressure to deal with stress more effectively. (Effects of stress are discussed in Chapter 7.)

Rhythms. A common physiologic rhythm is the **circadian rhythm.** This is an endogenous 24-hour rhythm that can be driven and altered by sleep-wake or dark-light 24-hour (diurnal) cycles. Hormone levels fluctuate predictably during these cycles. For example, cortisol rises early in the day, declines toward evening, and rises again toward the end of sleep to peak by morning (Fig. 48-5). GH, thyroid-stimulating hormone (TSH), and prolactin secretions peak during sleep.

The menstrual cycle is an example of a body rhythm that is longer than 24 hours *(ultradian)*. These rhythms must be considered when interpreting laboratory results for hormone levels. (See diagnostic studies section in this chapter and Chapter 51.)

Hypothalamus

Although the pituitary gland has been referred to as the "master gland," most of its functions rely on its interrelationship with the hypothalamus. Two important groups of hormones from the hypothalamus are *releasing* hormones and *inhibiting* hormones. The function of these hormones is to either stimulate the release or inhibit the release of hormones from the anterior pituitary (Table 48-2).

The hypothalamus also contains neurons, which receive input from the CNS, including the brainstem, limbic system, and cerebral cortex. Neurons from the hypothalamus create a circuit to facilitate coordination of the endocrine system and autonomic nervous system (ANS). In addition, the hypothalamus coordinates the expression of complex behavioral responses, such as anger, fear, and pleasure.

Pituitary

The pituitary gland *(hypophysis)* is located in the sella turcica under the hypothalamus at the base of the brain above the sphenoid bone (see Fig. 48-1). The pituitary is connected to the hypothalamus by the infundibular *(hypophyseal)* stalk. This

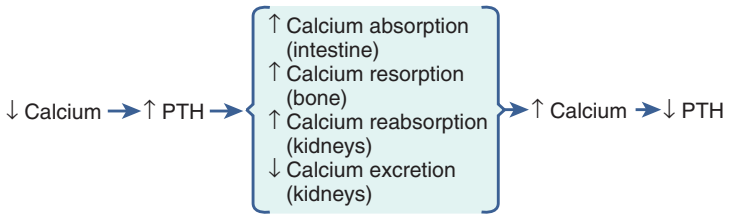

FIG. 48-4 Feedback mechanism between parathyroid hormone *(PTH)* and calcium.

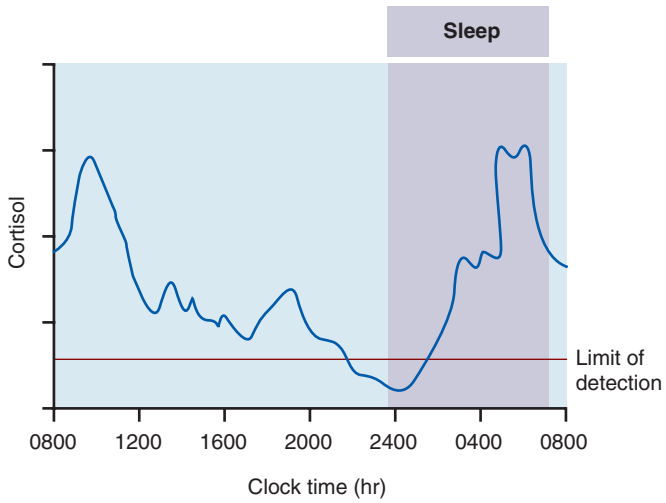

FIG. 48-5 Circadian rhythm of cortisol secretion.

stalk relays information between the hypothalamus and the pituitary. The pituitary consists of two major parts, the anterior lobe *(adenohypophysis)* and the posterior lobe *(neurohypophysis)*. A smaller intermediate lobe produces melanocyte-stimulating hormone.

Anterior Pituitary. The anterior lobe accounts for 80% of the gland by weight and is regulated by the hypothalamus through releasing and inhibiting hormones. These hypothalamic hormones reach the anterior pituitary through a network of capillaries known as the *hypothalamus-hypophyseal portal system.* The releasing and inhibiting hormones in turn affect the secretion of six hormones from the anterior pituitary (Fig. 48-6).

TABLE 48-2 HORMONES OF THE HYPOTHALAMUS

The following hormones from the hypothalamus target the anterior pituitary.

Releasing Hormones
- Corticotropin-releasing hormone (CRH)
- Thyrotropin-releasing hormone (TRH)
- Growth hormone–releasing hormone (GHRH), or somatotropin-releasing hormone
- Gonadotropin-releasing hormone (GnRH)
- Prolactin-releasing factor (PRF)

Inhibiting Hormones
- Somatostatin (inhibits growth hormone release)
- Prolactin-inhibiting factor (PIF)

Several hormones secreted by the anterior pituitary are referred to as **tropic hormones.** These are hormones that control the secretion of hormones by other glands. Thyroid-stimulating hormone (TSH) stimulates the thyroid gland to secrete thyroid hormones. Adrenocorticotropic hormone (ACTH) stimulates the adrenal cortex to secrete corticosteroids. Follicle-stimulating hormone (FSH) stimulates secretion of estrogen and the development of ova in women and sperm in men. Luteinizing hormone (LH) stimulates ovulation in women and secretion of sex hormones in both men and women. In men LH is sometimes referred to as interstitial cell–stimulating hormone (ICSH).

Growth hormone (GH) affects the growth and development of all body tissues. It also has numerous biologic actions, including a role in protein, fat, and carbohydrate metabolism. Prolactin stimulates breast development necessary for lactation after childbirth. Prolactin is also referred to as a lactogenic hormone.

Posterior Pituitary. The posterior pituitary is composed of nerve tissue and is essentially an extension of the hypothalamus. Communication between the hypothalamus and posterior pituitary occurs through nerve tracts known as the *median eminence.* The hormones secreted by the posterior pituitary, **antidiuretic hormone (ADH)** and oxytocin, are actually produced in the hypothalamus. These hormones travel down the nerve tracts from the hypothalamus to the posterior pituitary and are stored until their release is triggered by the appropriate stimuli (see Fig. 48-6).

The major physiologic role of ADH (also called arginine vasopressin) is regulation of fluid volume by stimulating

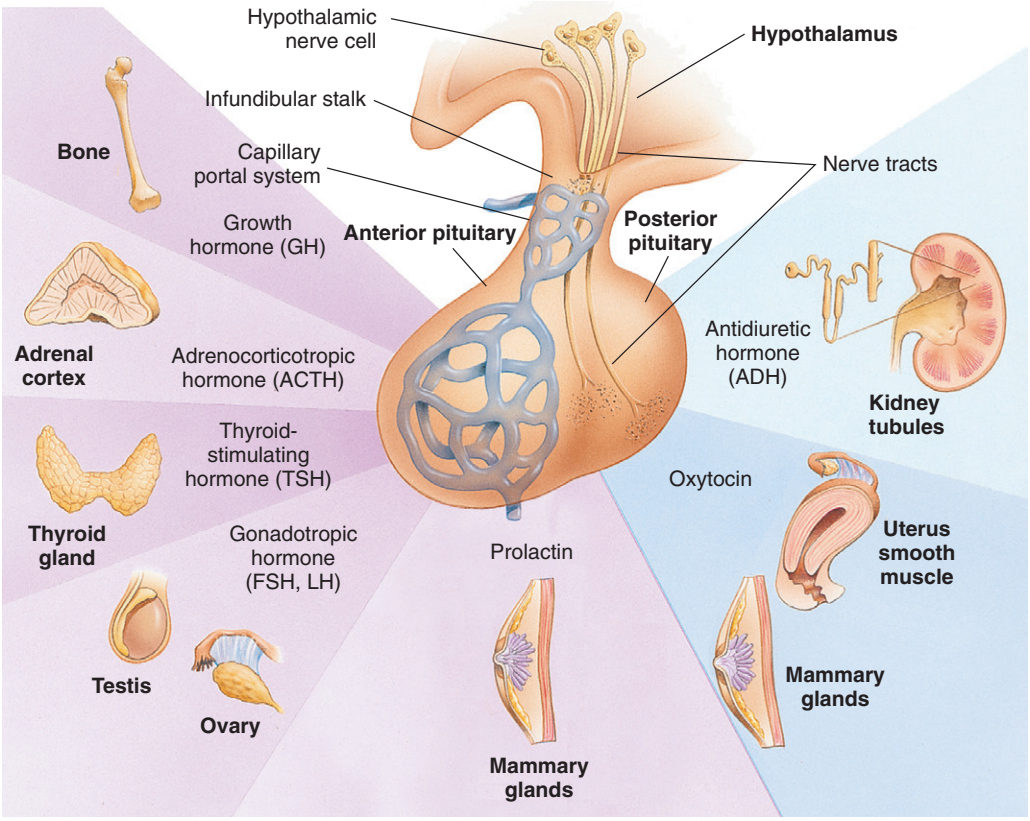

FIG. 48-6 Relationship between the hypothalamus, pituitary, and target organs. The hypothalamus communicates with the anterior pituitary via a capillary system and with the posterior pituitary via nerve tracts. The anterior and posterior pituitary hormones are shown with their target tissues. *FSH,* Follicle-stimulating hormone; *LH,* luteinizing hormone.

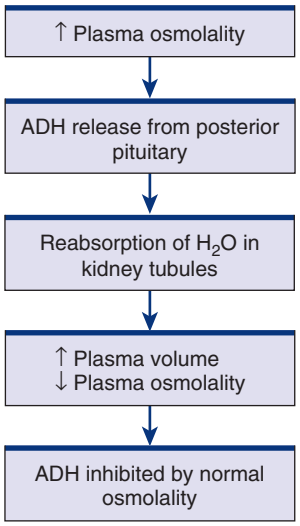

FIG. 48-7 Relationship of plasma osmolality to antidiuretic hormone *(ADH)* release and action.

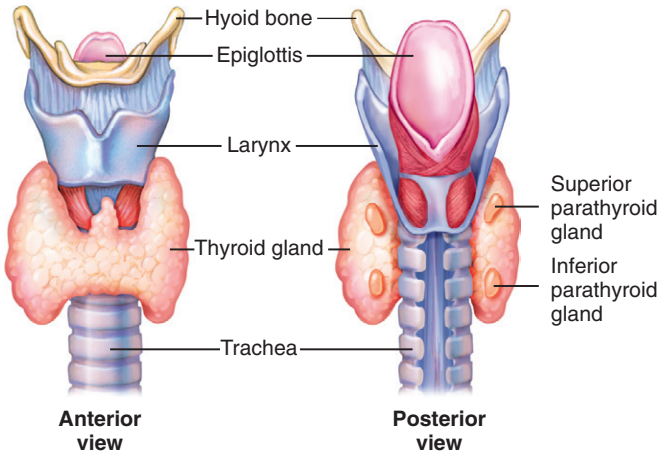

FIG. 48-8 Thyroid and parathyroid glands. Note the surrounding structures.

reabsorption of water in the renal tubules. ADH is also a potent vasoconstrictor. ADH secretion is stimulated by *plasma osmolality* (a measure of solute concentration of circulating blood) and hypovolemia (Fig. 48-7). Plasma osmolality increases when there is a decrease in ECF or an increase in solute concentration. The increased plasma osmolality activates osmoreceptors, which are extremely sensitive, specialized neurons in the hypothalamus. These activated osmoreceptors stimulate ADH release. Volume receptors in large veins, heart atria, and carotid arteries that sense pressure changes also contribute to ADH control. When ADH is released, the renal tubules reabsorb water and the urine becomes more concentrated. When ADH release is inhibited, renal tubules do not reabsorb water, resulting in a more dilute urine excretion.

Oxytocin stimulates ejection of milk into mammary ducts during lactation and contraction of the uterus; it may also affect sperm motility. Oxytocin secretion is increased by stimulation of touch receptors in the nipples of lactating women and vaginal pressure receptors during childbirth.

Pineal Gland

The pineal gland is located in the brain and is composed of photoreceptive cells. The secretion of the hormone **melatonin** is its primary function. Melatonin secretion is increased in response to exposure to the dark and decreased in response to light. The gland helps to regulate circadian rhythms and the reproductive system at the onset of puberty.

Thyroid Gland

The thyroid gland is located in the anterior portion of the neck in front of the trachea. It consists of two encapsulated lateral lobes connected by a narrow isthmus (Fig. 48-8). The thyroid gland is a highly vascular organ, and its size is regulated by TSH from the anterior pituitary. The three hormones produced and secreted by the thyroid gland are thyroxine (T_4), triiodothyronine (T_3), and calcitonin.

Thyroxine and Triiodothyronine. **Thyroxine (T_4)** accounts for 90% of thyroid hormone produced by the thyroid gland. However, **triiodothyronine (T_3)** is much more potent and has greater metabolic effects. About 20% of circulating T_3 is secreted directly by the thyroid gland, and the remainder is obtained by peripheral conversion of T_4. Iodine is necessary for the synthesis of both T_3 and T_4. These two hormones affect metabolic rate, caloric requirements, oxygen consumption, carbohydrate and lipid metabolism, growth and development, brain function, and other nervous system activities. More than 99% of thyroid hormones are bound to plasma proteins, especially thyroxine-binding globulin synthesized by the liver. Only the unbound "free" hormones are biologically active.

Thyroid hormone production and release is stimulated by TSH from the anterior pituitary gland. When circulating levels of thyroid hormone are low, the hypothalamus releases thyrotropin-releasing hormone (TRH), which in turn causes the anterior pituitary to release TSH. High circulating thyroid hormone levels inhibit the secretion of both TRH from the hypothalamus and TSH from the anterior pituitary gland.

Calcitonin. *Calcitonin* is produced by C cells (parafollicular cells) of the thyroid gland in response to high circulating calcium levels. Calcitonin inhibits the transfer of calcium from bone to blood, increases calcium storage in bone, and increases renal excretion of calcium and phosphorus, thereby lowering serum calcium levels. Calcitonin and PTH regulate calcium balance.

Parathyroid Glands

Two pairs of parathyroid glands are usually arranged behind each thyroid lobe (see Fig. 48-8). Although there are usually four glands, their number may range from two to six.

Parathyroid Hormone. The parathyroid glands secrete parathyroid hormone (PTH), also called *parathormone*. Its major role is to regulate the blood level of calcium. PTH acts on bone, the kidneys, and indirectly on the GI tract. PTH stimulates the transfer of calcium from the bone into the blood and inhibits bone formation, resulting in increased serum calcium and phosphate. In the kidney, PTH increases calcium reabsorption and phosphate excretion. In addition, PTH stimulates the renal conversion of vitamin D to its most active form (1,25-dihydroxyvitamin D_3). This active vitamin D promotes absorption of calcium and phosphorus by the GI tract, which ultimately increases bone mineralization. The secretion of PTH is directly regulated by a feedback system. When the serum calcium level is low, PTH secretion increases. When the serum calcium level rises, PTH secretion falls. In addition, high levels of active vitamin D inhibit PTH, and low levels of magnesium stimulate PTH secretion.

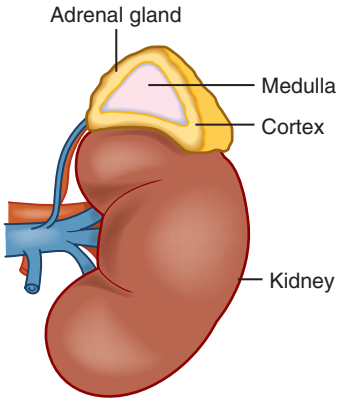

FIG. 48-9 The adrenal gland is composed of the adrenal cortex and the adrenal medulla.

Adrenal Glands

The adrenal glands are small, paired, highly vascularized glands located on the upper portion of each kidney. Each gland consists of two parts, the medulla and the cortex (Fig. 48-9). Each part has distinct functions, and the glands act independently from one another.

Adrenal Medulla. The adrenal medulla is the inner part of the gland and consists of sympathetic postganglionic neurons. The medulla secretes the **catecholamines** *epinephrine* (adrenaline), *norepinephrine* (noradrenaline), and *dopamine*. Catecholamines are synthesized from the amino acid phenylalanine. Catecholamines, usually considered neurotransmitters, are hormones when secreted by the adrenal medulla because they are released into the circulation. They are an essential part of the body's "fight or flight" response to stress (see Chapter 7).

Adrenal Cortex. The adrenal cortex is the outer part of the adrenal gland. It secretes several steroid hormones, including *glucocorticoids, mineralocorticoids,* and *androgens.* Cholesterol is the precursor for steroid hormone synthesis. Glucocorticoids (e.g., cortisol) are named for their effects on glucose metabolism. Mineralocorticoids (e.g., aldosterone) are essential for the maintenance of fluid and electrolyte balance. The term **corticosteroid** refers to hormones synthesized by the adrenal cortex excluding androgens.

Cortisol. **Cortisol,** the most abundant and potent glucocorticoid, is necessary to maintain life and protect the body from stress. Cortisol is secreted in a diurnal pattern (see Fig. 48-5). The major control of cortisol is through a negative feedback mechanism that involves the secretion of corticotropin-releasing hormone (CRH) from the hypothalamus. CRH stimulates the secretion of ACTH by the anterior pituitary.

One major function of cortisol is the regulation of blood glucose concentration through stimulation of hepatic glucose formation *(gluconeogenesis).* Cortisol decreases peripheral glucose use in the fasting state, inhibits protein synthesis, and stimulates the mobilization of glycerol and free fatty acids. Cortisol also helps maintain vascular integrity and fluid volume through its action on mineralocorticoid receptors. Cortisol levels are increased by stress, burns, infection, fever, acute anxiety, and hypoglycemia.

Glucocorticoids inhibit the inflammatory response and are considered antiinflammatory. Cortisol decreases the inflammatory response by stabilizing the membranes of cellular lysosomes and preventing increased capillary permeability. The lysosomal stabilization reduces the release of proteolytic enzymes and thereby their destructive effects on surrounding tissue. Cortisol can also inhibit production of prostaglandins, thromboxanes, and leukotrienes (see Chapter 12, Fig. 12-2) and alter the cell-mediated immune response.

Aldosterone. **Aldosterone** is a potent mineralocorticoid that maintains extracellular fluid volume. It acts on the renal tubule to promote renal reabsorption of sodium and excretion of potassium and hydrogen ions. Aldosterone synthesis and secretion are stimulated by angiotensin II, hyponatremia, and hyperkalemia. ANP and hypokalemia inhibit aldosterone synthesis and release.

Adrenal Androgens. The adrenal cortex secretes small amounts of androgens that are converted to sex steroids in peripheral tissues: testosterone in men and estrogen in women. The most common adrenal androgens are dehydroepiandrosterone (DHEA) and androstenedione. In postmenopausal women the major source of estrogen is from the peripheral conversion of adrenal androgen to estrogen. Because they are precursors to other sex steroids, their actions are similar to those of testosterone and estrogen.

Pancreas

The pancreas is a long, tapered, lobular, soft gland located behind the stomach and anterior to the first and second lumbar vertebrae. The pancreas has both exocrine and endocrine functions. The hormone-secreting portion of the pancreas is referred to as the **islets of Langerhans.** The islets account for less than 2% of the gland and consist of four types of hormone-secreting cells: α, β, delta, and F cells. α Cells produce and secrete the hormone glucagon. Insulin and amylin are produced and secreted by β cells. Somatostatin is produced and secreted by the delta cells. Pancreatic polypeptide (PP) is secreted by the F (or PP) cells.

Glucagon. **Glucagon** is synthesized and released from pancreatic α cells and the gut in response to low levels of blood glucose, protein ingestion, and exercise. Glucagon increases blood glucose by stimulating glycogenolysis, gluconeogenesis, and ketogenesis. Glucagon and insulin function in a reciprocal manner to maintain normal blood glucose levels. In the fasting state, hormones such as catecholamines, cortisol, and glucagon break down stored complex fuels *(catabolism)* to provide glucose as fuel for energy.

Insulin. **Insulin** is the principal regulator of metabolism and storage of ingested carbohydrates, fats, and proteins. Insulin facilitates glucose transport across cell membranes in most tissues. However, the brain, nerves, lens of the eye, hepatocytes, erythrocytes, and cells in the intestinal mucosa and kidney tubules are not dependent on insulin for glucose uptake. An increased blood glucose level is the major stimulus for insulin synthesis and secretion. Other stimuli to insulin secretion are increased amino acid levels and vagal stimulation. Insulin secretion is usually inhibited by low blood glucose levels, glucagon, somatostatin, hypokalemia, and catecholamines.

A major effect of insulin on glucose metabolism occurs in the liver, where the hormone enhances glucose incorporation into glycogen and triglycerides by altering enzymatic activity and inhibiting gluconeogenesis. After a meal, insulin is responsible for the storage of nutrients *(anabolism).* Another major effect occurs in peripheral tissues, where insulin facilitates glucose transport into cells, transport of amino acids across muscle membranes and their synthesis into protein, and transport of triglycerides into adipose tissue.

GERONTOLOGIC CONSIDERATIONS

EFFECTS OF AGING ON ENDOCRINE SYSTEM

Normal aging has many effects on the endocrine system (Table 48-3). These include (1) decreased hormone production and secretion, (2) altered hormone metabolism and biologic activity, (3) decreased responsiveness of target tissues to hormones, and (4) alterations in circadian rhythms.

Assessment of the effects of aging on the endocrine system may be difficult because the subtle changes of aging may mimic manifestations of endocrine disorders. Endocrine problems may manifest differently in an older adult than in a younger person. Older adults may have multiple co-morbidities and take medications that alter the body's usual response to endocrine dysfunction. Symptoms of endocrine dysfunction such as fatigue, constipation, or mental impairment are often missed because they are attributed solely to aging. For example, the symptoms of thyroid disease may be attributed to aging, resulting in delayed treatment.

It is important to assess renal function (serum creatinine, blood urea nitrogen [BUN]) in the older adult undergoing diagnostic studies with contrast medium. Older adults with renal dysfunction may be more prone to renal failure with the use of contrast medium.[4]

TABLE 48-3 GERONTOLOGIC ASSESSMENT DIFFERENCES

Endocrine System

Changes	Clinical Significance
Thyroid	
Atrophy of thyroid gland. TSH, T_3, and T_4 secretion are decreased. Increased nodules.	Increased incidence of hypothyroidism with aging. However, most older adults maintain adequate thyroid function. Thyroid hormone replacement dose lower in older adults.
Parathyroid	
Increased secretion of PTH and increased basal level of PTH.	Increased calcium resorption from bone. Hypercalcemia, hypercalciuria (may reflect defective renal mechanism).
Adrenal Cortex	
Adrenal cortex becomes more fibrotic and slightly smaller. Decreased metabolism of cortisol. Decreased plasma levels of adrenal androgens and aldosterone.	Decreased metabolic clearance rate for glucocorticoids.
Adrenal Medulla	
Increased secretion and basal level of norepinephrine. No change in plasma epinephrine levels.	Decreased responsiveness to β-adrenergic agonists and receptor blockers.
Decreased β-adrenergic receptor response to norepinephrine.	May partly explain increased incidence of hypertension with aging.
Pancreas	
Increase in fibrosis and fatty deposits in pancreas. Increased glucose intolerance and decreased sensitivity to insulin.	May partly contribute to increased incidence of diabetes mellitus with advanced aging.
Gonads	
Women: Decline in estrogen secretion.	Women experience symptoms associated with menopause and have increased risk for atherosclerosis and osteoporosis.
Men: Decline in testosterone secretion.	Men may or may not experience symptoms.

PTH, Parathyroid hormone; *T_3,* triiodothyronine; *T_4,* thyroxine; *TSH,* thyroid-stimulating hormone.

ASSESSMENT OF ENDOCRINE SYSTEM

Endocrine dysfunction may be the result of hypersecretion or hyposecretion of hormones. The onset of symptoms for specific disorders may be insidious and produce subtle or vague symptoms that are attributed to other physiologic and psychologic causes. Consequently, patients with endocrine dysfunction may be labeled as depressed, malingering, apathetic, or neurotic. In other instances, or in late stages of endocrine dysfunction, the patient may be seen with symptoms that are life threatening and demand immediate intervention.

Subjective Data

Information obtained from the patient can provide important clues as to the functioning of the endocrine system. Obtain a thorough history from the patient or a family member if the patient's mental acuity is compromised (Table 48-4).

Important Health Information

Past Health History. Patients with endocrine disorders often are seen with nonspecific complaints. The chief complaint may relate to not just one but a group of symptoms. The most common presenting problems include fatigue, weakness, menstrual problems, and weight changes. It is important to determine if the onset of symptoms has been gradual or sudden and what the patient has done about them.[5]

Because some of the more general signs of dysfunction are the easiest to overlook, you need to evaluate any reported or observed changes in weight, appetite, skin, libido, mental acuity, emotional stability, or energy levels.

CASE STUDY

Patient Introduction

iStockphoto/Thinkstock

L.M. is a 35-yr-old Hispanic woman who comes to the clinic complaining of "just not feeling well." She is accompanied by her female partner, H.H. L.M. states that she has gained a lot of weight despite trying to watch her diet and just seems to be getting more and more tired. H.H. voices concerns about changes in her partner's energy level.

Critical Thinking

As you read through this assessment chapter, think about L.M.'s concerns with the following questions in mind:

1. What are the possible causes of L.M.'s weight gain, fatigue, and irritability?
2. What would be your priority assessment of L.M.?
3. What questions would you ask L.M.?
4. What should be included in the physical assessment? What would you be looking for?
5. What diagnostic studies might you expect to be ordered?

Evolve Answers available at http://evolve.elsevier.com/Lewis/medsurg.

TABLE 48-4 HEALTH HISTORY

Endocrine System

Health Perception–Health Management
- What is your usual day like?
- Have you noticed any changes in your ability to perform your usual activities compared with last year? Five yr ago?*

Nutritional-Metabolic
- What is your weight and height?
- How much do you want to weigh?
- Have there been any changes in your appetite or weight?*
- Have you noticed any changes in the distribution of the hair anywhere on your body?*
- Have you noticed any changes in the color of your skin, particularly on your face, neck, hands, or body creases?*
- Has the texture of your skin changed? For example, does it seem thicker and drier than it used to?*
- Have you noticed any difficulty swallowing, throat pain, or hoarseness? Is the top button on your shirt or blouse more difficult to button?*
- Do you feel more nervous than you used to? Do you notice your heart pounding or that you sweat when you do not think you should be sweating?
- Do you have difficulty holding things because of shakiness of your hands?*
- Do you feel that most rooms are too hot or too cold? Do you frequently have to put on a sweater, or feel as though you need to open windows when others in the room seem comfortable?*
- Do you have or have you had any wounds that were slow to heal?*

Elimination
- Do you have to get up at night to urinate? If so, how many times? Do you keep water by your bed at night?
- Have you ever had a kidney stone?*
- Describe your usual bowel pattern. Have you noted any bowel changes?*
- Do you use anything, such as laxatives, to help you move your bowels?*

Activity-Exercise
- What is your usual activity pattern during a typical day?
- Do you have a planned exercise program? If yes, what is it and have you had to make any changes in this routine lately? If so, why and what kinds of changes?
- Do you experience fatigue with or without activity?*
- Have you had any trouble with breathing?*

Sleep-Rest
- How many hours do you sleep at night? Do you feel rested on awakening?
- Are you ever awakened by sweating during the night?*
- Do you have nightmares?*

Cognitive-Perceptual
- How is your memory? Have you noticed any changes?*
- Have you experienced any blurring or double vision?*
- When was your last eye examination?

Self-Perception–Self-Concept
- Have you noticed any changes in your physical appearance or size?*
- Are you concerned about your weight?*
- Do you feel you are able to do what you think you should be capable of doing? If not, why not?
- Does your health problem affect how you feel about yourself?*

Role-Relationship
- Do you have a support system or partner? Are you married? Do you have any children? Do you think you are able to take care of your family and home? If no, why not?
- Where do you work? What kind of work do you do? Are you able to do what is expected of you and what you expect of yourself?
- Are you retired? What type of work did you do before you retired? How do you spend your time now that you've retired?

Sexuality-Reproductive
Women
- When did you start to menstruate? Was this earlier or later than other women in your family?
- When was your last menstrual period? Do you have scant, heavy, or irregular menstrual flows?
- How many children have you had? How much did they weigh at birth? Were you told you had diabetes during any pregnancy?*
- Are you menopausal? If so, for how long?
- Are you attempting to get pregnant but cannot?*
- Are you postmenopausal? If so, do you have any bleeding from your uterus?

Men
- Have you noticed any changes in your ability to have an erection?*
- Are you trying to have children but cannot?*

Coping–Stress Tolerance
- What kind of stressors do you have?
- How do you deal with stress or problems?
- What is your support system? To whom do you turn when you have a problem?

Value-Belief
- Do you think medicine should still be taken even though you feel okay?
- Do any of your prescribed therapies cause any conflict in your value-belief system?*

*If yes, describe.

Medications. Ask about the use of all medications (both prescription and over-the-counter drugs), herbs, and dietary supplements. Ask about the reason for taking the drug, the dosage, and the length of time the drug has been taken. In particular, ask about the use of hormone replacements. Knowing that the patient is currently taking hormone replacements such as insulin, thyroid hormone, or corticosteroids (e.g., prednisone) alerts you to possible problems associated with the use of these agents (e.g., corticosteroids may cause increased blood glucose levels and bone loss with long-term use). The side and adverse effects of many nonhormone medications can contribute to problems affecting endocrine function (e.g., many drugs can affect blood glucose levels) (see eTable 49-1).

Surgery or Other Treatments. Inquire about past medical, surgical, and obstetric history, including number of pregnancies and live births. Ask about traumatic events, birth weight, growth patterns, and stages of physical and emotional development. The depth of information required may vary depending on the presenting condition. For example, data regarding past radiation therapy to the head and neck are especially important when thyroid or pituitary dysfunction is suspected.

Functional Health Patterns. Key questions to ask the patient with an endocrine problem are summarized in Table 48-4.

Health Perception–Health Management Pattern. Ask patients what their usual day is like and how they view their general health. Inquire as to how their perceptions compare to their

health a year ago. Ask if their health-related concerns are preventing them from completing things they would like to accomplish.

GENETIC RISK ALERT

Pituitary

- Nephrogenic diabetes insipidus can be inherited as a sex-linked or autosomal disorder.

Thyroid

- Genetics has a role in many cases of hypothyroid and hyperthyroid disorders.
  - Hashimoto's thyroiditis, the most common cause of hypothyroidism, is a chronic autoimmune disorder that has a genetic basis.
  - Graves' disease, a cause of hyperthyroidism, is an autoimmune disease in which genetic factors are involved.

Multiple Endocrine Neoplasia

- Multiple endocrine neoplasia is when two or more different endocrine tumors occur in a person and there is evidence for either a causative mutation or genetic transmission.
- The features of this disorder are relatively consistent within any one family.
- A common endocrine tumor is medullary thyroid carcinoma.
- Some people with this disorder also develop pheochromocytoma.

Diabetes Mellitus

- Genetics has a strong role in the development of type 2 diabetes, and to a lesser extent in type 1 diabetes.

Heredity often plays an important role in the development of endocrine dysfunction. Ask about the occurrence of diabetes mellitus, thyroid disease, and endocrine gland cancers, since these conditions have a familial tendency. A genetic assessment of family members may be appropriate.[5]

Nutritional-Metabolic Pattern. Reported changes in appetite and weight can indicate endocrine dysfunction. Weight loss with increased appetite may indicate hyperthyroidism or diabetes mellitus. Weight gain may indicate hypothyroidism or hypocortisolism. Truncal obesity, purple abdominal striae, and thin extremities occur in patients with hypercortisolism. Obese individuals are more likely to develop type 2 diabetes.

Ask if there have been problems with nausea, vomiting, or diarrhea. Difficulty swallowing or a change in neck size may indicate an enlarged thyroid gland. Increased SNS activity, including nervousness, palpitations, sweating, and tremors, may indicate thyroid dysfunction or a rare tumor of the adrenal medulla *(pheochromocytoma)*. Heat or cold intolerance may indicate hyperthyroidism or hypothyroidism, respectively.

Also ask about changes in the patient's skin, particularly on the face, neck, hands, or body creases. Ask if the patient has noticed any change in the distribution of hair anywhere on the body. Changes in the texture of the skin and whether it seems thicker or drier may indicate endocrine dysfunction. Hair loss can indicate hypopituitarism, hypothyroidism, hyperthyroidism, hypoparathyroidism, or increased testosterone and other androgens. Increased body hair may indicate hypercortisolism. Decreased skin pigmentation can occur in hypopituitarism, hypothyroidism, and hypoparathyroidism, whereas increased skin pigmentation, particularly in sun-exposed areas, can indicate hypocortisolism. A patient with hypothyroidism or excess GH may have skin that feels coarse or leathery. A patient with hyperthyroidism may mention fine, silky hair.

Elimination Pattern. Because maintenance of fluid balance is a major role of the endocrine system, questions related to elimination patterns may uncover endocrine dysfunction. For example, increased thirst and urination can indicate diabetes mellitus (pancreas disorder) or diabetes insipidus (pituitary disorder). Ask about the frequency and consistency of bowel movements. Frequent defecation may indicate hyperthyroidism or autonomic neuropathy of diabetes mellitus. Constipation is also seen in patients with hypothyroidism, hypoparathyroidism, and hypopituitarism.

Activity-Exercise Pattern. Ask about the usual pattern of activity during a typical day and if the patient has had to make any changes in that activity. Inquire how his or her energy levels compared with past levels. Ask if the patient experiences fatigue with or without activity or if he or she has excessive levels of energy on a daily basis.

Sleep-Rest Pattern. Ask the patient how many hours he or she typically sleeps, and if he or she feels rested on awakening.

CASE STUDY—cont'd

Subjective Data

iStockphoto/Thinkstock

A focused subjective assessment of L.M. revealed the following information:

PMH: Denies any medical or surgical history. Has not seen a health care provider (HCP) for 8 yr.

Medications: None.

Health Perception–Health Management: L.M. works as a receptionist for a local law firm and states it is all she can do some days to make it through the workday. She states that she frequently wakes up with a headache and goes to bed with the same headache, describing it as a dull, throbbing ache between her eyes. She definitely does not have the energy she had 5 yr ago or even 6 mo ago. She used to enjoy gardening and going out with their friends but now can barely manage work and coming home.

Nutritional-Metabolic: L.M. reports a steady weight gain over the past 6 mo, mainly in her abdominal area. She feels as if she looks pregnant but knows that is not possible. Her appetite has actually decreased but she has not been able to lose any weight. She says she feels "bloated." She also complains of facial hair growth and has noticed that she bruises easily. Whenever she gets a bug bite, it seems to take forever to heal. L.M. denies difficulty with swallowing, hoarseness, palpitations, or tremors.

Elimination: Denies any changes or difficulty with urination or bowel movements.

Activity-Exercise: L.M. states that she has no ambition to exercise. She is just too tired at the end of the workday and has no energy on the weekends either. She also complains of leg cramps with walking.

Sleep-Rest: Sleeps 10+ hr at night but does not feel rested on awakening.

Cognitive-Perceptual: L.M. is worried she is going crazy. She finds herself easily angered and irritable, frequently snapping at co-workers and her partner. She states this is not her usual self and she at first thought it was because she was dealing with a constant, dull headache. Lately, she has noticed that her vision is blurry and that is making work and life even more difficult and stressful. When asked about her headache, she states it hurts between her eyes. She rates the pain is a 4 on a scale of 0-10 and states that Tylenol or ibuprofen does not alleviate the pain. The pain is typically worse on arising in the morning and slowly decreases during the day.

Self-Perception–Self-Concept: L.M. hates the way she looks. She says when she looks in the mirror, she can't believe what she sees. She feels as if she has aged 10 yr over the past 6 mo and has gained weight in her face, neck, and trunk. She is concerned that her scalp hair is thinning and she is growing a beard. States that she is beginning to wonder if she is "turning into a man!"

Coping–Stress Tolerance: L.M. states that she is finding it more and more difficult to cope with the stresses of her job, her relationship with her partner, and life in general. She believes her emotions are very "raw and labile," totally different from the easy-going, smiling person she had once prided herself in being.

Inquire if anything prevents the patient from staying asleep such as nocturia (excessive urination at night), which may indicate diabetes. The patient with type 1 diabetes mellitus on a tight glucose control regimen who complains of sweating or nightmares may be experiencing hypoglycemia. Ask the patient about snoring, which could indicate sleep apnea; this is especially common in men with diabetes mellitus.

Cognitive-Perceptual Pattern. A patient with an endocrine dysfunction may manifest apathy or depression. Question both the patient and family to determine if any cognitive changes are present. Memory deficits and an inability to concentrate are common in endocrine disorders. Visual changes such as blurring or double vision could indicate endocrine problems. Headaches may indicate abnormal pituitary growth.

Self-Perception–Self-Concept Pattern. Endocrine disorders may affect the patient's self-perception because of the associated changes in physical appearance. Determine changes in weight, size of hands and facial features, and level of fatigue. The chronic nature of endocrine disorders and lifelong need for therapy can affect the patient's self-perception. Ask patients to describe how the present illness affects how they feel about themselves.

Role-Relationship Pattern. Ask whether there have been any changes in the patient's ability to maintain roles at home, at work, or in the community. Often the patient with an endocrine disorder is unable to sustain life's roles. However, in most cases the patient can be advised that, with adequate management, previous roles can be resumed. This can be reassuring for the patient and family.

Sexuality-Reproductive Pattern. Document the development of abnormal secondary sex characteristics such as facial hair *(hirsutism)* in women. Ask a detailed history of menstruation and pregnancy. Menstrual dysfunction may be seen in disorders of the ovaries and pituitary, thyroid, and adrenal glands. A history of large-birth-weight babies may indicate gestational diabetes, which may put the patient at a higher risk of developing diabetes mellitus. The inability to lactate may indicate a pituitary disorder.

Male sexual dysfunction may take the form of impotence, decreased libido, infertility, or the lack of development of secondary sexual characteristics. Retrograde ejaculation can occur in diabetes mellitus.

Coping–Stress Tolerance Pattern. Because some endocrine conditions are exacerbated by stress, ask patients about their level of stress and usual coping patterns. Patients' perception of the impact of their condition and treatments on their lifestyle is very important.

Value-Belief Pattern. Determining a patient's ability to make lifestyle changes is an important nursing function. Identify the patient's value-belief patterns so you can help to determine appropriate treatment regimens. This is particularly important in a condition such as diabetes mellitus, which may require major lifestyle changes. Other disorders, such as hypothyroidism or hypocortisolism, may be managed with medications but require lifelong monitoring with the health care provider.

Objective Data

Most endocrine glands (with the exception of the thyroid and testes) are inaccessible to direct examination. Assessment can be accomplished using objective data, including physical examination and diagnostic tests. It is imperative that you understand the actions of hormones so that you can assess the function of a gland by monitoring the target tissue.

Physical Examination. Specific clinical findings for the various endocrine problems are discussed in Chapters 49 and 50. Regardless of the type of endocrine dysfunction, the following general examination should be followed.[6]

Take a full set of vital signs at the beginning of the examination. Variations in temperature, tachycardia, bradycardia, hypotension, or hypertension may be seen with a variety of endocrine-related problems.

Assessment of the endocrine system includes a history of growth and development patterns, weight distribution and changes, and comparisons of these factors with normal findings. Body mass index (BMI) is a height-to-weight ratio used to assess nutritional status (see Chapter 41, Fig. 41-2).

Endocrine disorders may cause changes in mental and emotional status. Throughout the examination, assess the patient's orientation, alertness, memory, affect, personality, and anxiety and the appropriateness of his or her behavior.

Integument. Note the color and texture of the skin, hair, and nails. Note the overall skin color as well as pigmentation and possible ecchymosis (bruise). Hyperpigmentation, or "bronzing" of the skin (particularly on knuckles, elbows, knees, genitalia, and palmar creases), is a classic finding in Addison's disease. Palpate the skin for texture and moisture. Examine hair distribution not only on the head but also on the face, trunk, and extremities. Also assess the appearance and texture of the hair. Dull, brittle hair; excessive hair growth; or hair loss may indicate endocrine dysfunction. Assess any wounds and ask how long they have been present.

Head. Inspect the size and contour of the head. Facial features should be symmetric. Hyperreflexia and facial muscle contraction upon percussion of the facial nerve *(Chvostek's sign)* may occur in hypoparathyroidism. Inspect the eyes for position, symmetry, and shape. Large and protruding eyes (exophthalmos) are associated with hyperthyroidism. Assess visual acuity using a Snellen eye chart. Visual field loss may indicate a pituitary tumor. In the mouth, inspect the buccal mucosa, condition of teeth, and tongue size. Note hair distribution on the scalp and face. Hearing loss is common in acromegaly (from excess GH).[7]

Neck. The thyroid gland is not usually visible during inspection. A feature that distinguishes the thyroid from other masses in the neck is its upward movement on swallowing. Inspect the neck while the patient swallows a sip of water. The neck should appear symmetric without lumps or bulging.

If there is no noticeable enlargement of the thyroid gland, perform palpation using either a posterior or anterior approach. Because palpation may trigger the release of thyroid hormones, it should not be attempted by the inexperienced clinician. This is especially true when examining patients with a diagnosis of goiter or hyperthyroidism. Auscultate the lateral lobes of an enlarged thyroid gland with the stethoscope bell to identify a *bruit,* a soft swishing sound that may indicate a goiter or hyperthyroidism.

The thyroid gland is difficult to palpate and requires practice and validation by a more experienced practitioner. For *anterior palpation,* stand in front of the patient, with the patient's neck flexed. Place your thumb horizontally with the upper edge along the lower border of the cricoid cartilage. Then move your thumb over the isthmus as the patient swallows water. Place your fingers laterally to the anterior border of the sternocleidomastoid muscle, and palpate each lateral lobe before and while the patient swallows water.

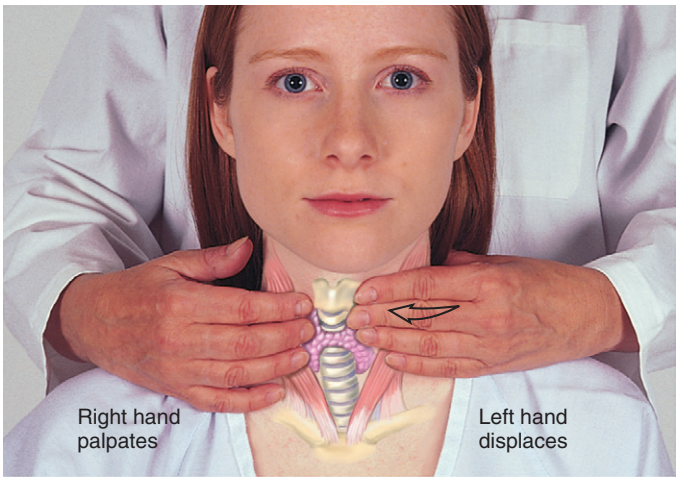

FIG. 48-10 Posterior palpation of the thyroid gland. (From Jarvis C: *Physical examination and health assessment,* ed 6, St Louis, 2012, Saunders.)

For *posterior palpation,* stand behind the patient (Fig. 48-10). With the thumbs of both hands resting on the nape of the patient's neck, use your index and middle fingers of both hands to feel for the thyroid isthmus and for the anterior surfaces of the lateral lobes. To relax the neck muscles, ask the patient to flex the neck slightly forward and to the right. Displace the thyroid cartilage to the right with your left hand and fingers. Palpate with your right hand after placing the thumb deep and behind the sternocleidomastoid muscle with the index and middle fingers in front of it. Ask the patient to swallow water, and the thyroid will move up.

Repeat this procedure on the left side. Palpate the thyroid for its size, shape, symmetry, and tenderness and for any nodules.

In a normal person, the thyroid is often not palpable. If palpable, it usually feels smooth with a firm consistency, but is not tender with gentle pressure. If nodules, enlargement, asymmetry, or hardness (abnormal findings) are present, refer the patient for further evaluation.

Thorax. Inspect the thorax for shape and characteristics of the skin. Note the presence of breast gynecomastia in men. Auscultate lung sounds and heart sounds, noting any adventitious lung sounds (wheezing, diminished sounds) or extra heart sounds.

CASE STUDY—cont'd

Objective Data: Physical Examination

iStockphoto/Thinkstock

A focused assessment of L.M. reveals the following:

L.M. is sitting on the edge of the examination table. She appears somewhat anxious. Her BP is 190/80, heart rate 84, respiratory rate 20, temp 37° C. Her weight is 182 lb, and she is 5 ft, 3 in tall. L.M.'s face is reddened and puffy, and she appears to have a lump on the back of her neck and shoulders. She has some acne on her face, along with some hair growth on her upper lip and chin area. Her abdomen is protruding but her arms and legs are thin. She has +1 edema in her ankles bilaterally. There are several ecchymotic areas on her upper and lower extremities, as well as purple stretch marks on her abdomen.

As you continue to read this chapter, consider diagnostic studies you would anticipate being performed for L.M.

FOCUSED ASSESSMENT

Endocrine System

Use this checklist to ensure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Excessive or increased thirst	Y	N
Excessive or decreased urination	Y	N
Excessive hunger	Y	N
Intolerance to heat or cold	Y	N
Excessive sweating	Y	N
Recent weight gain or loss	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values.

Potassium	✓
Glucose	✓
Sodium	✓
Glycosylated hemoglobin (Hb A1C)	✓
Thyroid studies: TSH, T_3, T_4	✓

Objective: Physical Examination

Inspect/Measure

Body temperature	✓
Height and weight	✓
Alertness and emotional state	✓
Skin for changes in color and texture	✓
Hair for changes in color, texture, and distribution	✓

Auscultate

Heart rate, blood pressure	✓

Palpate

Extremities for edema	✓
Skin for texture and temperature	✓
Neck for thyroid size, shape	✓

T_3, Triiodothyronine; T_4, thyroxine; *TSH,* thyroid-stimulating hormone.

Abdomen. Inspect the contour of the abdomen and note the symmetry and color. Cushing syndrome (hypercortisolism) causes the skin to be fragile, resulting in purple-blue striae across the abdomen. Note general obesity or truncal obesity. Auscultate bowel sounds.

Extremities. Assess the size, shape, symmetry, and general proportion of hands and feet. Inspect the skin for changes in pigmentation, lesions, and edema. Evaluate muscle strength and deep tendon reflexes. In the upper extremities, assess for tremors by placing a piece of paper on the outstretched fingers, palm down. Muscular spasms of the hand elicited on application of an occlusive blood pressure cuff for 3 minutes *(Trousseau's sign)* may be noted in hypoparathyroidism.

Genitalia. Inspect the hair distribution pattern, since it may be altered with hormone irregularities. Normally the shape of pubic hair is a diamond in men and an inverted triangle in women.[6] In men, palpate the testes. In women, note any clitoral enlargement.

Assessment abnormalities related to the endocrine system are presented in Table 48-5. A focused assessment of the endocrine system is presented on in the box above.

DIAGNOSTIC STUDIES OF ENDOCRINE SYSTEM

Diagnostic studies of the endocrine system are presented in Table 48-6. The selection of diagnostic studies is guided by

Text continued on p. 1151

TABLE 48-5 ASSESSMENT ABNORMALITIES

Endocrine System

Finding	Description	Possible Etiology and Significance
Integument		
Hyperpigmentation	Darkening of the skin, particularly in creases and skinfolds	Addison's disease caused by increased secretion of melanocyte-stimulating hormone; acanthosis nigricans
Depigmentation (vitiligo)	Patchy areas of light skin	May be a marker of autoimmune endocrine disorders
Striae	Purplish red marks below the skin surface. Usually seen on abdomen, breasts, and buttocks	Cushing syndrome
Changes in skin texture	Thick, cold, dry skin Thick, leathery, oily skin Warm, smooth, moist skin	Hypothyroidism Growth hormone excess (acromegaly) Hyperthyroidism
Changes in hair distribution	Hair loss Diminished axillary and pubic hair Hirsutism (excessive facial hair on women)	Hypothyroidism, hyperthyroidism, decreased pituitary secretion Cortisol deficiency Cushing syndrome, prolactinoma (a pituitary tumor)
Skin ulceration	Areas of ulcerated skin, most commonly found on legs and feet	Peripheral neuropathy and peripheral vascular disease, which are contributory factors in the development of diabetic foot ulcers
Edema	Generalized edema	Mucopolysaccharide accumulation in tissue in hypothyroidism
Head and Neck		
Visual changes	Decreased visual acuity and/or decreased peripheral vision	Pituitary gland enlargement or tumor leading to pressure on optic nerve
Exophthalmos	Eyeball protrusion from orbits	Occurs in hyperthyroidism as a result of fluid accumulation in eye and retroorbital tissue
Moon face	Periorbital edema and facial fullness	Cushing syndrome as a result of increased cortisol secretion
Myxedema	Puffiness, periorbital edema, masklike affect	Hydrophilic mucopolysaccharides infiltrating dermis in patients with hypothyroidism
Goiter	Generalized enlargement of thyroid gland	Hyperthyroidism, hypothyroidism, iodine deficiency
Thyroid nodule(s)	Localized enlargement of thyroid gland	May be benign or malignant
Cardiovascular		
Chest pain	Angina caused by increased metabolic demands, effusions	Hyperthyroidism, hypothyroidism
Dysrhythmias	Tachycardia, atrial fibrillation	Hypothyroidism or hyperthyroidism, hypoparathyroidism or hyperparathyroidism, pheochromocytoma
Hypertension	Elevated blood pressure caused by increased metabolic demands and catecholamines	Hyperthyroidism, pheochromocytoma, Cushing syndrome
Musculoskeletal		
Changes in muscular strength or muscle mass	Generalized weakness and/or fatigue	Common symptoms associated with many endocrine problems, including pituitary, thyroid, parathyroid, and adrenal dysfunctions Diabetes mellitus, diabetes insipidus
	Decreased muscle mass	Specifically seen in those with growth hormone deficiency and in Cushing syndrome secondary to protein wasting
Enlargement of bones and cartilage	Coarsening of facial features. Increases in size of hands and feet over a period of several years	Gradual enlargement and thickening of bony tissue occurring with growth hormone excess in adults as seen in acromegaly
Nutrition		
Changes in weight	Weight loss	Hyperthyroidism caused by increases in metabolism, type 1 diabetes mellitus, diabetic ketoacidosis
Altered glucose levels	Weight gain Increased serum glucose	Hypothyroidism, Cushing syndrome, type 2 diabetes mellitus Diabetes mellitus, Cushing syndrome, growth hormone excess
Neurologic		
Lethargy	State of mental sluggishness or somnolence	Hypothyroidism
Tetany	Intermittent involuntary muscle spasms usually involving the extremities	Severe hypocalcemia that can occur with hypoparathyroidism
Seizure	Sudden involuntary contraction of muscles	Consequence of a pituitary tumor Fluid and electrolyte imbalance associated with excessive ADH secretion Complications of diabetes mellitus, severe hypothyroidism
Increased deep tendon reflexes	Hyperreflexia	Hyperthyroidism, hypoparathyroidism

TABLE 48-5 ASSESSMENT ABNORMALITIES—cont'd

Endocrine System

Finding	Description	Possible Etiology and Significance
Gastrointestinal		
Constipation	Passage of infrequent hard stools	Hypothyroidism or calcium imbalances caused by hyperparathyroidism
Reproductive		
Changes in reproductive function	Menstrual irregularities, decreased libido, decreased fertility, impotence	Reproductive function is significantly affected by various endocrine abnormalities, including pituitary hypofunction, growth hormone excess, thyroid dysfunction, and adrenocortical dysfunction
Other		
Polyuria	Excessive urine output	Diabetes mellitus (secondary to hyperglycemia) or diabetes insipidus (associated with decreased ADH)
Polydipsia	Excessive thirst	Extreme water losses in diabetes mellitus (with severe hyperglycemia) and diabetes insipidus, dehydration
Decreased urine output	ADH leading to reabsorption of water from kidney tubules	Syndrome of inappropriate antidiuretic hormone (SIADH)
Thermoregulation	Cold insensitivity Heat intolerance	Hypothyroidism caused by a slowing of metabolic processes Hyperthyroidism caused by excessive metabolism

ADH, Antidiuretic hormone.

TABLE 48-6 DIAGNOSTIC STUDIES

Endocrine System

Study	Purpose and Description	Nursing Responsibility
Pituitary Studies		
Blood Studies		
Growth hormone (GH) (somatotropin)	Evaluates GH secretion. Used to identify GH deficiency or GH excess. GH levels are affected by time of day, food intake, and stress. Difficult to interpret significance of isolated GH level. Further evaluation requires stimulation tests (see below). *Men:* <4 ng/mL (<4.0 mcg/L) *Women:* <18 ng/mL (<18 mcg/L) Values >50 ng/mL (>50 mcg/L) suggest acromegaly.	Make sure that patient has been fasting. Emotional and physical stress may alter results. Indicate patient fasting status and recent activity level on the laboratory slip. Send blood sample to laboratory immediately.
Somatomedin C (insulin-like growth factor 1 [IGF-1])	Evaluates GH secretion. Provides a more accurate reflection of mean plasma concentration of GH because it is not subject to circadian rhythm and fluctuations. Low levels indicate GH deficiency. High levels indicate GH excess. *Reference interval:* 135-449 ng/mL	Overnight fasting is preferred but not necessary.
Growth hormone (GH) stimulation	***Insulin tolerance test:*** Regular insulin given IV and blood drawn at –30, 0, 30, 45, 60, and 90 min for measurement of glucose and GH. *Reference interval:* GH >5 mcg/L ***Arginine-GHRH test:*** GHRH bolus followed by 30-min infusion of arginine. *Reference interval:* GH >4.1 mcg/L	Patient must be NPO after midnight. Water is permitted on morning of test. IV access is established for administration of medications and frequent blood sampling. Continually assess for hypoglycemia and hypotension. Keep 50% dextrose and 5% dextrose IV solution at the bedside in case severe hypoglycemia occurs.
Gonadotropins • Follicle-stimulating hormone (FSH) • Luteinizing hormone (LH)	Useful in distinguishing primary gonadal problems from pituitary insufficiency. In women, there are marked differences during menstrual cycle and in postmenopausal period. Levels are low in pituitary insufficiency and high in primary gonadal failure. ***FSH*** *Women:* Follicular phase: 1.37-9.9 mU/mL Ovulatory phase: 6.17-17.2 mU/mL Luteal phase: 1.09-9.2 mU/mL Postmenopause: 19.3-100.6 mU/mL *Men:* 1.42-15.4 mU/mL ***LH*** *Women*: Follicular phase: 1.68-15 IU/L Ovulatory phase: 21.9-56.6 IU/L Postmenopause: 14.2-52.3 IU/L *Men:* 1.24-7.8 IU/L	There is no special preparation of the patient. Only one blood tube is needed for both FSH and LH. Note on the laboratory slip time of menstrual cycle or whether woman is menopausal.

GHRH, Growth hormone–releasing hormone.

Continued

TABLE 48-6 DIAGNOSTIC STUDIES—cont'd

Endocrine System

Study	Purpose and Description	Nursing Responsibility
Pituitary Studies—cont'd		
***Blood Studies*—cont'd**		
Water deprivation (restriction) (ADH stimulation)	Used to differentiate causes of diabetes insipidus (DI), including central DI, nephrogenic DI, and psychogenic polydipsia. ADH (vasopressin) is administered. *Reference interval:* In patients with central DI, urine osmolality increases after ADH. In patients with nephrogenic DI, no or minimal response to ADH.	CAUTION: Patient is NPO for test. Severe dehydration may occur with central or nephrogenic DI during this test. Should be performed only if serum sodium is normal and urine osmolality is <300 mOsm/kg. Obtain baseline weight and urine and plasma osmolality. Assess urine hourly for volume and specific gravity. Send hourly urine samples to laboratory for osmolality determination. Send blood samples for sodium and osmolality every 2 hr. Discontinue test and rehydrate if patient's weight drops >2 kg at any time. Rehydrate with oral fluids. Check orthostatic BP and pulse after rehydration to ensure adequate fluid volume.
Radiologic Studies		
Magnetic resonance imaging (MRI)	Examination of choice for radiologic evaluation of the pituitary gland and hypothalamus. Useful in identifying tumors involving the hypothalamus or pituitary.	Inform patient of the need to lie as still as possible during the test. Explain that tests are painless and noninvasive.
Computed tomography (CT) scan	Used to detect tumor and size of tumor. Oral and/or IV contrast medium may be used.	Inform patient of procedure. Assess renal function before test. Contrast medium may induce renal failure in compromised patients. Patient must lie still during the procedure. If IV contrast is used, check for iodine or shellfish allergy.
Thyroid Studies		
Blood Studies		
Thyroid-stimulating hormone (TSH) (thyrotropin)	Measures levels of TSH. Considered the most sensitive diagnostic test used for evaluating thyroid dysfunction. *Reference interval:* 0.4-4.2 μU/mL (0.4-4.2 mU/L)	Explain blood draw procedure to the patient. No specific preparations are necessary.
Thyroxine (T_4), total	Measures total serum level of T_4. Useful in evaluating thyroid function and monitoring thyroid therapy. *Reference interval:* 4.6-11.0 mcg/dL (59-142 nmol/L)	See above.
Free thyroxine (FT_4)	Measures active component of total T_4. Because level remains constant, considered better indicator of thyroid function than total T_4. *Reference interval:* 0.8-2.7 ng/dL (10-35 pmol/L)	Instruct patient that FT_4 levels may be measured until symptoms of hyperthyroidism have abated and levels have returned to normal.
Triiodothyronine (T_3), total	Measures serum levels of T_3. Helpful in diagnosing hyperthyroidism if T_4 levels are normal. *Ages 20-50:* 70-204 ng/dL (1.08-3.14 nmol/L) *Ages >50:* 40-181 ng/dL (0.62-2.79 nmol/L)	No specific preparation.
Free triiodothyronine (FT_3)	Measures active component of total T_3. *Reference interval:* 260-480 pg/dL (4.0-7.4 pmol/L)	See above.
T_3 uptake (T_3 resin uptake)	Indirectly measures binding capacity of thyroid-binding globulin. *Reference interval:* 24%-34%	See above.
Thyroid antibodies (Ab) • Thyroid peroxidase (TPO) Ab • Thyroglobulin Ab • Thyroid-stimulating Ab	Measures levels of thyroid antibodies. Assist in the diagnosis of an autoimmune thyroid disease and separate it from other forms of thyroiditis. One or more antibody tests may be ordered depending on symptoms.	See above.
Thyroglobulin	Identifies functioning thyroid tissue or thyroid cancer cells. Primarily used as a tumor marker for patients being treated for thyroid cancer. *Reference interval:* *Men:* 0.5-53 ng/mL *Women:* 0.5-43 ng/mL	See above.
Radiologic Studies		
Ultrasound	Evaluates thyroid nodule(s) to determine if it is a fluid-filled (cystic) or solid tumor and follows change over time.	Explain that gel and a transducer will be used over the neck. The test lasts 15 min. No fasting or sedation required.

ADH, Antidiuretic hormone.

TABLE 48-6 DIAGNOSTIC STUDIES—cont'd

Endocrine System

Study	Purpose and Description	Nursing Responsibility
Thyroid scan and uptake	***Scan:*** Used to evaluate nodules of thyroid. Radioactive isotopes are given orally or IV. Scanner passes over thyroid and makes graphic record of radiation emitted. Normal thyroid scan reveals homogeneous pattern with symmetric lobes. Benign nodules appear as warm spots because they take up radionuclide. Malignant tumors appear as cold spots because they tend not to take up radionuclide. ***Radioactive iodine uptake (RAIU):*** Provides direct measure of thyroid activity. Evaluates function of thyroid nodules. Patient is given radioactive iodine either orally or IV. The uptake by the thyroid gland is measured with a scanner at several time intervals such as 2-4 hr and at 24 hr. The values of RAIU are expressed in percentage of uptake. *Reference interval:* For 2-4 hr, 3%-19% For 24 hr, 11%-30%	Explain procedure to the patient. Reaction to iodine in allergic patients is rare because amount of iodine in preparation is minimal. Instruct patient to drink increased amount of fluids for 24-48 hr unless contraindicated. Radionuclide will be eliminated 6-24 hr.
Parathyroid Studies		
Blood Studies		
Parathyroid hormone (PTH)	Measures PTH level in serum. Must be interpreted in terms of concomitantly drawn serum calcium level. *Reference interval:* 50-330 pg/mL (50-330 ng/L)	Fasting specimen preferred. Inform patient that blood sample will be drawn. Keep sample on ice.
Calcium (total)	Used to detect bone and parathyroid disorders. Hypercalcemia can indicate primary hyperparathyroidism, and hypocalcemia can indicate hypoparathyroidism. *Reference interval:* 8.6-10.2 mg/dL (2.15-2.55 mmol/L)	See above.
Calcium (ionized)	Free form of calcium unaffected by variable serum albumin levels. *Reference interval:* 4.64-5.28 mg/dL (1.16-1.32 mmol/L)	See above.
Phosphate	Measures inorganic phosphorus. ↑ Levels indicate primary hypoparathyroidism or secondary causes (e.g., renal failure). ↓ Levels indicate hyperparathyroidism. Phosphorus and calcium levels are inversely related. *Reference interval:* 2.4-4.4 mg/dL (0.78-1.42 mmol/L)	See above.
Radiologic Studies		
Parathyroid scan	Uses radioactive isotopes that are taken up by cells in parathyroid glands to obtain an image of the glands and any abnormally active areas. Assists in identifying the number and location of parathyroid glands.	No food, fluid, or medication restrictions before test.
Adrenal Studies		
Blood Studies		
Cortisol (total)	Measures amount of total cortisol in serum and evaluates status of adrenal cortex function. *Reference interval:* At 8 AM: 5-23 mcg/dL (138-635 nmol/L) At 4 PM: 3-16 mcg/dL (83-441 nmol/L)	Cortisol has diurnal variation; levels are higher in morning than in evening. Sample should be drawn in morning; evening samples may also be ordered. Note if patient does night shift work. Mark time of blood draw on laboratory slip. Stress and excessive physical activity produce elevated results.
Aldosterone	Used to assess for hyperaldosteronism. *Reference interval:* Upright posture: 7-30 ng/dL (0.19-0.83 nmol/L) Supine position: 3-16 ng/dL (0.08-0.44 nmol/L)	Usually morning blood sample is preferred. Inform patient that the required position, supine or sitting/standing, must be maintained for 2 hr before the specimen is drawn.
Adrenocorticotropic hormone (ACTH) (corticotropin)	Measures plasma level of ACTH. Although ACTH is a pituitary hormone, it controls adrenal cortex secretion, thus helping to determine if underproduction or overproduction of cortisol is caused by dysfunction of the adrenal gland or pituitary gland. *Reference interval:* Morning: <120 pg/mL (<26 pmol/L) Evening: <85 pg/mL (<19 pmol/L)	Patient should be NPO after midnight before morning blood draw between 6-8 AM. Diurnal levels correspond with variation of cortisol levels. Levels are higher in morning, lower in evening. ACTH is unstable; use prechilled blood tube and place on ice and send to laboratory immediately.
ACTH stimulation with cosyntropin	Used to evaluate adrenal function. After baseline cortisol sample is drawn, give cosyntropin (synthetic ACTH) by IV bolus. Cortisol samples are drawn 30 and 60 min after bolus. Plasma cortisol at 60 min should increase by >7 mcg/dL from baseline.	Obtain baseline cortisol level at beginning of cosyntropin infusion. Inject cosyntropin with a plastic syringe and collect blood samples in plastic heparinized tubes. Administer test with continuous-infusion method. Monitor site and rate of IV infusion. Ensure sample collection at appropriate times.

Continued

TABLE 48-6 DIAGNOSTIC STUDIES—cont'd

Endocrine System

Study	Purpose and Description	Nursing Responsibility
Adrenal Studies—cont'd		
***Blood Studies*—cont'd**		
ACTH suppression (dexamethasone suppression)	Assesses adrenal function. Especially helpful if hyperactivity (Cushing syndrome) is suspected. *Overnight method:* Dexamethasone (Decadron) 1 mg (low dose) or 4 mg (high dose) is given at 11 PM to suppress secretion of corticotropin-releasing hormone. Plasma cortisol sample is drawn at 8 AM. *Reference interval:* Cortisol level <3 mcg/dL (<0.08 μmol/L) for low dose and <50% of baseline in high dose indicates normal adrenal response.	Ensure that patient has fasted. Inform patient that blood sample will be taken. Observe venipuncture site for bleeding and hematoma formation. Do not test acutely ill patients or those under stress. Stress-stimulated ACTH may override suppression. Screen patient for drugs such as estrogen and corticosteroids that may give false-positive results. Ensure accurate timing of medication and sample collection.
Metanephrine	Screens for pheochromocytoma more accurately than urinary vanillylmandelic acid (VMA) and catecholamine measurements.	Ask about recent history of vigorous exercise, high levels of stress, or starvation (may artificially ↑ levels). Ingestion of caffeine, alcohol, levodopa, lithium, nitroglycerin, acetaminophen, and medications containing epinephrine or norepinephrine can alter test results.
Urine Studies		
17-Ketosteroids	Measures androgen metabolites in urine and evaluates adrenocortical and gonadal function. *Reference interval:* *Men:* 6-20 mg/day (20-70 μmol/day) *Women:* 6-17 mg/day (20-60 μmol/day)	Instruct patient regarding 24-hr urine collection. Tell patient that specimen must be kept refrigerated or iced during entire collection period. Determine whether preservative is required.
Cortisol (free)	Measures free (unbound) cortisol. Preferred test to evaluate hypercortisolism. *Reference interval:* 20-90 mcg/24 hr (55-248 nmol/day)	Instruct patient about 24-hr urine collection and avoidance of stressful situations and excessive physical exercise. Some drugs (e.g., reserpine, diuretics, phenothiazines, insulin, amphetamines) may alter results.
Vanillylmandelic acid (VMA)	Measures urinary excretion of catecholamine metabolite. Levels are increased in pheochromocytoma. *Reference interval:* 1.4-6.5 mg/24 hr (7-33 μmol/day)	Keep 24-hr urine collection at pH <3.0 with HCl acid as preservative. Keep on ice. Consult with laboratory or health care provider about patient discontinuing any drugs 3 days before urine collection.
Radiologic Studies		
Computed tomography (CT)	Abdominal CT is radiologic examination of choice for the adrenal gland. Used to detect tumor and size or metastatic spread. Oral and/or IV contrast medium may be used.	Inform patient of procedure. Patient must lie still during the procedure. Assess renal function if IV contrast is used. Check for iodine or shellfish allergy.
Magnetic resonance imaging (MRI)	Same as MRI above.	Same as MRI above.
Pancreatic Studies		
Blood Studies		
Fasting blood glucose (FBG)	Measures circulating glucose level. *Reference interval:* 70-99 mg/dL (3.9-5.5 mmol/L).	Patient should fast 8-12 hr. Water intake is permitted. Many medications may influence results.
Oral glucose tolerance test (OGTT)	Used to evaluate abnormal FBG levels that do not clearly indicate diabetes. Patient drinks 75 g of glucose; samples for glucose are drawn at baseline and at 30, 60, and 120 min. Test takes 2 hr to complete. *Reference interval:* <100 mg/dL (5.5 mmol/L) at baseline, <200 mg/dL (11.1 mmol/L) at 30 and 60 min, and <140 mg/dL (7.8 mmol/L) at 120 min. Values >200 mg/dL (11.1 mmol/L) at 120 min are considered diagnostic for diabetes mellitus.	Perform test on ambulatory patients after fasting 8-12 hr. Many drugs may influence results, including caffeine and smoking. Ensure that patient's diet 3 days before test includes 150-300 g of carbohydrate with intake of at least 1500 cal/day.
Glycosylated hemoglobin (Hb A1C [A1C])	Indicates the amount of glucose linked to hemoglobin. Assesses long-term glycemic control during previous 3 mo. *Reference interval:* 4.0%-6.0% ADA treatment goal <7%	Inform patient that fasting is not necessary and that blood sample will be drawn. Observe venipuncture site for bleeding or hematoma formation.
Urine Studies		
Glucose	Estimate amount of glucose in urine by using an enzymatic method. Dipstick is dipped into the urine and read for color changes after 1 min. *Reference interval:* Negative	Use freshly voided urine. Many drugs alter glucose readings. Errors are great if directions are not followed exactly.

ADA, American Diabetes Association.

TABLE 48-6 DIAGNOSTIC STUDIES—cont'd

Endocrine System

Study	Purpose and Description	Nursing Responsibility
Ketones	Measures amount of acetone (a type of ketone) excreted in urine as result of incomplete fat metabolism. Tested with a dipstick as described above. Positive result can indicate lack of insulin and diabetic acidosis. *Reference interval:* Negative	Use freshly voided urine specimen. Test is often done with glucose test. Directions must be followed exactly. Certain drugs can produce false-positive or false-negative results.
Radiologic Studies		
Computed tomography (CT)	Abdominal CT is the radiologic examination of choice for pancreas. Used to identify tumors or cysts. Oral and/or IV contrast medium may be ordered.	Inform patient of procedure. Patient must lie still during the procedure. If IV contrast is used, check for iodine and shellfish allergy. Assess renal function if contrast is used.

ADA, American Diabetes Association; *ADH,* antidiuretic hormone; *GHRH,* growth hormone–releasing hormone.

pertinent findings from the history and physical examination. Laboratory studies may include direct measurement of the hormone level, or they may involve an indirect indication of gland function by evaluating blood or urine components affected by the hormone such as glucose or electrolytes.

Hormones with fairly constant basal levels such as T_4 require a single measurement. Note the time of the sample collection on the laboratory slip. Information about night shift work is important for hormones with circadian or sleep-related secretion (e.g., cortisol). Evaluation of other hormones may require multiple blood samplings such as in suppression tests (e.g., dexamethasone) and stimulation tests (e.g., glucose tolerance). In these situations, it is often necessary to obtain IV access to administer the testing medication and fluids and to draw multiple blood samples.

Disorders associated with the pituitary gland can manifest in a wide variety of ways because of the number of hormones produced. Many diagnostic studies evaluate these hormones either directly or indirectly (see Table 48-6).

A number of tests are available to evaluate thyroid function. The most sensitive and accurate laboratory test is measurement of TSH. Thus it is often recommended as a first diagnostic test for evaluation of thyroid function.[8] Common additional tests ordered in the presence of an abnormal TSH level include total T_4, free T_4, and total T_3. Free T_4 is the unbound thyroxine and is a more accurate reflection of thyroid function than total T_4.

The only hormone secreted by the parathyroid glands is PTH. Because PTH regulates serum calcium and phosphate levels, abnormalities in PTH secretion are reflected in these levels. For this reason, diagnostic tests for the parathyroid gland typically include PTH, serum calcium, and serum phosphate levels.

Diagnostic tests associated with the adrenal cortex function focus on the three types of hormones secreted: glucocorticoids, mineralocorticoids, and androgens. These hormone levels can be measured both in blood plasma and in urine. The urine studies often require 24-hour urine collection to eliminate the impact of short-term fluctuations in plasma hormone levels.[9]

The tests found in Table 48-6 are used to evaluate the metabolism of glucose. They are important in the diagnosis and management of diabetes mellitus. (Diagnostic studies for diabetes mellitus are also discussed in Chapter 49.)

CASE STUDY—cont'd

Objective Data: Diagnostic Studies

iStockphoto/Thinkstock

The health care provider orders the following initial diagnostic studies to be drawn in the morning after an 8-hr fast:

- CBC, basic metabolic panel (electrolytes, BUN, creatinine)
- Fasting blood glucose (FBG)
- TSH, free T_4
- Plasma cortisol levels
- Plasma ACTH levels

CBC results reveal a WBC of 12,200/μL and a decreased lymphocyte count at 800 cells/μL. The rest of the CBC is within normal limits (WNL).

The FBG is 130 mg/dL. The plasma cortisol and ACTH levels are elevated. Thyroid studies are WNL.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A characteristic common to all hormones is that they
   - **a.** circulate in the blood bound to plasma proteins.
   - **b.** influence cellular activity of specific target tissues.
   - **c.** accelerate the metabolic processes of all body cells.
   - **d.** enter a cell to alter the cell's metabolism or gene expression.

2. A patient is receiving radiation therapy for cancer of the kidney. The nurse monitors the patient for signs and symptoms of damage to the
   - **a.** pancreas.
   - **b.** thyroid gland.
   - **c.** adrenal glands.
   - **d.** posterior pituitary gland.

3. A patient has a serum sodium level of 152 mEq/L (152 mmol/L). The normal hormonal response to this situation is
   a. release of ADH.
   b. release of ACTH.
   c. secretion of aldosterone.
   d. secretion of corticotropin-releasing hormone.
4. All cells in the body are believed to have intracellular receptors for
   a. insulin.
   b. glucagon.
   c. growth hormone.
   d. thyroid hormone.
5. When obtaining subjective data from a patient during assessment of the endocrine system, the nurse asks specifically about
   a. energy level.
   b. intake of vitamin C.
   c. employment history.
   d. frequency of sexual intercourse.
6. Endocrine disorders often go unrecognized in the older adult because
   a. symptoms are often attributed to aging.
   b. older adults rarely have identifiable symptoms.
   c. endocrine disorders are relatively rare in the older adult.
   d. older adults usually have subclinical endocrine disorders that minimize symptoms.
7. An abnormal finding by the nurse during an endocrine assessment would be *(select all that apply)*
   a. blood pressure of 100/70 mm Hg.
   b. excessive facial hair on a woman.
   c. soft, formed stool every other day.
   d. 3-lb weight gain over last 6 months.
   e. hyperpigmented coloration in lower legs.
8. A patient has a total serum calcium level of 3 mg/dL (1.5 mEq/L). If this finding reflects hypoparathyroidism, the nurse would expect further diagnostic testing to reveal
   a. decreased serum PTH.
   b. increased serum ACTH.
   c. increased serum glucose.
   d. decreased serum cortisol levels.

LEARNING OUTCOMES

1. Describe the pathophysiology and clinical manifestations of diabetes mellitus.
2. Differentiate between type 1 and type 2 diabetes mellitus.
3. Describe the collaborative care of the patient with diabetes mellitus.
4. Describe the role of nutrition and exercise in the management of diabetes mellitus.
5. Discuss the nursing management of a patient with newly diagnosed diabetes mellitus.
6. Describe the nursing management of the patient with diabetes mellitus in the ambulatory and home care settings.
7. Relate the pathophysiology of acute and chronic complications of diabetes mellitus to the clinical manifestations.
8. Explain the collaborative care and nursing management of the patient with acute and chronic complications of diabetes mellitus.

This chapter discusses the pathophysiology, clinical manifestations, complications, and collaborative care of diabetes mellitus. The nurse's role in teaching to promote patient management of diet, activities, and drugs for good control of diabetes is emphasized.

DIABETES MELLITUS

Diabetes mellitus (DM) is a chronic multisystem disease related to abnormal insulin production, impaired insulin utilization, or both. Diabetes mellitus is a serious health problem throughout the world, and its prevalence is rapidly increasing. Currently in the United States an estimated 25.8 million people, or 8.3% of the population, have diabetes mellitus, and 79 million more people have prediabetes.[1] Approximately 7 million people with diabetes mellitus have not been diagnosed and are unaware that they have the disease. Diabetes mellitus is the seventh leading cause of death in the United States, but it is likely to be underreported. The annual cost of diabetes exceeds $174 billion, with $116 billion in direct medical costs.[2]

Reviewed by Teressa Sanders Hunter, RN, PhD, Assistant Professor, Langston University, School of Nursing and Health Professions, Langston, Oklahoma; Jane Faith Kapustin, PhD, CRNP, BC-ADM, FAANP, Associate Professor and Assistant Dean for the Master's and DNP Programs and Faculty Practice as Adult NP, Medical Center for Diabetes and Endocrinology, Baltimore, Maryland; Nancy Karnes, RN, MSN, CCRN, CDE, Faculty Nursing Program, Bellevue College, Bellevue, Washington; Lorraine Nowakowski-Grier, MSN, APRN, BC, CDE, Diabetes Nurse Practitioner, Christiana Care Health Services, Newark, Delaware; Susan A. Sandstrom, RN, MSN, BC, CNE, Associate Professor in Nursing (retired), College of Saint Mary, Omaha, Nebraska; and Elaine K. Strouss, RN, MSN, Associate Professor of Nursing, Community College of Beaver County, Monaca, Pennsylvania.

The long-term complications of diabetes make it a devastating disease. Diabetes is the leading cause of adult blindness, end-stage kidney disease, and nontraumatic lower limb amputations. It is also a major contributing factor to heart disease and stroke. Adults with diabetes have heart disease death rates two to four times higher than adults without diabetes. The risk for stroke is also two to four times higher among people with diabetes. In addition, it is estimated that 67% of adults with diabetes have hypertension.[1]

Etiology and Pathophysiology

Current theories link the causes of diabetes, singly or in combination, to genetic, autoimmune, and environmental factors (e.g., virus, obesity). Regardless of its cause, diabetes is primarily a disorder of glucose metabolism related to absent or insufficient insulin supply and/or poor utilization of the insulin that is available.

The American Diabetes Association (ADA) recognizes four different classes of diabetes. The two most common are type 1 and type 2 diabetes mellitus (Table 49-1). The two other classes are gestational diabetes and other specific types of diabetes with various causes.

Normal Insulin Metabolism. Insulin is a hormone produced by the β cells in the islets of Langerhans of the pancreas. Under normal conditions, insulin is continuously released into the bloodstream in small pulsatile increments, with increased release when food is ingested (Fig. 49-1). Insulin lowers blood glucose and facilitates a stable, normal glucose range of approximately 70 to 120 mg/dL (3.9 to 6.66 mmol/L). The average amount of insulin secreted daily by an adult is approximately 40 to 50 U, or 0.6 U/kg of body weight.

Insulin promotes glucose transport from the bloodstream across the cell membrane to the cytoplasm of the cell. The rise in plasma insulin after a meal stimulates storage of glucose as glycogen in liver and muscle, inhibits gluconeogenesis, enhances fat deposition of adipose tissue, and increases protein synthesis. For this reason insulin is an *anabolic,* or storage, hormone. The fall in insulin level during normal overnight fasting facilitates the release of stored glucose from the liver, protein from muscle, and fat from adipose tissue.

Skeletal muscle and adipose tissue have specific receptors for insulin and are considered insulin-dependent tissues. Insulin is required to "unlock" these receptor sites, allowing the transport of glucose into the cells to be used for energy. Other tissues (e.g., brain, liver, blood cells) do not directly depend on insulin for glucose transport but require an adequate glucose supply for normal function. Although liver cells are not considered insulin-dependent tissue, insulin receptor sites on the liver facilitate hepatic uptake of glucose and its conversion to glycogen.

Other hormones (glucagon, epinephrine, growth hormone, and cortisol) work to oppose the effects of insulin and are referred to as *counterregulatory hormones.* These hormones increase blood glucose levels by stimulating glucose production and output by the liver and by decreasing the movement of glucose into the cells. The counterregulatory hormones and insulin usually maintain blood glucose levels within the normal range by regulating the release of glucose for energy during food intake and periods of fasting.

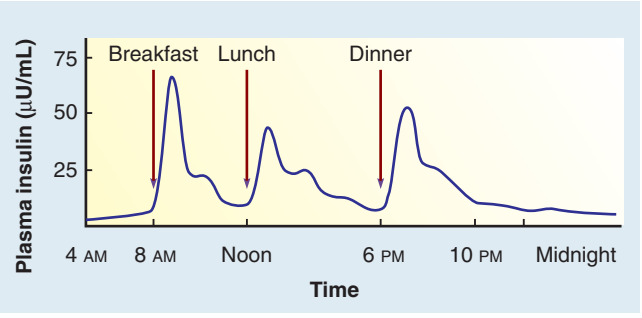

FIG. 49-1 Normal endogenous insulin secretion. In the first hour or two after meals, insulin concentrations rise rapidly in blood and peak at about 1 hour. After meals, insulin concentrations promptly decline toward preprandial values as carbohydrate absorption from the gastrointestinal tract declines. After carbohydrate absorption from the gastrointestinal tract is complete and during the night, insulin concentrations are low and fairly constant, with a slight increase at dawn.

TABLE 49-1 COMPARISON OF TYPE 1 AND TYPE 2 DIABETES MELLITUS

Factor	Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus
Age at onset	More common in young people but can occur at any age.	Usually age 35 yr or older but can occur at any age. Incidence is increasing in children.
Type of onset	Signs and symptoms usually abrupt, but disease process may be present for several years.	Insidious, may go undiagnosed for years.
Prevalence	Accounts for 5%-10% of all types of diabetes.	Accounts for 90%-95% of all types of diabetes.
Environmental factors	Virus, toxins.	Obesity, lack of exercise.
Primary defect	Absent or minimal insulin production.	Insulin resistance, decreased insulin production over time, and alterations in production of adipokines.
Islet cell antibodies	Often present at onset.	Absent.
Endogenous insulin	Absent.	Initially increased in response to insulin resistance. Secretion diminishes over time.
Nutritional status	Thin, normal, or obese.	Frequently overweight or obese. May be normal.
Symptoms	Polydipsia, polyuria, polyphagia, fatigue, weight loss.	Frequently none, fatigue, recurrent infections. May also experience polyuria, polydipsia, and polyphagia.
Ketosis	Prone at onset or during insulin deficiency.	Resistant except during infection or stress.
Nutritional therapy	Essential.	Essential.
Insulin	Required for all.	Required for some. Disease is progressive and insulin treatment may need to be added to treatment regimen.
Vascular and neurologic complications	Frequent.	Frequent.

Insulin is synthesized from a precursor, proinsulin. Enzymes split proinsulin to form insulin and C-peptide, and then the two substances are released in equal amounts. Therefore measuring C-peptide in serum and urine is a useful clinical indicator of pancreatic β cell function.

Type 1 Diabetes Mellitus. *Type 1 diabetes mellitus,* formerly known as juvenile-onset diabetes or insulin-dependent diabetes, accounts for approximately 5% of all people with diabetes. Type 1 diabetes generally affects people under 40 years of age, and 40% develop it before 20 years of age. The incidence of type 1 diabetes has increased 3% to 5% over recent decades, and for unknown reasons it is occurring more frequently in younger children.[3]

Etiology and Pathophysiology. Type 1 diabetes is an immune-mediated disease, caused by autoimmune destruction of the pancreatic β cells, the site of insulin production. This eventually results in a total absence of insulin production. Autoantibodies to the islet cells cause a reduction of 80% to 90% of normal function before hyperglycemia and other manifestations occur (Fig. 49-2). A genetic predisposition and exposure to a virus are factors that may contribute to the pathogenesis of immune-related type 1 diabetes.

Genetic Link

Predisposition to type 1 diabetes is related to human leukocyte antigens (HLAs). (See Chapter 14 for a discussion of HLAs and disease associations.) Theoretically, when an individual with certain HLA types is exposed to a viral infection, the β cells of the pancreas are destroyed, either directly or through an autoimmune process. The HLA types associated with an increased risk for type 1 diabetes include HLA-DR3 and HLA-DR4 (see Genetics in Clinical Practice box).

Idiopathic diabetes is a form of type 1 diabetes that is strongly inherited and not related to autoimmunity. It occurs only in a small number of people with type 1 diabetes, most often of Hispanic, African, or Asian ancestry.[3] Latent autoimmune diabetes in adults (LADA), a slowly progressing autoimmune form of type 1 diabetes, usually occurs in people who are over the age of 35 who are not obese.[4]

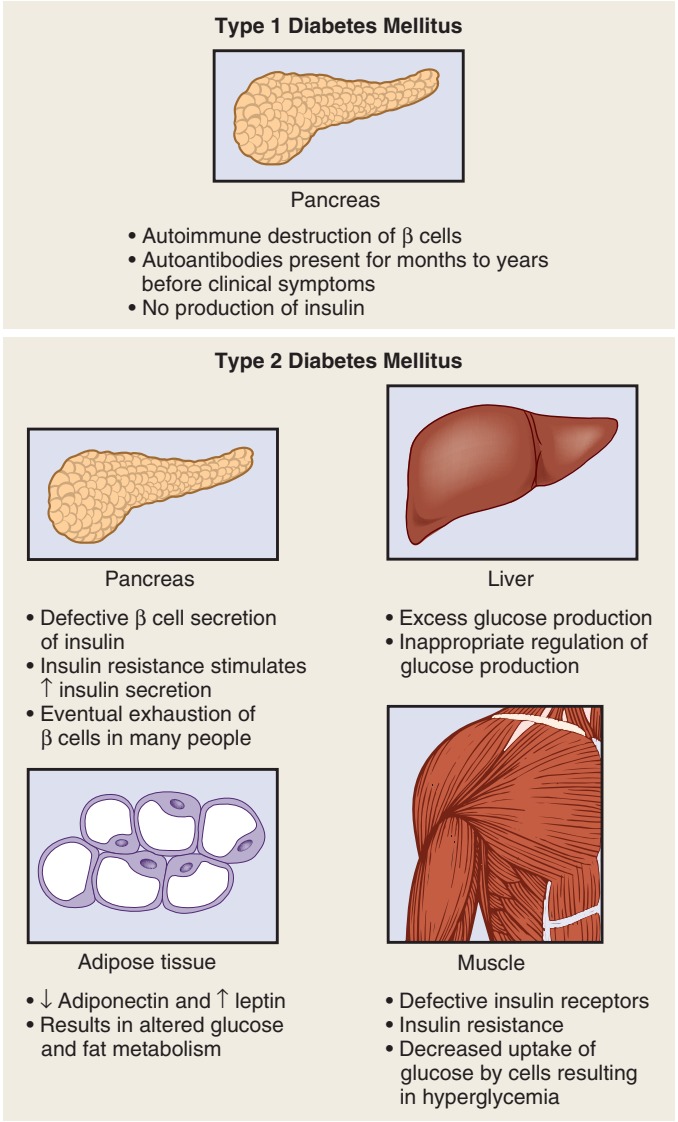

FIG. 49-2 Altered mechanisms in type 1 and type 2 diabetes mellitus.

GENETICS IN CLINICAL PRACTICE

Types 1 and 2 Diabetes Mellitus

Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus	Maturity-Onset Diabetes of the Young (MODY)
Genetic Basis		
• Increased susceptibility (40%-50%) when one has specific human leukocyte antigens (HLA-DR3, HLA-DR4). • Polygenic (>40 genes influence susceptibility).	• Polygenic (>25 genes influence susceptibility).	• Autosomal dominant. • Monogenic (single gene). • Caused by mutations in any of six MODY genes (types 1-6). • Mutations in genes lead to β-cell dysfunction.
Risk to Offspring		
• Risk to offspring of diabetic mothers is 1%-4%. • Risk to offspring of diabetic fathers is 5%-6%. • When one identical twin has type 1 diabetes, the other gets the disease about 30%-40% of the time.	• Risk to offspring is 8%-14%. • When one identical twin gets type 2 diabetes, the other gets it about 60%-75% of the time.	• If one parent has MODY, a child has a 50% chance of developing disease. • If one parent has MODY, a child has a 50% chance of being a carrier.
Clinical Implications		
• Disease is a result of complex interaction of genetic, autoimmune, and environmental factors.	• Disease is a result of complex genetic interactions, which are modified by environmental factors such as body weight and exercise.	• MODY accounts for 1% to 5% of people with diabetes. • Characterized by young age of onset (often before age 25). • Not associated with obesity or hypertension. • Treatment varies depending on the genetic mutation that caused MODY.

Onset of Disease. In type 1 diabetes the islet cell autoantibodies responsible for β-cell destruction are present for months to years before the onset of symptoms. Manifestations of type 1 diabetes develop when the person's pancreas can no longer produce sufficient amounts of insulin to maintain normal glucose. Once this occurs, the onset of symptoms is usually rapid, and patients often are initially seen with impending or actual ketoacidosis. The patient usually has a history of recent and sudden weight loss and the classic symptoms of *polydipsia* (excessive thirst), *polyuria* (frequent urination), and *polyphagia* (excessive hunger).

The individual with type 1 diabetes requires insulin from an outside source *(exogenous insulin)* to sustain life. Without insulin, the patient will develop diabetic ketoacidosis (DKA), a life-threatening condition resulting in metabolic acidosis. Newly diagnosed patients with type 1 diabetes may experience a remission, or "honeymoon period," for 3 to 12 months after treatment is initiated. During this time, the patient requires little injected insulin because β-cell insulin production remains sufficient for glucose control. Eventually, as more β cells are destroyed and blood glucose levels increase, the honeymoon period ends and the patient will require insulin on a permanent basis.

Type 2 Diabetes Mellitus. *Type 2 diabetes mellitus* was formerly known as adult-onset diabetes (AODM) or non–insulin-dependent diabetes (NIDDM). Type 2 diabetes mellitus is, by far, the most prevalent type of diabetes, accounting for approximately 90% to 95% of patients with diabetes.[2] Risk factors for developing type 2 diabetes include being overweight or obese, being older, and having a family history of type 2 diabetes. Although the disease is seen less frequently in children, the incidence is increasing due to the increasing prevalence of childhood obesity. Type 2 diabetes is more prevalent in some ethnic populations. African Americans, Asian Americans, Hispanics, Native Hawaiians or other Pacific Islanders, and Native Americans have a higher rate of type 2 diabetes than whites.[4]

Etiology and Pathophysiology. In type 2 diabetes the pancreas usually continues to produce some *endogenous* (self-made) insulin. However, the insulin that is produced is either insufficient for the needs of the body or is poorly used by the tissues, or both. The presence of endogenous insulin is a major distinction between type 1 and type 2 diabetes. (In type 1 diabetes, there is an absence of endogenous insulin.)

Many factors contribute to the development of type 2 diabetes. The most powerful risk factor is obesity, especially abdominal and visceral adiposity.

Genetic Link

Although the genetics of type 2 diabetes is not yet fully understood, it is likely multiple genes are involved. Genetic mutations that lead to insulin resistance and a higher risk for obesity have been found in many people with type 2 diabetes. Individuals with a first-degree relative with the disease are 10 times more likely to develop type 2 diabetes.

Four major metabolic abnormalities have a role in the development of type 2 diabetes (see Fig. 49-2). The first factor is **insulin resistance,** a condition in which body tissues do not respond to the action of insulin because insulin receptors are unresponsive, are insufficient in number, or both. Most insulin receptors are located on skeletal muscle, fat, and liver cells. When insulin is not properly used, the entry of glucose into the cell is impeded, resulting in hyperglycemia. In the early stages of insulin resistance, the pancreas responds to high blood glucose by producing greater amounts of insulin (if β-cell function is normal). This creates a temporary state of hyperinsulinemia that coexists with hyperglycemia.

A second factor in the development of type 2 diabetes is a marked decrease in the pancreas's ability to produce insulin, as the β cells become fatigued from the compensatory overproduction of insulin or when β-cell mass is lost. The underlying basis for the failure of β cells to adapt is unknown. It may be linked to the adverse effects of chronic hyperglycemia or high circulating free fatty acids.

A third factor is inappropriate glucose production by the liver. Instead of properly regulating the release of glucose in response to blood levels, the liver does so in a haphazard way that does not correspond to the body's needs at the time.

A fourth factor is altered production of hormones and cytokines by adipose tissue *(adipokines)*. Adipokines secreted by adipose tissue appear to play a role in glucose and fat metabolism and are likely to contribute to the pathophysiology of type 2 diabetes.[5] Adipokines are thought to cause chronic inflammation, a factor involved in insulin resistance, type 2 diabetes, and cardiovascular disease (CVD). The two main adipokines believed to affect insulin sensitivity are adiponectin and leptin.

Individuals with *metabolic syndrome* are at an increased risk for the development of type 2 diabetes. Metabolic syndrome has five components: elevated glucose levels, abdominal obesity, elevated blood pressure (BP), high levels of triglycerides, and decreased levels of high-density lipoproteins (HDLs) (see Table 41-10). An individual with three of the five components is considered to have metabolic syndrome.[6] Overweight individuals with metabolic syndrome can prevent or delay the onset of diabetes through a program of weight loss and regular physical activity. (See Chapter 41 for a discussion of metabolic syndrome.)

Onset of Disease. The disease onset in type 2 diabetes is usually gradual. The person may go for many years with undetected hyperglycemia that might produce few, if any, symptoms. Many people are diagnosed on routine laboratory testing or when they undergo treatment for other conditions, and elevated glucose or glycosylated hemoglobin (A1C or Hb A1C [not commonly used]) levels are found.

Prediabetes. Individuals diagnosed with prediabetes are at increased risk for the development of type 2 diabetes. **Prediabetes** is defined as **impaired glucose tolerance (IGT), impaired fasting glucose (IFG),** or both. It is an intermediate stage between normal glucose homeostasis and diabetes where the blood glucose levels are elevated, but not high enough to meet the diagnostic criteria for diabetes. A diagnosis of IGT is made if the 2-hour oral glucose tolerance test (OGTT) values are 140 to 199 mg/dL (7.8 to 11.0 mmol/L).[3] IFG is diagnosed when fasting blood glucose levels are 100 to 125 mg/dL (5.56 to 6.9 mmol/L).

Persons with prediabetes usually do not have symptoms. However, long-term damage to the body, especially the heart and blood vessels, may already be occurring. It is important for you to encourage patients to undergo screening and to provide instruction about managing risk factors for diabetes. Patients with prediabetes can take action to prevent or delay the development of type 2 diabetes. Those with prediabetes should have their blood glucose and A1C tested regularly and monitor for symptoms of diabetes, such as polyuria, polyphagia, and polydipsia. Maintaining a healthy weight, exercising regularly, and

eating a healthy diet have all been found to reduce the risk of developing overt diabetes in people with prediabetes.

Gestational Diabetes. *Gestational diabetes* develops during pregnancy and occurs in about 2% to 10% of pregnancies in the United States.[7] Women with gestational diabetes have a higher risk for cesarean delivery, and their babies have increased risk for perinatal death, birth injury, and neonatal complications. Women who are at high risk for gestational diabetes should be screened at the first prenatal visit.[8] Those at high risk include women who are obese, are of advanced maternal age, or have a family history of diabetes. Women with an average risk for gestational diabetes are screened using an OGTT at 24 to 28 weeks of gestation. Most women with gestational diabetes have normal glucose levels within 6 weeks postpartum. Be aware that women with a history of gestational diabetes have a 35% to 60% chance of developing type 2 diabetes within 10 years.[7] Gestational diabetes and management of the pregnant patient with diabetes are specialized areas not covered in detail in this chapter. Consult an obstetric text for more information.

Other Specific Types of Diabetes. Diabetes occurs in some people because of another medical condition or treatment of a medical condition that causes abnormal blood glucose levels. Conditions that may cause diabetes can result from damage to, injury to, interference with, or destruction of the β-cell function in the pancreas. These include Cushing syndrome, hyperthyroidism, recurrent pancreatitis, cystic fibrosis, hemochromatosis, and parenteral nutrition. Commonly used medications that can induce diabetes in some people include corticosteroids (prednisone), thiazides, phenytoin (Dilantin), and atypical antipsychotics (e.g., clozapine [Clozaril]). Diabetes caused by medical conditions or medications can resolve when the underlying condition is treated or the medication discontinued. (Drugs that can alter blood glucose levels are listed in eTable 49-1 available on the website for this chapter.)

Clinical Manifestations

Type 1 Diabetes Mellitus. Because the onset of type 1 diabetes is rapid, the initial manifestations are usually acute. The classic symptoms are *polyuria, polydipsia,* and *polyphagia.* The osmotic effect of glucose produces the manifestations of polydipsia and polyuria. Polyphagia is a consequence of cellular malnourishment when insulin deficiency prevents utilization of glucose for energy. Weight loss may occur because the body cannot get glucose and turns to other energy sources, such as fat and protein. Weakness and fatigue may result because body cells lack needed energy from glucose. Ketoacidosis, a complication most common in those with untreated type 1 diabetes, is associated with additional clinical manifestations and is discussed later in this chapter.

Type 2 Diabetes Mellitus. The clinical manifestations of type 2 diabetes are often nonspecific, although it is possible that an individual with type 2 diabetes will experience some of the classic symptoms associated with type 1 diabetes, including polyuria, polydipsia, and polyphagia. Some of the more common manifestations associated with type 2 diabetes are fatigue, recurrent infections, recurrent vaginal yeast or candidal infections, prolonged wound healing, and visual changes.

Diagnostic Studies

The diagnosis of diabetes mellitus is made through one of the following four methods.

1. A1C of 6.5% or higher.
2. Fasting plasma glucose (FPG) level greater than or equal to 126 mg/dL (7.0 mmol/L). *Fasting* is defined as no caloric intake for at least 8 hours.
3. Two-hour plasma glucose level greater than or equal to 200 mg/dL (11.1 mmol/L) during an OGTT, using a glucose load of 75 g.
4. In a patient with classic symptoms of hyperglycemia (polyuria, polydipsia, unexplained weight loss) or hyperglycemic crisis, a random plasma glucose greater than or equal to 200 mg/dL (11.1 mmol/L).

If a patient is seen with a hyperglycemic crisis or clear symptoms of hyperglycemia (polyuria, polydipsia, polyphagia) with a random plasma glucose greater than or equal to 200 mg/dL, repeat testing is not warranted.[3] Otherwise, criteria 1 through 3 should be confirmed by repeat testing to rule out laboratory error. It is preferable for the repeat test to be the same test used initially. For example, if a random blood glucose test showed an elevated blood glucose, that same test should be used again when the person is retested.

The accuracy of test results depends on adequate patient preparation and attention to the many factors that may influence the test results. For example, factors that can falsely elevate values include recent severe restrictions of dietary carbohydrate, acute illness, medications (e.g., contraceptives, corticosteroids), and restricted activity such as bed rest. A patient with impaired gastrointestinal absorption or one who has recently taken acetaminophen may have false-negative test results.

A1C measures the amount of glycosylated hemoglobin as a percentage of total hemoglobin (e.g., A1C of 6.5% means that 6.5% of the total hemoglobin has glucose attached to it). The amount of hemoglobin that is glycosylated depends on the blood glucose level. When blood glucose levels are elevated over time, the amount of glucose attached to hemoglobin molecules increases. This glucose remains attached to the red blood cell (RBC) for the life of the cell (approximately 120 days). Therefore the A1C test provides a measurement of glycemic control over the previous 2 to 3 months, with increases in the A1C reflecting elevated blood glucose levels. The A1C has several advantages over the FPG, including greater convenience, since fasting is not required.[3] Diseases affecting RBCs (e.g., iron deficiency anemia or sickle cell anemia) can influence the A1C and should be considered when interpreting test results.

A1C results may be reviewed with patients using the same units (mg/dL or mmol/L) that patients see routinely in blood glucose measurements. An *estimated average glucose* (eAG) can be determined from the A1C. The $eAG = 28.7 \times A1C - 46.7$, or the eAG may be obtained by using an online calculator at *http://professional.diabetes.org/glucosecalculator.aspx*. For example, an A1C of 8.0% is equivalent to a glucose level of 183 mg/dL.

All patients with diabetes and prediabetes should have their A1C monitored regularly to determine the success of the current treatment plan and make changes in the plan if glycemic goals are not achieved. The ADA identifies an A1C goal for patients with diabetes of less than 7.0%. The American College of Endocrinology recommends an A1C of less than 6.5%. When the A1C is maintained at near-normal levels, the risk for the development of microvascular and macrovascular complications is greatly reduced. For individuals with prediabetes, monitoring the A1C can detect overt diabetes and provide feedback on efforts to prevent diabetes.

Fructosamine can also be used to assess glucose control. Fructosamine is formed by a chemical reaction of glucose with plasma protein. It reflects glucose control in the previous 1 to 3 weeks. Fructosamine levels may show a change in glucose control before A1C does.

Islet cell autoantibody testing is primarily ordered to help distinguish between autoimmune type 1 diabetes and diabetes from other causes. Autoantibodies can develop to one or several of the autoantigens—GAD65, IA-2, or insulin.

Collaborative Care

The goals of diabetes management are to reduce symptoms, promote well-being, prevent acute complications of hyperglycemia, and prevent or delay the onset and progression of long-term complications. These goals are most likely to be met when the patient is able to maintain blood glucose levels as near to normal as possible. Diabetes is a chronic disease that requires daily decisions about food intake, blood glucose testing, medication, and exercise. Patient teaching, which enables the patient to become the most active participant in his or her own care, is essential to achieve glycemic goals. Nutritional therapy, drug therapy, exercise, and self-monitoring of blood glucose are the tools used in the management of diabetes (Table 49-2).

The three major types of glucose-lowering agents (GLAs) used in the treatment of diabetes are insulin, oral agents (OAs), and noninsulin injectable agents. All individuals with type 1 diabetes require insulin. For some people with type 2 diabetes, a regimen of proper nutrition, regular physical activity, and maintenance of desirable body weight is sufficient to attain optimal blood glucose control. However, eventually most people with type 2 diabetes will require medication management because diabetes is a progressive disease.

TABLE 49-2 COLLABORATIVE CARE

Diabetes Mellitus

Diagnostic

- History and physical examination
- Blood tests, including fasting blood glucose, postprandial blood glucose, A1C, fructosamine, lipid profile, blood urea nitrogen and serum creatinine, electrolytes, islet cell autoantibodies
- Urine for complete urinalysis, microalbuminuria, and acetone (if indicated)
- Blood pressure
- ECG (if indicated)
- Funduscopic examination (dilated eye examination)
- Dental examination
- Neurologic examination, including monofilament test for sensation to lower extremities
- Ankle-brachial index (ABI) (if indicated) (see Table 38-3)
- Foot (podiatric) examination
- Monitoring of weight

Collaborative Therapy

- Patient and caregiver teaching and follow-up programs
- Nutritional therapy (see Table 49-8)
- Exercise therapy (see Tables 49-9 and 49-10)
- Self-monitoring of blood glucose (SMBG) (see Table 49-11)
- Drug therapy
  - Insulin (see Fig. 49-3 and Tables 49-3 and 49-4)
  - Oral and noninsulin injectable agents (see Table 49-7)
  - Enteric-coated aspirin (81-162 mg/day)
  - Angiotensin-converting enzyme (ACE) inhibitors (see Table 33-7)
  - Angiotensin II receptor blockers (ARBs) (see Table 33-7)
  - Antihyperlipidemic drugs (see Table 34-5)

Drug Therapy: Insulin

Exogenous (injected) insulin is needed when a patient has inadequate insulin to meet specific metabolic needs. People with type 1 diabetes require exogenous insulin to survive and may need multiple daily injections of insulin (often four or more) or continuous insulin infusion via an insulin pump to adequately control blood glucose levels. People with type 2 diabetes may require exogenous insulin during periods of severe stress such as illness or surgery. In addition, since type 2 diabetes is a progressive disease, over time the combination of nutritional therapy, exercise, OAs, and noninsulin injectable agents may no longer adequately control blood glucose levels. At that point exogenous insulin would be added as a permanent part of the management plan. People with type 2 diabetes may also need up to four injections per day to adequately control their blood glucose levels. Occasionally insulin pumps are used for patients with type 2 diabetes who have not achieved good glycemic control with other therapies.

Types of Insulin. Today only genetically engineered human insulin made in laboratories is used. The insulin is derived from common bacteria (e.g., *Escherichia coli*) or yeast cells using recombinant deoxyribonucleic acid (DNA) technology (see eFig. 14-1 available on the website for Chapter 14). In the past, insulin was extracted from beef and pork pancreas, but their use was associated with high rates of allergic reactions and complications. These forms of insulin are no longer available.

Insulins differ by their onset, peak action, and duration (Fig. 49-3) and are categorized as rapid-acting, short-acting, intermediate-acting, and long-acting insulin (Table 49-3).

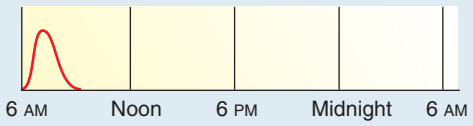
Insulin Regimens. Examples of insulin regimens are presented in Table 49-4. The insulin regimen that most closely mimics endogenous insulin production is the basal-bolus regimen, which uses rapid- or short-acting (bolus) insulin before meals and intermediate- or long-acting (basal) background insulin once or twice a day. The basal-bolus regimen is **intensive insulin therapy,** consisting of multiple daily insulin injections together with frequent self-monitoring of blood

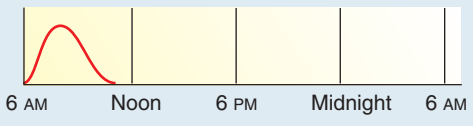
TABLE 49-3 DRUG THERAPY

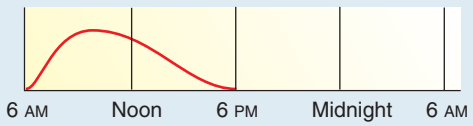
Types of Insulin

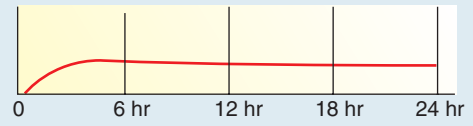
Classification	Examples	Clarity of Solution
Rapid-acting insulin	lispro (Humalog) aspart (NovoLog) glulisine (Apidra)	Clear
Short-acting insulin	regular (Humulin R, Novolin R)	Clear
Intermediate-acting insulin	NPH (Humulin N, Novolin N)	Cloudy
Long-acting insulin	glargine (Lantus) detemir (Levemir)	Clear
Combination therapy (premixed)	NPH/regular 70/30* (Humulin 70/30, Novolin 70/30) NPH/regular 50/50* (Humulin 50/50) lispro protamine/lispro 75/25* (Humalog Mix 75/25) lispro protamine/lispro 50/50* (Humalog Mix 50/50) aspart protamine/aspart 70/30* (NovoLog Mix 70/30)	Cloudy

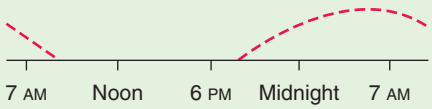
*These numbers refer to percentages of each type of insulin.

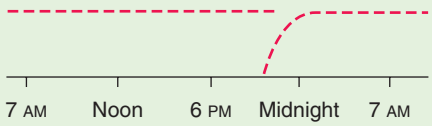


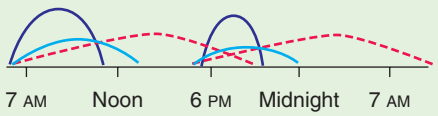


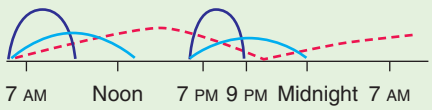


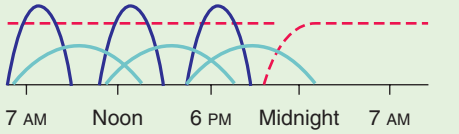


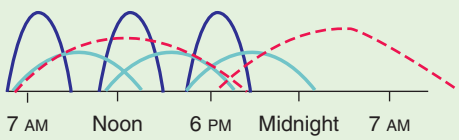












INSULIN PREPARATION	ONSET, PEAK, DURATION	EXAMPLE
Rapid acting lispro (Humalog) aspart (NovoLog) glulisine (Apidra)	*Onset:* 10–30 min *Peak:* 30 min–3 hr *Duration:* 3–5 hr	
Short acting Regular (Humulin R, Novolin R)	*Onset:* 30 min–1 hr *Peak:* 2–5 hr *Duration:* 5–8 hr	
Intermediate acting NPH (Humulin N, Novolin N)	*Onset:* 1.5–4 hr *Peak:* 4–12 hr *Duration:* 12–18 hr	
Long acting glargine (Lantus) detemir (Levemir)	*Onset:* 0.8–4 hr *Peak:* no pronounced peak *Duration:* 24+ hr	

FIG. 49-3 Commercially available insulin preparations showing onset, peak, and duration of action. Individual patient responses to each type of insulin are different and affected by many different factors.

TABLE 49-4 DRUG THERAPY

Insulin Regimens

Regimen	Type of Insulin and Frequency	Action Profile	Comments
Once a day Single dose	Intermediate (NPH) *At bedtime*		One injection should provide nighttime coverage.
	OR Long-acting (glargine [Lantus], detemir [Levemir]) *In AM or at bedtime*		One injection will last 24 hr with no peaks and less chance for hypoglycemia. Does not cover postprandial blood glucose levels.
Twice a day Split-mixed dose	NPH and regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast and at dinner*		Two injections provide coverage for 24 hr. Patient must adhere to a set meal plan.
Three times a day Combination of mixed and single dose	NPH and regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast* + Regular or rapid *Before dinner* + NPH *At bedtime*		Three injections provide coverage for 24 hr, particularly during early AM hours. Decreased potential for 2-3 AM hypoglycemia.
Basal-bolus Multiple dose	Regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast, lunch, and dinner* + Long-acting (glargine or detemir) *Once a day* OR Regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast, lunch, and dinner* + NPH *Twice a day*	 	More flexibility is allowed at mealtimes and for amount of food intake. Good postprandial control. Preprandial blood glucose checks and establishing and following individualized algorithms are necessary. Patients with type 1 diabetes require basal insulin to cover 24 hr. Most physiologic approach, except for pump.

Rapid-acting (lispro, aspart, glulisine) insulin.
Short-acting (regular) insulin.
Intermediate-acting (NPH) or long-acting (glargine, detemir) insulin.

glucose. The goal is to achieve a near-normal glucose level of 70 to 130 mg/dL before meals.

Other, less intense regimens can also give good glucose control for some people. Ideally, the patient and the health care provider should select a regimen together. The criteria for selection are based on the desired and feasible levels of glycemic control and the patient's lifestyle, diet, and activity patterns. If a less intense regimen is not giving the person optimal control, the health care provider should encourage a more intense approach.

Mealtime Insulin (Bolus). To control postprandial blood glucose levels, the timing of rapid- and short-acting insulin in relation to meals is crucial. Rapid-acting synthetic insulin analogs, which include lispro (Humalog), aspart (NovoLog), and glulisine (Apidra), have an onset of action of approximately 15 minutes and should be injected within 15 minutes of mealtime. The rapid-acting analogs most closely mimic natural insulin secretion in response to a meal.

Short-acting regular insulin has an onset of action of 30 to 60 minutes and should be injected 30 to 45 minutes before a meal to ensure that the onset of action coincides with meal absorption. Because timing an injection 30 to 45 minutes before a meal is difficult for people to incorporate into their lifestyles, the flexibility that rapid-acting insulins offer is preferred by those taking insulin with their meals.[9] Short-acting insulin is also more likely to cause hypoglycemia because of a longer duration of action.

Long- or Intermediate-Acting (Basal) Background Insulin. In addition to mealtime insulin, people with type 1 diabetes must also use a long- or intermediate-acting basal (background) insulin to control blood glucose levels in between meals and overnight. Without 24-hour background insulin, people with type 1 diabetes are more prone to developing DKA.

Many people with type 2 diabetes who use oral medications also require insulin to adequately control blood glucose levels. The long-acting insulins, glargine (Lantus) and detemir (Levemir), are often added to the medication regimen. This type of insulin is released steadily and continuously, and for most people do not have a peak of action (see Fig. 49-3). Although they are typically used for once-daily subcutaneous administration, detemir can be given twice daily. Because they lack peak action time, the risk for hypoglycemia from this type of insulin is greatly reduced. Glargine and detemir must not be diluted or mixed with any other insulin or solution in the same syringe. Mealtime insulin may also be added if oral agents and long-acting insulin are not adequate to achieve glycemic goals.

Intermediate-acting insulin (NPH) is also used as a basal insulin. It has a duration of 12 to 18 hours. The disadvantage of NPH is that it has a peak ranging from 4 to 12 hours, which can result in hypoglycemia. NPH is the only basal insulin that can be mixed with short- and rapid-acting insulins. NPH is a cloudy insulin that must be gently agitated before administration.

Combination Insulin Therapy. For those who want to use only one or two injections per day, a short- or rapid-acting insulin is mixed with intermediate-acting insulin in the same syringe. This allows the patient to have both mealtime and basal coverage without having to administer two separate injections. Although this may be more appealing to the patient, most patients achieve better control with basal-bolus therapy. Patients may mix the two types of insulin themselves or may use a commercially premixed formula or pen (see Table 49-3). Premixed formulas offer convenience to patients, who do not have to draw up and mix insulin from two different vials. This is especially helpful to those who lack the visual, manual, or cognitive skills to mix insulin themselves. However, the convenience of these formulas sacrifices the potential for optimal blood glucose control because there is less opportunity for flexible dosing based on need.

Storage of Insulin. As a protein, insulin requires special storage considerations. Heat and freezing alter the insulin molecule. Insulin vials and insulin pens currently in use may be left at room temperature for up to 4 weeks unless the room temperature is higher than 86° F (30° C) or below freezing (less than 32° F [0° C]). Prolonged exposure to direct sunlight should be avoided. A patient who is traveling in hot climates may store insulin in a thermos or cooler to keep it cool (not frozen). Unopened insulin vials and insulin pens should be stored in the refrigerator.

Patients who are traveling or caregivers of patients who are sight impaired or who lack the manual dexterity to fill their own syringes may prefill insulin syringes. Prefilled syringes containing two different insulins are stable for up to 1 week when stored in the refrigerator, whereas syringes containing only one type of insulin are stable up to 30 days.[10]

Syringes should be stored in a vertical position with the needle pointed up to avoid clumping of suspended insulin in the needle. Before injection, gently roll prefilled syringes between the palms 10 to 20 times to warm the insulin and resuspend the particles. Some insulin combinations are not appropriate for prefilling and storage because the mixture can alter the onset, action, and/or peak times of either of the types. Consult a pharmacy reference as needed when mixing and prefilling different types of insulin.

Administration of Insulin. Routine doses of insulin are usually administered by subcutaneous injection. Regular insulin can be given IV when immediate onset of action is desired. Insulin is not taken orally because it is inactivated by gastric juices.

Insulin Injection. The steps in administering a subcutaneous insulin injection are outlined in Table 49-5. Teach this technique to new insulin users and review periodically with long-term users. Never assume that because the patient already uses insulin, he or she knows and practices the correct insulin injection technique. The patient may not have understood prior instructions, or changes in eyesight may result in inaccurate preparation. The patient may not see air bubbles in the syringe or may improperly read the scale on the syringe. The patient receiving mixed insulins in the same syringe needs to learn the proper technique for combining them if commercially prepared premixed insulins are not used (Fig. 49-4).

The speed with which peak serum concentrations are reached varies with the anatomic site for injection. The fastest subcutaneous absorption is from the abdomen, followed by the arm, thigh, and buttock. Although the abdomen is the preferred injection site, other sites are appropriate as well (Fig. 49-5). Caution the patient about injecting into a site that is to be exercised. For example, the patient should not inject insulin into the thigh and then go jogging. Exercise of the injection site, together with the increased body heat and circulation generated by the exercise, may increase the rate of absorption and speed the onset of insulin action.

Teach patients to rotate the injection within one anatomic site, such as the abdomen, for at least 1 week before using a different site, such as the right thigh. This allows for better

TABLE 49-5 PATIENT & CAREGIVER TEACHING GUIDE

Insulin Therapy

Include the following instructions when teaching the patient and caregiver about insulin therapy.

1. Wash hands thoroughly.
2. Always inspect insulin bottle before using it. Make sure that it is the proper type and concentration, expiration date has not passed, and top of bottle is in perfect condition. The insulin (except for NPH) should look clear and colorless. Discard if it appears discolored or if you see particles in the solution.
3. If insulin solutions are cloudy (see Table 49-3), gently roll the insulin bottle between the palms of hands to mix the insulin.
4. Select proper injection site (see Fig. 49-5).
5. Cleanse the skin with soap and water or alcohol.
6. Pinch up the skin, and push the needle straight into the pinched-up area (90-degree angle). If you are very thin or using a $\frac{5}{16}$-in needle, you may need to use a 45-degree angle.
7. Push the plunger all the way down, let go of pinched skin, leave needle in place for 5 sec to ensure that all insulin has been injected, and then remove needle.
8. Destroy and dispose of single-use syringe safely.

insulin absorption. It may be helpful to think of the abdomen as a checkerboard, with each ½-in square representing an injection site. Injections are rotated systematically across the board, with each injection site at least ½ to 1 in away from the previous injection site.

Most commercial insulin is available as U100, indicating that 1 mL contains 100 U of insulin. U100 insulin must be used with a U100-marked syringe. Disposable plastic insulin syringes are available in a variety of sizes, including 1.0, 0.5, and 0.3 mL. The 0.5-mL size may be used for doses of 50 U or less, and the 0.3-mL syringe can be used for doses of 30 U or less. The 0.5- and 0.3-mL syringes are in 1-U increments. This provides more accurate delivery when the dose is an odd number. The 1.0-mL syringe is necessary for patients who require more than 50 U of insulin. The 1.0-mL syringe is in 2-U increments. When patients change from a 0.3- or a 0.5-mL to a 1.0-mL syringe, make them aware of the dose increment difference.

Insulin syringe needles come in the following lengths: 6 mm ($\frac{1}{4}$ in), 8 mm ($\frac{5}{16}$ in), and 12.7 mm (½ in).[11] Needle gauges also vary among syringes. The needle gauges available are 28, 29, 30, and 31. The higher the gauge number, the smaller the diameter, thus resulting in a more comfortable injection. Only the person using the syringe should recap the needle; never recap a needle used for a patient. The use of an alcohol swab on the site before self-injection is no longer recommended. Routine hygiene such as washing with soap and rinsing with water is adequate. This applies primarily to patient self-injection technique. When injection occurs in a health care facility, policy may dictate site preparation with alcohol to prevent health care–associated infection (HAI). Perform injections at a 45- to 90-degree angle, depending on the thickness of the patient's fat pad.

An insulin pen is a compact portable device loaded with an insulin cartridge that serves the same function as a needle and syringe (Fig. 49-6). Pen needles are available in lengths of 4 mm ($\frac{5}{32}$ in), 5 mm ($\frac{3}{16}$ in), 8 mm ($\frac{5}{16}$ in), and 12.7 mm (½ in) and in three gauges, 29, 31, and 32. Many patients prefer using insulin pens because of greater convenience and flexibility.[12] They are portable and compact, are more discreet than using a vial and syringe, and provide consistent and accurate dosing.

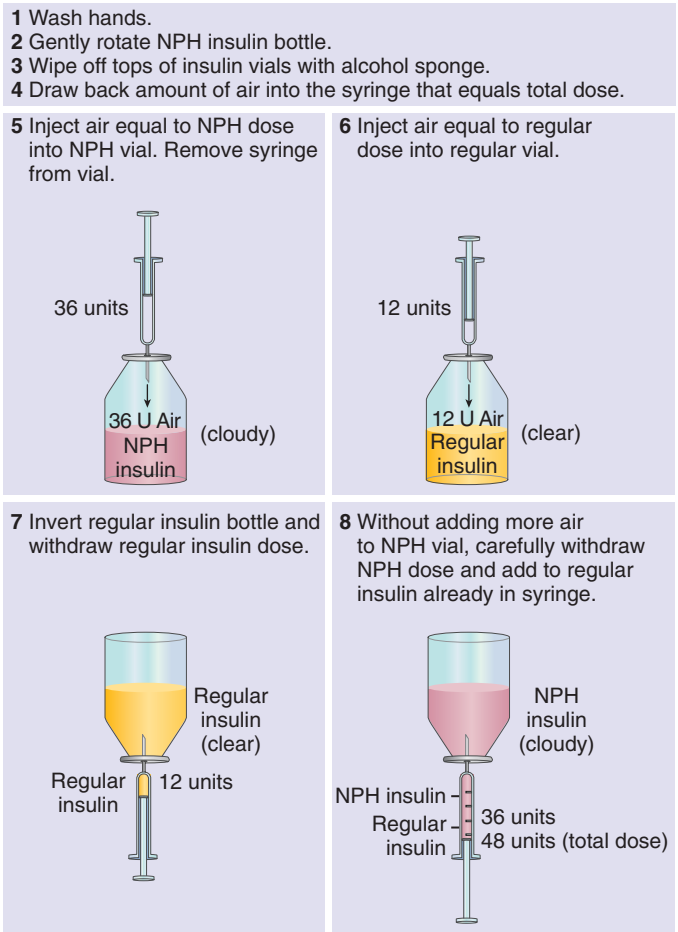


FIG. 49-4 Mixing insulins. This step-order process avoids the problem of contaminating regular insulin with intermediate-acting insulin.

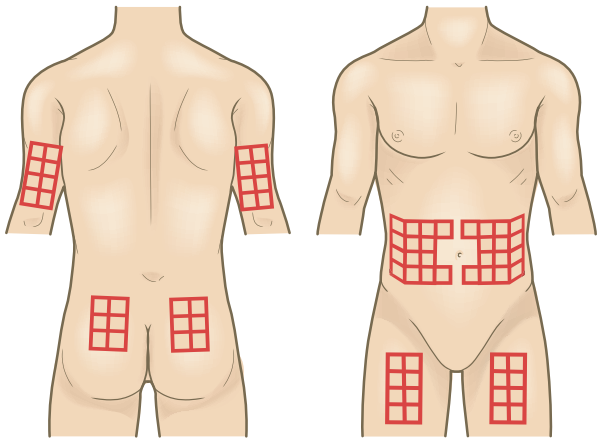

FIG. 49-5 Injection sites for insulin.

For patients with poor vision, the pen is a better option, since they can hear the clicks of the pen as the dose is selected. Insulin pens come packaged with printed instructions, including pictures of the steps to take when using the pen. These instructions are helpful when teaching new users and reviewing technique with current users of a pen.

Insulin Pump. Continuous subcutaneous insulin infusion can be administered using an *insulin pump,* a small battery-operated device that resembles a standard paging device in size

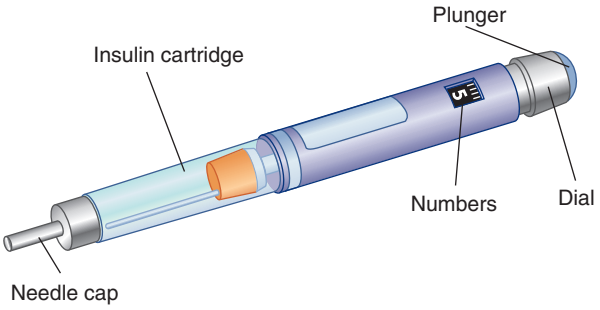

FIG. 49-6 Parts of insulin pen.

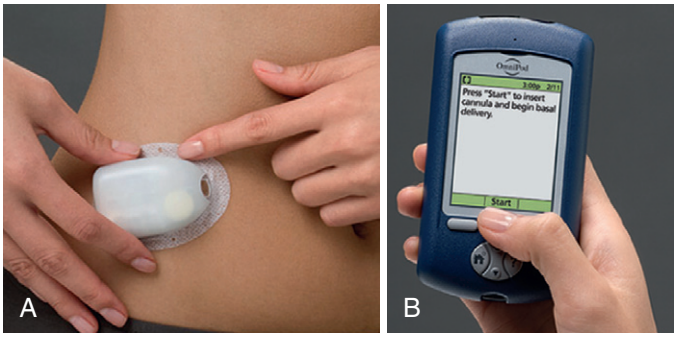

FIG. 49-7 **A,** OmniPod Insulin Management System. The Pod holds and delivers insulin. **B,** The Personal Diabetes Manager (PDM) wirelessly programs insulin delivery via the Pod. The PDM has a built-in glucose meter. (Courtesy of Insulet Corporation.)

and appearance. Most insulin pumps are worn on the belt or under clothing and loaded with rapid-acting insulin, which is connected via plastic tubing to a catheter inserted into the subcutaneous tissue in the abdominal wall. Insulet Corporation has an insulin pump that is a tubing-free system (Fig. 49-7). All insulin pumps are programmed to deliver a continuous infusion of rapid-acting insulin 24 hours a day, known as the *basal rate.* Basal insulin can be temporarily increased or decreased based on carbohydrate intake, activity changes, or illness. Some individuals require different basal rates at different times of the day.

At mealtime, the user programs the pump to deliver a bolus infusion of insulin appropriate to the amount of carbohydrate ingested and an additional amount, if needed, to bring down high preprandial blood glucose. The insertion site is changed every 2 to 3 days to avoid site infection and to promote good insulin absorption. Insulin pump users must check their blood glucose level at least four times per day. Testing eight times or more per day is common.

A major advantage of the insulin pump is the potential for tight glucose control. This is possible because insulin delivery is similar to the normal physiologic pattern. Pumps offer the benefit of a more normal lifestyle, allowing users more flexibility with meal and activity patterns. Problems and complications of insulin pump therapy are infection at the insertion site, an increased risk for DKA if the insulin infusion is disrupted because of a problem at the infusion site, and the increased cost of the pump and supplies.[13]

Problems With Insulin Therapy. Problems associated with insulin therapy include hypoglycemia, allergic reactions, lipodystrophy, and the Somogyi effect. Hypoglycemia is discussed in detail later in this chapter. (Guidelines for assessing patients treated with insulin and other GLAs are presented in Table 49-6.)

TABLE 49-6 ASSESSING THE PATIENT TREATED WITH GLUCOSE-LOWERING AGENTS

Category	Assessment
For Patient With Newly Diagnosed Diabetes or for Reevaluation of Drug Regimen	
Cognitive	• Is patient or caregiver able to understand why insulin or OAs are being used as part of diabetes management? • Is patient or caregiver able to understand concepts of asepsis, combining insulins, and side effects of medications? • Is patient able to remember to take >1 dose/day? • Does patient take medications at right times in relation to meals?
Psychomotor	• Is patient or caregiver physically able to prepare and administer accurate doses of the drugs?
Affective	• What emotions and attitudes are patient and caregiver displaying concerning diagnosis of diabetes and insulin or OA treatment?
For Follow-up of GLA-Treated Patient	
Effectiveness of therapy	• Is patient having symptoms of hyperglycemia? • Does blood glucose record show good or poor control? • Is A1C consistent with glucose records?
Side effects of therapy	• Is atrophy or hypertrophy present at injection sites? • Has patient had hypoglycemic episodes? If so, how often? What time of day? What were the symptoms of hypoglycemia? • Are there complaints of nightmares, night sweats, or early morning headaches? • Has patient had a skin rash or GI upset since taking OAs? • Has patient gained or lost weight?
Self-management behaviors	• If patient is having hyperglycemic or hypoglycemic episodes, how are those episodes managed? • Has patient analyzed episodes to determine reason for hyperglycemic or hypoglycemic episodes? • How much insulin or OA is patient taking and at what time of day? Is patient adjusting insulin dose? Under what circumstances and by how much? • Has exercise pattern changed? • Is patient adhering to the meal plan? Are meals taken at times corresponding to peak insulin action?

A1C, Glycosylated hemoglobin; *GLA,* glucose-lowering agent; *OA,* oral agent.

Allergic Reactions. Local inflammatory reactions to insulin may occur, such as itching, erythema, and burning around the injection site. Local reactions may be self-limiting within 1 to 3 months or may improve with a low dose of antihistamine. A true insulin allergy is rare. It is manifested by a systemic response with urticaria and possibly anaphylactic shock. Zinc or protamine used as a preservative in the insulin and the latex or rubber stoppers on the vials have been implicated in allergic reactions.

Lipodystrophy. *Lipodystrophy* (atrophy of subcutaneous tissue) may occur if the same injection sites are used frequently. The use of human insulin has significantly reduced the risk for

lipodystrophy. *Hypertrophy,* a thickening of the subcutaneous tissue, eventually regresses if the patient does not use the site for at least 6 months. The use of hypertrophied sites may result in erratic insulin absorption.

Somogyi Effect and Dawn Phenomenon. Hyperglycemia in the morning may be due to the **Somogyi effect.** A high dose of insulin produces a decline in blood glucose levels during the night. As a result, counterregulatory hormones (e.g., glucagon, epinephrine, growth hormone, cortisol) are released, stimulating lipolysis, gluconeogenesis, and glycogenolysis, which in turn produce rebound hyperglycemia. The danger of this effect is that when blood glucose levels are measured in the morning, hyperglycemia is apparent and the patient (or the health care professional) may increase the insulin dose.

If a patient is experiencing morning hyperglycemia, checking blood glucose levels between 2:00 and 4:00 AM for hypoglycemia will help determine if the cause is the Somogyi effect. The patient may report headaches on awakening and recall having night sweats or nightmares. A bedtime snack, a reduction in the dose of insulin, or both can help to prevent the Somogyi effect.

The **dawn phenomenon** is also characterized by hyperglycemia that is present on awakening. It has been suggested that two counterregulatory hormones, growth hormone and cortisol, excreted in increased amounts in the early morning hours are responsible. The dawn phenomenon affects a majority of people with diabetes and tends to be most severe when growth hormone is at its peak in adolescence and young adulthood.

Careful assessment is required to document the Somogyi effect or dawn phenomenon because the treatment for each differs. The treatment for Somogyi effect is less insulin. The treatment for dawn phenomenon is an increase in insulin or an adjustment in administration time. Your assessment must include insulin dose, injection sites, and variability in the time of meals or insulin administration. Ask the patient to measure and document bedtime, nighttime (between 2:00 and 4:00 AM), and morning fasting blood glucose levels on several occasions. If the predawn levels are less than 60 mg/dL (3.3 mmol/L) and signs and symptoms of hypoglycemia are present, the insulin dosage should be reduced. If the 2:00 to 4:00 AM blood glucose is high, the insulin dosage should be increased. In addition, counsel the patient on appropriate bedtime snacks.

Drug Therapy: Oral and Noninsulin Injectable Agents

OAs and noninsulin injectable agents work to improve the mechanisms by which the body produces and uses insulin and glucose. These drugs work on three defects of type 2 diabetes: (1) insulin resistance, (2) decreased insulin production, and (3) increased hepatic glucose production. These drugs may be used in combination with agents from other classes or with insulin to achieve blood glucose goals. Oral and noninsulin injectable agents are listed in Table 49-7.

Biguanides. The most widely used oral diabetes agent is metformin, the only medication in the biguanide class available in the United States. Forms of metformin include Glucophage (immediate release), Glucophage XR (extended release), Fortamet (extended release), and Riomet (liquid form of metformin). The primary action of metformin is to reduce glucose production by the liver. It also enhances insulin sensitivity at the tissue level and improves glucose transport into the cells. Additionally, it has beneficial effects on plasma lipids.

Metformin is the first-choice drug for most people with type 2 diabetes.[14] Because it may cause moderate weight loss, metformin may be useful for people with type 2 diabetes and prediabetes who are overweight or obese. It is also used in the prevention of type 2 diabetes in those with prediabetes who are less than age 60 and have risk factors such as hypertension or a history of gestational diabetes.

Patients who are undergoing surgery or any radiologic procedures that involve the use of a contrast medium are instructed to temporarily discontinue metformin before surgery or the procedure. They should not resume the metformin until 48 hours afterward, once their serum creatinine has been checked and is normal.[10]

DRUG ALERT: Metformin

- Do not use in patients with kidney disease, liver disease, or heart failure. Lactic acidosis is a rare complication of metformin accumulation.
- IV contrast media that contain iodine pose a risk of acute kidney injury, which could exacerbate metformin-induced lactic acidosis.
- To reduce risk of kidney injury, discontinue metformin a day or two before the procedure.
- May be resumed 48 hours after the procedure assuming kidney function is normal.
- Do not use in people who drink excessive amounts of alcohol.

Sulfonylureas. Sulfonylureas include glipizide (Glucotrol, Glucotrol XL), glyburide (Micronase, DiaBeta, Glynase), and glimepiride (Amaryl). The primary action of the sulfonylureas is to increase insulin production by the pancreas. Therefore hypoglycemia is the major side effect with sulfonylureas.

Meglitinides. Like the sulfonylureas, repaglinide (Prandin) and nateglinide (Starlix) increase insulin production by the pancreas. However, because they are more rapidly absorbed and eliminated than sulfonylureas, they are less likely to cause hypoglycemia. When they are taken just before meals, pancreatic insulin production increases during and after the meal, mimicking the normal response to eating. Instruct patients to take meglitinides any time from 30 minutes before each meal right up to the time of the meal. These drugs should not be taken if a meal is skipped.

α-Glucosidase Inhibitors. Also known as "starch blockers," these drugs work by slowing down the absorption of carbohydrate in the small intestine. Acarbose (Precose) and miglitol (Glyset) are the available drugs in this class. Taken with the first bite of each main meal, they are most effective in lowering postprandial blood glucose. Their effectiveness is measured by checking 2-hour postprandial glucose levels.

Thiazolidinediones. Sometimes referred to as "insulin sensitizers," these agents include pioglitazone (Actos) and rosiglitazone (Avandia). They are most effective for people who have insulin resistance. These agents improve insulin sensitivity, transport, and utilization at target tissues. Because they do not increase insulin production, thiazolidinediones do not cause hypoglycemia when used alone. However, these drugs are rarely used today because of their adverse effects. Rosiglitazone is associated with adverse cardiovascular events (e.g., myocardial infarction) and can be obtained only through restricted access programs. Pioglitazone can worsen heart failure and is associated with an increased risk of bladder cancer.

Dipeptidyl Peptidase-4 (DPP-4) Inhibitors. Incretin hormones are released by the intestines throughout the day, but levels increase in response to a meal. When glucose levels are normal or elevated, incretins increase insulin synthesis and release from the pancreas, as well as decrease hepatic glucose production. The incretin hormones are normally inactivated by dipeptidyl peptidase-4 (DPP-4).

TABLE 49-7 DRUG THERAPY

Oral Agents and Noninsulin Injectable Agents

Type	Mechanism of Action	Side Effects
Oral Agents		
Biguanide		
metformin (Glucophage, Glucophage XR, Riomet, Fortamet, Glumetza)	Increases rate of hepatic glucose production; augment glucose uptake by tissues, especially muscles.	Diarrhea, lactic acidosis. Needs to be held 1-2 days before IV contrast media given and for 48 hr after.
Sulfonylureas		
glipizide (Glucotrol, Glucotrol XL) glyburide (Micronase, DiaBeta, Glynase PresTab) glimepiride (Amaryl)	Stimulate release of insulin from pancreatic islets. Decrease glycogenolysis and gluconeogenesis. Enhance cellular sensitivity to insulin.	Weight gain, hypoglycemia.
Meglitinides		
nateglinide (Starlix) repaglinide (Prandin)	Stimulate a rapid and short-lived release of insulin from the pancreas.	Weight gain, hypoglycemia.
α-Glucosidase Inhibitors		
acarbose (Precose) miglitol (Glyset)	Delay absorption of glucose from GI tract.	Gas, abdominal pain, diarrhea.
Thiazolidinediones		
pioglitazone (Actos) rosiglitazone (Avandia)	Increase glucose uptake in muscle; decrease endogenous glucose production.	Weight gain, edema. *pioglitazone:* increases risk for bladder cancer and exacerbates heart failure. *rosiglitazone:* increases risk for cardiovascular events (e.g., myocardial infarction, stroke).
Dipeptidyl Peptidase-4 (DPP-4) Inhibitors		
linagliptin (Tradjenta) saxagliptin (Onglyza) sitagliptin (Januvia) alogliptin (Nesina)	Enhance activity of incretins, stimulate release of insulin from pancreatic β cells, decrease hepatic glucose production.	Pancreatitis, allergic reactions.
Dopamine Agonist		
bromocriptine (Cycloset)	Activates dopamine receptors in the central nervous system. Unknown how it improves glycemic control.	Orthostatic hypotension.
Combination Therapy		
Glucovance	metformin and glyburide	See side effects for individual drugs.
Metaglip	metformin and glipizide	Same as above.
Avandamet	rosiglitazone and metformin	Same as above.
Duetact	pioglitazone and glimepiride	Same as above.
Actoplus Met, Actoplus Met XR	metformin and pioglitazone	Same as above.
Janumet, Janumet XR	metformin and sitagliptin	Same as above.
Jentadueto	linagliptin and metformin	Same as above.
PrandiMet	metformin and repaglinide	Same as above.
Avandaryl	rosiglitazone and glimepiride	Same as above.
Juvisync	sitagliptin and simvastatin	Same as above.
Kombiglyze	saxagliptin and metformin	Same as above.
Kazano	alogliptin and metformin	Same as above.
Oseni	alogliptin and pioglitazone	Same as above.
Noninsulin Injectable Agents		
Glucagon-Like Peptide-1 (GLP-1) Receptor Agonists*		
exenatide (Byetta) exenatide extended-release (Bydureon) liraglutide (Victoza)	Stimulate release of insulin, decrease glucagon secretion and gastric emptying; increase satiety.	Nausea, vomiting, hypoglycemia, diarrhea, headache.
Amylin Analog**†		
pramlintide (Symlin)	Decreases gastric emptying, glucagon secretion, and endogenous glucose output from liver. Increases satiety.	Hypoglycemia, nausea, vomiting, decreased appetite, headache.

*Administered subcutaneously
†Administered subcutaneously only in abdomen or thigh.

DPP-4 inhibitors (also known as gliptins) include sitagliptin (Januvia), saxagliptin (Onglyza), linagliptin (Tradjenta), and alogliptin (Nesina). DPP-4 inhibitors block the action of the DPP-4 enzyme, which is responsible for inactivating incretin hormones (gastric inhibitory peptide [GIP] and glucagon-like peptide-1 [GLP-1]). The result is an increase in insulin release, decrease in glucagon secretion, and decrease in hepatic glucose production. Since the DPP-4 inhibitors are glucose dependent, they lower the potential for hypoglycemia. The main benefit of these drugs over other medications for diabetes with similar effects is the absence of weight gain as a side effect.

Sodium-Glucose Co-Transporter 2 (SGLT2) Inhibitors. Canagliflozin (Invokana) is the first drug in a new class of drugs known as sodium-glucose co-transporter 2 (SGLT2) inhibitors. It works by blocking the reabsorption of glucose by the kidney, increasing glucose excretion, and lowering blood glucose levels in diabetics.

Dopamine Receptor Agonist. Bromocriptine (Cycloset) is a dopamine receptor agonist that improves glycemic control. The mechanism of action is unknown. Patients with type 2 diabetes are thought to have low levels of dopamine activity in the morning. These low levels of dopamine may interfere with the body's ability to control blood glucose. Bromocriptine increases dopamine receptor activity. It can be used alone or as an add-on to another type 2 diabetes treatment.

Combination Oral Therapy. Many combination drugs are currently available. These drugs combine two different classes of medications to treat diabetes. Examples of these agents are listed in Table 49-7. One advantage of combined therapy is improved patient adherence.

Glucagon-Like Peptide Receptor Agonists. Exenatide (Byetta), exenatide extended-release (Bydureon), and liraglutide (Victoza) simulate GLP-1 (one of the incretin hormones), which is found to be decreased in people with type 2 diabetes. These drugs increase insulin synthesis and release from the pancreas, inhibit glucagon secretion, decrease gastric emptying, and reduce food intake by increasing satiety.

These drugs may be used as monotherapy or adjunct therapy for patients with type 2 diabetes who have not achieved optimal glucose control on OAs. Exenatide and liraglutide are administered using a subcutaneous injection in a prefilled pen. In contrast to exenatide, which is given twice a day, and liraglutide, which is given once daily, Bydureon is given once every 7 days. The delayed gastric emptying that occurs with these medications may affect the absorption of oral medications. Advise patients to take fast-acting oral medications at least 1 hour before injecting exenatide or liraglutide.

DRUG ALERT: Exenatide (Byetta)
- Acute pancreatitis and kidney problems have been associated with its use.

DRUG ALERT: Liraglutide (Victoza)
- Do not use in patients with a personal or family history of medullary thyroid cancer.
- Acute pancreatitis has been associated with its use.

Amylin Analog. Pramlintide (Symlin) is the only available amylin analog. Amylin, a hormone secreted by the β cells of the pancreas in response to food intake, slows gastric emptying, reduces glucagon secretion, and increases satiety.[10] Pramlintide is used in addition to mealtime insulin in patients with type 1 or type 2 diabetes who do not have good glucose control on ideal insulin therapy. It is only used concurrently with insulin and is not a replacement for insulin. Pramlintide is administered before major meals subcutaneously into the thigh or abdomen. It cannot be injected into the arm because absorption from this site is too variable. The drug cannot be mixed in the same syringe with insulin.

The concurrent use of pramlintide and insulin increases the risk of severe hypoglycemia during the 3 hours after injection, especially in patients with type 1 diabetes. Instruct patients to eat a meal with at least 250 calories and keep a form of fast-acting glucose on hand in the event that hypoglycemia develops. When pramlintide is used, the bolus dose of insulin should be reduced.

DRUG ALERT: Pramlintide (Symlin)
- Can cause severe hypoglycemia when used with insulin.

Other Drugs Affecting Blood Glucose Levels. Both the patient and the health care provider must be aware of drug interactions that can potentiate hypoglycemic and hyperglycemic effects. For example, β-adrenergic blockers can mask symptoms of hypoglycemia and prolong the hypoglycemic effects of insulin. Thiazide and loop diuretics can potentiate hyperglycemia by inducing potassium loss, although low-dose therapy with a thiazide is usually considered safe. See eTable 49-1 (available on the website) for a list of medications that may influence glycemic control.

Nutritional Therapy

Individualized nutritional therapy, consisting of counseling, education, and ongoing monitoring, is a cornerstone of care for people with diabetes and prediabetes.[15] Adherence to a dietary regimen is challenging for many people. Achieving nutritional goals requires a coordinated team effort that takes into account the person's behavioral, cognitive, socioeconomic, cultural, and religious backgrounds and preferences. Because of these complexities, it is recommended that a dietitian with expertise in diabetes management take the lead. The dietitian should conduct a dietary assessment and develop an individualized food plan. Additional team members may include nurses, certified diabetes educators, clinical nurse specialists, health care providers, and social workers.

Guidelines from the ADA indicate that, within the context of an overall healthy eating plan, a person with diabetes can eat the same foods as a person who does not have diabetes. This means that the same principles of good nutrition that apply to the general population also apply to the person with diabetes. Table 49-8 describes nutritional therapy for patients with diabetes. According to the ADA, the overall goal of nutrition therapy is to assist people with diabetes in making healthy nutritional choices that will lead to improved metabolic control. Additional specific goals include the following:

- Maintain blood glucose levels as near normal as safely possible to prevent or reduce the risk for complications of diabetes.
- Achieve lipid profiles and BP levels that reduce the risk for CVD.
- Prevent or slow the rate of development of chronic complications of diabetes by modifying nutrient intake and lifestyle.
- Address individual nutritional needs while taking into account personal and cultural preferences and respecting the individual's willingness to change eating and dietary habits.
- Maintain the pleasure of eating by allowing as many food choices as appropriate.

TABLE 49-8 NUTRITIONAL THERAPY

Diabetes Mellitus

Component	Recommendations
Total carbohydrate	• Minimum of 130 g/day. • Include carbohydrate from fruits, vegetables, grains, legumes, and low-fat milk. • Monitor by carbohydrate counting, exchange lists, or use of appropriate proportions (eFig. 49-1). • Glycemic index may provide additional benefit. • Sucrose-containing food can be substituted for other carbohydrates in the meal plan. • Fiber intake at 25-30 g/day. • Nonnutritive sweeteners are safe when consumed within FDA daily intake levels.
Protein	• 15%-20% of total calories. • High-protein diets are not recommended for weight loss.
Fat	• Limit saturated fat to <7% of total calories. • *Trans* fat should be minimized. • Dietary cholesterol <200 mg/day. • ≥2 servings of fish per week to provide polyunsaturated fatty acids.
Alcohol	• Limit to moderate amount (maximum 1 drink per day for women and 2 drinks per day for men). • Alcohol should be consumed with food to reduce risk of nocturnal hypoglycemia in those using insulin or insulin secretagogues. • Moderate alcohol consumption has no acute effect on glucose and insulin concentrations, but carbohydrate taken with the alcohol (mixed drink) may raise blood glucose.

Source: American Diabetes Association: Clinical practice recommendations: nutrition recommendations and interventions for diabetes, *Diabetes Care* 31:S61, 2008.

Type 1 Diabetes Mellitus. Meal planning should be based on the individual's usual food intake and preferences and balanced with insulin and exercise patterns. The insulin regimen should be developed with the patient's eating habits and activity pattern in mind. Day-to-day consistency in timing and amount of food eaten is important for those individuals using conventional, fixed insulin regimens. Patients using rapid-acting insulin can adjust the dose before the meal based on the current blood glucose level and the carbohydrate content of the meal. Intensified insulin therapy, such as multiple daily injections or the use of an insulin pump, allows considerable flexibility in food selection and can be adjusted for alterations from usual eating and exercise habits.

Type 2 Diabetes Mellitus. Nutritional therapy in type 2 diabetes should emphasize achieving glucose, lipid, and BP goals. Modest weight loss has been associated with improved insulin resistance. Therefore weight loss is recommended for all individuals with diabetes who are overweight or obese.[15]

No one proven strategy or method can be uniformly recommended. A nutritionally adequate meal plan with appropriate serving sizes, a reduction of saturated and *trans* fats, and low carbohydrates can bring about decreased calorie consumption. Spacing meals is another strategy that spreads nutrient intake throughout the day. A weight loss of 5% to 7% of body weight often improves glycemic control, even if desirable body weight is not achieved. Weight loss is best attempted by a moderate decrease in calories and an increase in caloric expenditure. Regularly exercising and learning new behaviors and attitudes can facilitate long-term lifestyle changes. Monitoring of blood glucose levels, A1C, lipids, and BP provides feedback on how well the goals of nutritional therapy are being met.

Food Composition. The nutrient balance of a diabetic diet is essential to maintain blood glucose levels. Nutritional energy intake should be balanced with the patient's energy output. Each patient's individual meal plan should be constructed with her or his lifestyle and health goals in mind. The following are general recommendations for nutrient balance.

Carbohydrates. Carbohydrates include sugars, starches, and fiber. Carbohydrates provide important sources of energy, fiber, vitamins, and minerals and are therefore important to all people, including those with diabetes. Foods containing carbohydrates from whole grains, fruits, vegetables, and low-fat milk should be included as part of a healthy meal plan. The recommended dietary allowance for carbohydrates is a minimum of 130 g/day.[15]

Glycemic index (GI) is the term used to describe the rise in blood glucose levels after a person has consumed a carbohydrate-containing food. The GI of foods was developed to compare the postprandial responses to carbohydrate-containing foods. Foods with a high GI raise glucose levels faster and higher than foods with a low GI.

GI of 100 refers to the response to 50 g of glucose or white bread in a normal person without diabetes. All other food with an equivalent carbohydrate value is measured against this standard. For example, the GI of an apple is 52, regular milk 27, baked potato 93, cornflake cereal 119, and baked beans 69. An online calculator for GI is available at *www.glycemicindex.com*. The use of GI may provide a modest additional benefit over consideration of total carbohydrates alone.[15]

With all individuals, dietary fiber should be included as part of a healthy meal plan. There is no evidence that a person with diabetes should consume more fiber than an individual who does not have diabetes. The current recommendation for the general population is 25 to 30 g/day.[15]

Nutritive and nonnutritive sweeteners may be included in a healthy meal plan in moderation. Nonnutritive sweeteners include the sugar substitutes saccharine, aspartame, sucralose, neotame, and acesulfame-K.

Fats. Dietary fat provides energy, carries fat-soluble vitamins, and provides essential fatty acids. The ADA recommends limiting saturated fat to less than 7% of total calories. Less than 200 mg/day of cholesterol and limited *trans* fats are also recommended as part of a healthy meal plan. Decreasing fat and cholesterol intake assists in reducing the risk for CVD.

Protein. The amount of daily protein in the diet for people with diabetes and normal renal function is the same as for the general population. The suggested protein intake is 15% to 20% of the total calories consumed. High-protein diets are not recommended as a weight loss method for people with diabetes.

Alcohol. Alcohol inhibits gluconeogenesis (breakdown of glycogen to glucose) by the liver. This can cause severe hypoglycemia in patients on insulin or oral hypoglycemic medications that increase insulin secretion. Encourage patients to honestly discuss their use of alcohol with their health care providers because its use can make blood glucose more difficult to control.

Moderate alcohol consumption can sometimes be safely incorporated into the meal plan if blood glucose levels are well controlled and if the patient is not on medications that will cause adverse effects. Moderate consumption is defined as one drink per day for women and two drinks per day for men. A

patient can reduce the risk for alcohol-induced hypoglycemia by eating carbohydrates when drinking alcohol. To decrease the carbohydrate content, recommend using sugar-free mixes and drinking dry, light wines.

Patient Teaching Related to Nutritional Therapy. Most often the dietitian initially teaches the principles of the nutritional therapy regimen. Whenever possible, work with dietitians as part of an interdisciplinary diabetes care team. Some patients who have limited insurance coverage or live in remote areas do not have access to a dietitian. In these cases, you may need to assume responsibility for teaching basic dietary management to patients with diabetes.

Carbohydrate counting is a meal planning technique used to keep track of the amount of carbohydrates eaten with each meal and per day. Often patients are advised to limit carbohydrates to a predetermined number. The amount of total carbohydrates per day depends on previous glycemic control, age, weight, activity level, patient preference, and prescribed medications. A serving size of carbohydrates is 15 g. Patients usually start with 45 to 60 g of carbohydrate per meal. For some patients, insulin regimens are tailored to the number of carbohydrates that a patient will consume at the meal, with a set number of units of insulin given per gram of carbohydrate (e.g., 1 U/15 g carbohydrate, 2 U/25 g carbohydrate). Teach the patient about the foods that contain carbohydrates, how to read food labels, and appropriate serving sizes.

Diabetes exchange lists are another method for meal planning. Instead of counting carbohydrates, the individual is given a meal plan with specific numbers of helpings from a list of exchanges for each meal and snack. The exchanges are starches, fruits, milk, meat, sweets, fats, and free foods. The patient chooses foods from the various exchanges based on the prescribed meal plan. This method may be easier for some patients than carbohydrate counting. Another advantage is that this approach helps the patient limit portion sizes and overall food intake, an important component of weight management.

MyPlate was developed by the U.S. Department of Agriculture (USDA) to represent national nutritional guidelines. This simple method helps the patient visualize the amount of vegetables, starch, and meat that should fill a 9-in plate. For a person with diabetes, each meal needs to have one half of the plate filled with nonstarchy vegetables, one fourth filled with a starch, and one fourth filled with a protein (see eFig. 49-1 available on the website). A glass of nonfat milk and a small piece of fresh fruit complete the meal.[16]

Whenever possible, include family members and caregivers in nutrition education and counseling, particularly the person who cooks for the household. However, the responsibility for maintaining a diabetic diet should not fall to someone other than the person with diabetes. Reliance on another person to make health decisions interferes with the patient's ability to develop self-care skills, which is essential in the management of diabetes. Foster independence, even in patients with visual or cognitive impairment. It is also important to discuss traditional foods with the patient. To improve adherence, the diet needs to be individualized to take into account the patient's preferences and foods that are culturally appropriate.

Exercise

Regular, consistent exercise is an essential part of diabetes and prediabetes management.[17] The ADA recommends that people with diabetes perform at least 150 min/wk (30 minutes, 5 days/wk) of a moderate-intensity aerobic physical activity (Table 49-9). The ADA also encourages people with type 2 diabetes to perform resistance training three times a week in the absence of contraindications.[18]

TABLE 49-9 ACTIVITIES THAT AFFECT CALORIC EXPENDITURE

Light Activity (100-200 kcal/hr)	Moderate Activity (200-350 kcal/hr)	Vigorous Activity (400-900 kcal/hr)
• Driving a car	• Active housework	• Aerobic exercise
• Fishing	• Bicycling (light)	• Bicycling (vigorous)
• Light housework	• Bowling	• Hard labor
• Secretarial work	• Dancing	• Ice skating
• Teaching	• Gardening	• Outdoor sports
• Walking casually	• Golf	• Running
	• Roller skating	• Soccer
	• Walking briskly	• Tennis
		• Wood chopping

Exercise decreases insulin resistance and can have a direct effect on lowering blood glucose levels. It also contributes to weight loss, which further decreases insulin resistance. The therapeutic benefits of regular physical activity may result in a decreased need for diabetes medications to reach target blood glucose goals. Regular exercise may also help reduce triglyceride and low-density lipoprotein (LDL) cholesterol levels, increase high-density lipoprotein (HDL), reduce BP, and improve circulation.[6]

Any new exercise program for diabetic patients should be started only after medical clearance. Patients should start slowly with gradual progression toward the desired goal. Patients who use insulin, sulfonylureas, or meglitinides are at increased risk for hypoglycemia when they increase physical activity, especially if they exercise at the time of peak drug action or eat too little to maintain adequate blood glucose levels. This can also occur if a normally sedentary patient with diabetes has an unusually active day.

The glucose-lowering effects of exercise can last up to 48 hours after the activity, so it is possible for hypoglycemia to occur long after the activity. It is recommended that patients who use medications that can cause hypoglycemia schedule exercise about 1 hour after a meal or that they have a 10- to 15-g carbohydrate snack and check their blood glucose before exercising. They can eat small carbohydrate snacks every 30 minutes during exercise to prevent hypoglycemia. Patients using medications that place them at risk for hypoglycemia should always carry a fast-acting source of carbohydrate, such as glucose tablets or hard candies, when exercising. Table 49-10 describes exercise guidelines for patients with diabetes.

Although exercise is generally beneficial to blood glucose levels, strenuous activity can be perceived by the body as a stress, causing a release of counterregulatory hormones and a temporary elevation of blood glucose. In a person with type 1 diabetes who is hyperglycemic and ketotic, exercise can worsen these conditions. Therefore vigorous activity should be avoided if the blood glucose level is over 250 mg/dL and ketones are present in the urine. If hyperglycemia is present without ketosis, it is not necessary to postpone exercise.[4]

Monitoring Blood Glucose

Self-monitoring of blood glucose (SMBG) is a critical part of diabetes management. By providing a current blood glucose

TABLE 49-10 PATIENT & CAREGIVER TEACHING GUIDE

Exercise for Patients With Diabetes Mellitus

Include the following information in the exercise teaching plan for the patient and caregiver.

1. Exercise does not have to be vigorous to be effective. The blood glucose–reducing effects of exercise can be attained with activity such as brisk walking.
2. The exercises selected should be enjoyable to foster regularity.
3. It is important to have properly fitting footwear.
4. The exercise session should have a warm-up period and a cool-down period. The exercise program should be started gradually and increased slowly.
5. Exercise is best done after meals, when the blood glucose level is rising.
6. Exercise plans should be individualized and monitored by the health care provider.
7. It is important to self-monitor blood glucose levels before, during, and after exercise to determine the effect exercise has on blood glucose level at particular times of the day.
   - *Before exercise, if blood glucose ≤100 mg/dL,* eat a 15-g carbohydrate snack. After 15 to 30 min, retest blood glucose levels. Do not exercise if <100 mg/dL.
   - *Before exercise, if blood glucose ≥250 mg/dL* in a person with type 1 diabetes and ketones are present, avoid vigorous activity.
8. Delayed exercise-induced hypoglycemia may occur several hours after the completion of exercise.
9. Taking a glucose-lowering medication does not mean that planned or spontaneous exercise cannot occur.
10. It is important to compensate for extensive planned and spontaneous activity by monitoring blood glucose levels to make adjustments in the insulin dose (if taken) and food intake.

FIG. 49-8 Blood glucose monitors are used to measure blood glucose levels. Medtronic OneTouch UltraLink glucose meter. (Courtesy of Medtronic Diabetes.)

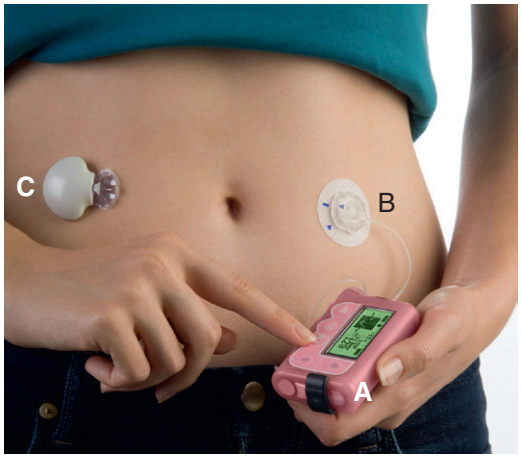

FIG. 49-9 The MiniMed Paradigm® REAL-Time Revel™ Insulin Pump *(A)* delivers insulin through a thin plastic tubing to an infusion set, which has a cannula *(B)* that sits under the skin. Continuous glucose monitoring occurs through a tiny sensor *(C)* inserted under the skin. Sensor data are sent continuously to the insulin pump through wireless technology giving a more complete picture of glucose levels, which can lead to better treatment decisions and better glucose control. (MiniMed Paradigm® REAL-Time Revel™ Insulin Pump manufactured by the diabetes division of Medtronic, Inc.)

reading, SMBG enables the patient to make decisions regarding food intake, activity patterns, and medication dosages. It also produces accurate records of daily glucose fluctuations and trends, and it alerts the patient to acute episodes of hyperglycemia and hypoglycemia. Furthermore, it provides patients with a tool for achieving and maintaining specific glycemic goals. SMBG is recommended for all insulin-treated patients with diabetes. Other patients with diabetes use SMBG to help achieve and maintain glycemic goals and monitor for acute fluctuations in blood glucose.

The frequency of monitoring depends on several factors, including the patient's glycemic goals, type of diabetes, medication regimen, patient's ability to perform the test independently, and patient's willingness to test. Patients who use multiple insulin injections or insulin pumps should monitor their blood glucose four or more times a day. Patients using less frequent insulin injections, noninsulin therapy, or nutritional therapy will monitor as often as needed to achieve their glycemic goals.[10]

Patients who perform SMBG use portable blood glucose monitors (glucometers). A wide variety of blood glucose monitors are available (Fig. 49-8). Disposable lancets are used to obtain a small drop of capillary blood (usually from a finger stick) that is placed onto a reagent strip. After a specified time, the monitor displays a digital reading of the capillary blood glucose value. The technology of SMBG is rapidly changing, with newer and more convenient systems being introduced on an ongoing basis.

Newer systems allow the user to collect blood from alternative sites such as the forearm or palm. Alternate site testing is not recommended with rapidly changing blood glucose readings, during pregnancy, or when symptoms of low blood glucose are present. The data from some glucose monitors can be uploaded to a computer and e-mailed to health care providers for review, allowing for more frequent and efficient adjustment of the plan of care if needed.

Continuous glucose monitoring (CGM) systems provide another route for monitoring glucose. The CGM systems available include the (1) Dexcom Seven by Dexcom, (2) MiniMed Paradigm® REAL-Time Revel™ by Medtronic (Fig. 49-9), (3) Guardian REAL-Time by Medtronic, and (4) FreeStyle Navigator by Abbott. Using a sensor inserted subcutaneously, the systems display glucose values that are updated every 1 to 5 minutes. The patient inserts the sensor using an automatic insertion device. Data are sent from the sensor to a transmitter, which displays the glucose value on either an insulin pump (MiniMed Paradigm® REAL-Time Revel™ and Guardian REAL-

Time) or a pager-like receiver (Dexcom Seven and FreeStyle Navigator). The glucose monitor can be used without an insulin pump.

CGMs assist the patient and the health care provider in identifying trends and patterns in glucose levels and are useful for the management of insulin therapy or when continuous blood glucose readings are clinically important. The patient is alerted to episodes of hypoglycemia and hyperglycemia, thus allowing corrective action to be quickly taken. These systems still require finger-stick measurements using a blood glucose monitor to calibrate the sensor and to make treatment decisions.

The blood glucose level reported by a laboratory is sometimes higher than the patient's home glucose monitor or the hospital's portable monitor. This is because some home monitors give capillary blood glucose values from whole blood (via finger stick), whereas tests performed in laboratories provide plasma readings. Plasma samples, or venous samples, are approximately 10% to 12% higher. Most current monitors are automatically calibrated to give a "plasma" test result (even though whole blood was used for the sample) so that the home readings can be more readily compared with laboratory values. It is important to read the literature accompanying a monitor to find out if it is displaying values as whole blood or plasma.

Because errors in monitoring technique can cause errors in management strategies, comprehensive patient teaching is essential. Initial instruction should be followed up with regular reassessment. Review the instructions that accompany each product. Teach patients to use and interpret control solutions. Control solution should be used when first using a glucometer, when a new bottle of strips is used, or when there is a reason to believe that the readings are not correct. Table 49-11 lists the steps to include when teaching the patient how to perform SMBG.

People with type 1 diabetes often test their blood glucose before meals. This is because many patients use insulin pumps or multiple daily injections and base the insulin dose on the carbohydrates in a meal or make adjustments if the preprandial value is above or below target. Testing 2 hours after the first bite of food is taken helps a person see how effectively he or she judged what was eaten or to determine if the bolus insulin dose was adequate for that meal.

Blood glucose testing should be performed whenever hypoglycemia is suspected so that immediate action can be taken. During times of illness, the person should test blood glucose levels at 4-hour intervals to determine the effects of the illness on glucose levels. Teach the patient to test blood glucose before and after exercise to determine the effects of exercise on metabolic control. This is especially important in the patient with type 1 diabetes.

A patient who is visually impaired, cognitively impaired, or limited in manual dexterity needs careful evaluation of the degree to which SMBG can be performed independently. Nurses preparing patients for discharge from the hospital, and nurses working in home health and outpatient settings, may need to identify caregivers who can assume this responsibility. Adaptive devices are available to help patients with certain limitations. These include talking meters and other equipment for the visually impaired.

TABLE 49-11 PATIENT & CAREGIVER TEACHING GUIDE

Self-Monitoring of Blood Glucose (SMBG)

Include the following instructions when teaching the patient and caregiver about SMBG.

1. Wash hands in warm water. It is not necessary to clean the site with alcohol, and it may interfere with test results. Finger should be dry before puncturing it.
2. If it is difficult to obtain an adequate drop of blood for testing, warm the hands in warm water or let the arms hang dependently for a few minutes before the finger puncture is made.
3. A penlet lancing device is usually used. Place the lancet in the device, following the instructions that come with it. If the puncture is made on the finger, use the side of the finger pad rather than near the center. Fewer nerve endings are along the side of the finger pad. If an alternative site is used (e.g., forearm), special equipment may be needed. Refer to manufacturer's instructions for alternative site use, except during hypoglycemic episodes.
4. Set penlet device to make a puncture just deep enough to obtain a sufficiently large drop of blood. Unnecessarily deep punctures may cause pain and bruising.
5. Follow instructions on monitor for testing the blood.
6. Record results. Compare with personal target blood glucose goals.

Bariatric Surgery

Bariatric surgery may be considered for patients with type 2 diabetes who have a body mass index (BMI) greater than 35 kg/m^2, especially if the diabetes or associated co-morbidities are difficult to control with lifestyle and drug therapy (see Evidence-Based Practice box on p. 1170). Patients with type 2 diabetes who have undergone bariatric surgery need lifelong lifestyle support and monitoring. (Bariatric surgery is discussed in Chapter 41.)

Pancreas Transplantation

Pancreas transplantation can be used as a treatment option for patients with type 1 diabetes. Usually it is done for patients who have end-stage kidney disease and have had or plan to have a kidney transplant. Kidney and pancreas transplants are often performed together, or a pancreas may be transplanted after a kidney transplant. If renal failure is not present, the ADA recommends that pancreas transplantation be considered only for patients who exhibit the following three criteria: (1) a history of frequent, acute, and severe metabolic complications (e.g., hypoglycemia, hyperglycemia, ketoacidosis) requiring medical attention; (2) clinical and emotional problems with the use of exogenous insulin therapy that are so severe as to be incapacitating; and (3) consistent failure of insulin-based management to prevent acute complications.

Successful pancreas transplantation can improve the quality of life for people with diabetes, primarily by eliminating the need for exogenous insulin, frequent blood glucose measurements, and many of the dietary restrictions imposed by the disorder. Transplantation can also eliminate the acute complications commonly experienced by patients with type 1 diabetes (e.g., hypoglycemia, hyperglycemia). However, pancreas transplantation is only partially successful in reversing the long-term renal and neurologic complications of diabetes. The patient will also require lifelong immunosuppression to prevent rejection of the organ. Complications can result from immunosuppressive therapy. (Immunosuppressive therapy is discussed in Chapter 14.)

Pancreatic islet cell transplantation is another potential treatment measure. During this procedure, the islets are harvested

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Bariatric Surgery for Obese Adults With Type 2 Diabetes

Clinical Question

In severely obese adults (P), how do gastric bypass and biliopancreatic diversion (I) compare with medical therapy (C) for remission from type 2 diabetes mellitus (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Sixty adults with type 2 diabetes for ≥5 yr with a BMI ≥35 kg/m^2 and Hb A1C ≥7.0%.
- Roux-en-Y gastric bypass (n = 20), biliopancreatic diversion (n = 20), or medical therapy (n = 20).
- At 2 yr, more patients in the gastric bypass and biliopancreatic diversion groups achieved diabetes remission than in the medical therapy group.
- Bypass and biliopancreatic diversion each reduced A1C, glucose levels, and BMI more than medical therapy.

Conclusion

- Bariatric surgery (gastric bypass and biliopancreatic diversion) decreases BMI, improves glycemic control, and increases remission from type 2 diabetes more than medical therapy in severely obese adults.

Implications for Nursing Practice

- In addition to behavioral and medical approaches, bariatric surgery often normalizes blood glucose levels, reduces or avoids the need for drugs, and provides a potentially cost-effective approach to treating the disease.
- Bariatric surgery is an appropriate treatment for people with type 2 diabetes and obesity not achieving recommended treatment targets with medical therapies, especially when there are other major co-morbidities.

Reference for Evidence

Mingrone G, Panunzi S, De Gaetano A, et al: Bariatric surgery versus conventional medical therapy for type 2 diabetes, *N Engl J Med* 366: 1577, 2012.

P, Patient population of interest; *I*, intervention or area of interest; *C*, comparison of interest or comparison group; *O*, outcomes of interest (see p. 12).

from the pancreas of a deceased organ donor. Most recipients require the use of two or more pancreases. The islets are infused via a catheter through the upper abdomen into the portal vein of the liver. With only the islets transplanted, pain and recovery time are diminished compared with whole pancreas transplants. Currently this procedure is experimental in the United States. Research is continuing to investigate the best ways to implant the islet cells and to prevent their rejection.

CULTURALLY COMPETENT CARE

DIABETES MELLITUS

Because culture can have a strong influence on dietary preferences and meal preparation practices, culturally competent care has special relevance for the patient with diabetes. For example, certain ethnic and cultural groups, such as Hispanics, Native Americans, and African Americans, have a high incidence of diabetes. The increased prevalence can be attributed to genetic predisposition, environmental factors, and dietary choices.

CULTURAL & ETHNIC HEALTH DISPARITIES

Diabetes Mellitus

- The highest incidence of diabetes is among Native Americans and Alaska Natives (16.5% are being treated for diabetes).
- Pima Indians in Arizona have the highest rate of diabetes in the world (50% of adults have diabetes).
- The rates of diabetes are non-Hispanic whites 7.1%, Asian Americans 8.4%, Hispanics 11.8%, and non-Hispanic blacks 12.6%.
- Diabetes is 1.5 times more likely to cause death in Hispanics and 2.2 times more likely to cause death in African Americans than in non-Hispanic whites.
- Complications from diabetes are a major cause of death among Native Americans. Native Americans have a six times higher rate of end-stage kidney disease and a four times higher rate of amputation than other people with diabetes.
- Treatment for end-stage kidney disease for men with diabetes is 1.6 times higher in Hispanics and 2.7 times higher in African Americans compared with non-Hispanic white men.

Explore the influences of culture on food choices and meal planning with the patient as part of the health history. When giving diet instructions, consider the patient's cultural food preferences. Nutritional resources specifically designed for members of different cultural groups are available from the ADA.

NURSING MANAGEMENT DIABETES MELLITUS

NURSING ASSESSMENT

Table 49-12 provides initial subjective and objective data that should be obtained from a person with diabetes mellitus. After the initial assessment, perform periodic patient assessments on a regular basis.

NURSING DIAGNOSES

Nursing diagnoses related to diabetes mellitus may include, but are not limited to, those found in eNursing Care Plan 49-1.

PLANNING

The overall goals are for the patient with diabetes mellitus to (1) engage in self-care behaviors to actively manage his or her diabetes, (2) experience few or no episodes of acute hyperglycemic or hypoglycemic emergencies, (3) maintain blood glucose levels at normal or near-normal levels, (4) prevent or minimize chronic complications of diabetes, and (5) adjust lifestyle to accommodate the diabetes regimen with a minimum of stress.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Your role in health promotion is to identify, monitor, and teach the patient at risk for diabetes. Obesity is the primary risk factor for type 2 diabetes. The findings from the Diabetes Prevention Program indicated that a modest weight loss of 5% to 7% of body weight and regular exercise of 30 minutes five times a week lowered the risk of developing type 2 diabetes up to 58%.[18]

The ADA recommends routine screening for type 2 diabetes for all adults who are overweight or obese (BMI greater than or equal to 25 kg/m^2) or have one or more risk factors. For people who do not have risk factors for diabetes, screening should begin at age 45. Table 49-13 provides criteria to test for prediabetes and diabetes. If results are normal, repeat testing at 3-year

TABLE 49-12 NURSING ASSESSMENT

Diabetes Mellitus

Subjective Data

Important Health Information

Past health history: Mumps, rubella, coxsackievirus or other viral infections; recent trauma, infection, or stress; pregnancy, gave birth to infant >9 lb; chronic pancreatitis; Cushing syndrome; acromegaly; family history of type 1 or type 2 diabetes mellitus

Medications: Use of and adherence to regimen with insulin or OAs; corticosteroids, diuretics, phenytoin (Dilantin)

Surgery or other treatments: Any recent surgery

Functional Health Patterns

Health perception–health management: Positive family history; malaise; date of last eye and dental examination

Nutritional-metabolic: Obesity; weight loss (type 1), weight gain (type 2); thirst, hunger; nausea and vomiting; poor healing (especially involving the feet), adherence to diet in patients with previously diagnosed diabetes

Elimination: Constipation or diarrhea; frequent urination, frequent bladder infections, nocturia, urinary incontinence

Activity-exercise: Muscle weakness, fatigue

Cognitive-perceptual: Abdominal pain; headache; blurred vision; numbness or tingling of extremities; pruritus

Sexuality-reproductive: Erectile dysfunction; frequent vaginal infections; decreased libido

Coping–stress tolerance: Depression, irritability, apathy

Value-belief: Commitment to lifestyle changes involving diet, medication, and activity patterns

Objective Data

Eyes

Soft, sunken eyeballs;* vitreal hemorrhages; cataracts

Integumentary

Dry, warm, inelastic skin; pigmented lesions (on legs); ulcers (especially on feet); loss of hair on toes; acanthosis nigricans

Respiratory

Rapid, deep respirations (Kussmaul respirations)*

Cardiovascular

Hypotension;* weak, rapid pulse*

Gastrointestinal

Dry mouth; vomiting;* fruity breath*

Neurologic

Altered reflexes; restlessness; confusion; stupor; coma

Musculoskeletal

Muscle wasting

Possible Findings

Serum electrolyte abnormalities; fasting blood glucose level ≥126 mg/dL; oral glucose tolerance test >200 mg/dL; random glucose ≥200 mg/dL; leukocytosis; ↑ blood urea nitrogen, creatinine, triglycerides, cholesterol, LDL, VLDL; ↓ HDL; A1C >6.0%; glycosuria; ketonuria; albuminuria; acidosis

*Indicates manifestations of diabetic ketoacidosis.
A1C, Glycosylated hemoglobin; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein; *OAs,* oral agents; *VLDL,* very-low-density lipoprotein.

TABLE 49-13 TESTING FOR DIABETES IN ASYMPTOMATIC, UNDIAGNOSED INDIVIDUALS

Who Should Be Tested

1. Testing should be considered in all adults who are overweight (BMI >25 kg/m^2) and have additional risk factors:
   - First-degree relative with diabetes
   - Physically inactive
   - Members of a high-risk ethnic population (e.g., African American, Hispanic, Native American, Asian American, Pacific Islander)
   - Women who delivered a baby weighing >9 lb or were diagnosed with gestational diabetes mellitus
   - Hypertensive (≥140/90 mm Hg) or on therapy for hypertension
   - HDL cholesterol level ≤35 mg/dL (0.90 mmol/L) and/or a triglyceride level ≥250 mg/dL (2.82 mmol/L)
   - Women with polycystic ovary syndrome
   - A1C ≥5.7%, IGT, or IFG on previous testing
   - Other clinical conditions associated with insulin resistance (e.g., severe obesity, acanthosis nigricans)
2. In the absence of the above criteria, testing for diabetes should begin at age 45 yr.
3. If results are normal, testing should be repeated at least at 3-yr intervals, with consideration of more frequent testing depending on initial results and risk status.

What Testing Should Be Used

To test for diabetes or to assess risk of future diabetes, A1C, FPG, or 2-hour OGTT is appropriate.

Source: American Diabetes Association: Clinical practice recommendations: standards of medical care, *Diabetes Care* 36 (Suppl):S11, 2013.
A1C, Glycosylated hemoglobin; *BMI,* body mass index; *FPG,* fasting plasma glucose; *HDL,* high-density lipoprotein; *IFG,* impaired fasting glucose; *IGT,* impaired glucose tolerance; *OGTT,* oral glucose tolerance test.

HEALTHY PEOPLE

Prevention and Early Detection of Diabetes Mellitus

- Increase level of exercise because physical activity reduces the risk of type 2 diabetes.
- Maintain a healthy weight because obesity increases the risk of type 2 diabetes.
- If overweight, lose weight and get on a regular exercise program to reduce the risk of diabetes.
- Use a diet that is low in fat content, total calories, and processed foods and high in whole grains, fruits, and vegetables.
- If overweight and over age 45, get a diabetes screening test done.

intervals.[3] Many factors put an individual at an increased risk for diabetes. These include age, ethnicity (being Native American, Hispanic, African American, Asian, Pacific Islander), obesity, having a baby that weighs more than 9 lb, having gestational diabetes, and a family history of diabetes. A diabetes risk test is available at *www.diabetes.org/risk-test.jsp*. The diabetes risk test determines if the person is at risk for prediabetes or diabetes based on the number of risk factors present.

ACUTE INTERVENTION. Acute situations involving the patient with diabetes include hypoglycemia, DKA, and hyperosmolar hyperglycemic syndrome (HHS). Nursing management for these situations is discussed in more detail later in this chapter. Other areas of acute intervention relate to management during stress, such as during acute illness and surgery.

Stress of Acute Illness and Surgery. Both emotional and physical stress can increase the blood glucose level and result in hyperglycemia. Because stress is unavoidable, certain situations may require more intense treatment, such as extra insulin, to maintain glycemic goals and avoid hyperglycemia.

Acute illness, injury, and surgery are situations that may evoke a counterregulatory hormone response, resulting in hyperglycemia. Even common illnesses such as a viral upper

respiratory tract infection or the flu can cause this response. When patients with diabetes are ill, they should check blood glucose at least every 4 hours. An acutely ill patient with type 1 diabetes with a blood glucose greater than 240 mg/dL (13.3 mmol/L) should test his or her urine for ketones every 3 to 4 hours.

Patients should report to the health care provider when glucose levels are over 300 mg/dL for two tests in a row or urine ketone levels are moderate to large. A patient with type 1 diabetes may need an increase in insulin to prevent DKA. Insulin therapy may be required for a patient with type 2 diabetes to prevent or treat hyperglycemic symptoms and avoid an acute hyperglycemic emergency. In critically ill patients, insulin therapy may be started if the blood glucose is persistently greater than 180 mg/dL. These patients have a higher targeted blood glucose goal, which is usually 140 to 180 mg/dL.

Food intake is important during times of stress and illness, when the body requires extra energy. If patients are able to eat normally, they should continue with their regular meal plan while increasing the intake of noncaloric fluids, such as water, diet gelatin, and other decaffeinated beverages, and continue taking OAs, noninsulin injectable agents, and insulin as prescribed. When illness causes patients to eat less than normal, they should continue to take OAs, noninsulin injectable agents, and/or insulin as prescribed while supplementing food intake with carbohydrate-containing fluids. Examples include low-sodium soups, juices, and regular decaffeinated soft drinks. It is important to tell the patient to contact a health care provider if the patient is unable to keep down food or fluid.

During the intraoperative period, adjustments in the diabetes regimen can be planned to ensure glycemic control. The patient is given IV fluids and insulin (if needed) immediately before, during, and after surgery when there is no oral intake. The patient with type 2 diabetes who has been on OAs should understand that this is a temporary measure, not a sign of worsening diabetes.

When caring for an unconscious surgical patient receiving insulin, be alert for hypoglycemic signs such as sweating, tachycardia, and tremors. Frequent monitoring of blood glucose will prevent episodes of severe hypoglycemia.

AMBULATORY AND HOME CARE. Successful management of diabetes requires ongoing interaction among the patient, caregiver, and health care team. It is important that a certified diabetes educator (CDE) be involved in the care of the patient and the family. Because diabetes is a complex chronic condition, a great deal of patient contact takes place in outpatient and home settings. The major goal of patient care in these settings is to enable the patient (with the help of a caregiver) to reach an optimal level of independence in self-care activities. Unfortunately, many patients with diabetes face challenges in reaching these goals. Diabetes increases the risk for other chronic conditions that can affect self-care activities. These include visual impairment, lower extremity problems that affect mobility, and other functional limitations related to a stroke.

An important nursing function is to assess the ability of patients and caregivers in performing activities such as SMBG and insulin injection. Assistive devices for self-administration of insulin include syringe magnifiers, vial stabilizers, and dosing aids for the visually impaired. In some cases, referrals are made to help the patient achieve the self-care goal. These may include an occupational therapist, a social worker, a home care nurse, a home health aide, or a dietitian.

A diagnosis of diabetes affects the patient in many profound ways. Self-management of the disease is demanding. Patients with diabetes continually face lifestyle choices that affect the foods they eat, their activities, and demands on their time and energy. The requirements of scheduled meals, SMBG, medication, and insulin management may interfere with the patient's other responsibilities. Any change in the daily routine is difficult. In addition, they face the challenge of preventing or dealing with the devastating complications of diabetes.

Careful assessment of what it means to the patient to have diabetes should be the starting point of teaching. The goals of teaching should be mutually determined by you and the patient, based on individual needs and therapeutic requirements. Identify the patient's support system, and include them in planning, teaching, and counseling. When family members and other individuals close to the patient are included, they can support the patient's self-care behaviors. Additionally, they can provide care if self-care is not possible. Encourage the family and caregivers to provide emotional support and encouragement as the patient deals with the reality of living with a chronic disease.

Insulin Therapy. Nursing responsibilities for the patient receiving insulin include proper administration, assessment of the patient's response to insulin therapy, and teaching the patient about administration and side effects of insulin (see Table 49-5). Table 49-6 lists guidelines for assessing a patient using glucose-lowering agents, including insulin and OAs.

Assessment of the patient who is a new user of insulin must include an evaluation of his or her ability to safely manage this therapy. This includes the ability to understand the interaction of insulin, diet, and activity and to recognize and treat the symptoms of hypoglycemia appropriately. If the patient does not have the cognitive skills to do these things, identify and teach another responsible person. The patient or caregiver must have the cognitive and manual skills needed to prepare and inject insulin. Otherwise, additional resources will be needed to assist the patient. For patients with cognitive, physical, and other barriers, consider referral to a CDE because he or she has the specialized knowledge and skills to promote self-care behaviors for these patients.

Many patients are fearful when they first begin using insulin.[19] Some find it difficult to self-inject because they are afraid of needles or the pain associated with an injection. Others may think that the insulin is not necessary or that they will experience hypoglycemia after an injection. Explore the patient's underlying fears before beginning the teaching. Assessment of the patient's beliefs and concerns regarding starting insulin will guide the teaching, counseling, and plan of care. Having open discussion with patients, providing educational materials and programs, and working with a diabetes educator are all beneficial for patients starting insulin.

Follow-up assessment of the patient who has been using insulin therapy includes an inspection of injection sites for signs of lipodystrophy and other reactions, review of insulin preparation and injection technique, a history pertaining to the occurrence of hypoglycemic episodes, and assessment of the patient's method for handling hypoglycemic episodes. A review of the patient's recorded blood glucose tests is vital in assessing overall glycemic control and making any needed adjustments.

Oral and Noninsulin Injectable Agents. Your responsibilities for the patient taking oral and noninsulin injectable agents are similar to those for the patient taking insulin. Proper adminis-

tration of these drugs, assessment of the patient's use of and response to these drugs, and teaching the patient and family are all essential nursing actions.

Your assessment is valuable in determining the most appropriate drug for a patient. Factors such as the patient's mental status, eating habits, home environment, attitude toward diabetes, and medication history all play a significant role in determining the most appropriate drug. For example, frail older adults who live alone are at high risk for severe hypoglycemia because low blood glucose is frequently undetected or untreated in this population. This is especially true if the patient has cognitive impairment. In these cases, an OA that does not cause hypoglycemia, or a shorter-acting OA, would be most appropriate.

Patient teaching is essential. Some patients may assume that their diabetes is not a serious condition if they are only taking a pill for glycemic control. Instruct the patient that these agents will help control blood glucose and help prevent serious long- and short-term complications of diabetes. Teach patients that OAs and noninsulin injectable agents are used in addition to diet and activity as therapy for diabetes and the importance of following their meal and activity plans. Patients should not take extra pills if they have overeaten. If the patient uses sulfonylureas and metformin, instruct the patient about prevention, symptom recognition, and management of hypoglycemia.

Personal Hygiene. The potential for infection requires diligent skin and dental hygiene practices. Because of the susceptibility to periodontal disease, encourage daily brushing and flossing in addition to regular visits to the dentist. When having dental work done, the patient should inform the dentist that he or she has diabetes. Teach patients regarding the importance of sharing their diagnosis with dentists and other health care professionals.

Routine care includes regular bathing, with particular emphasis on foot care. Advise patients to inspect their feet daily, avoid going barefoot, and wear shoes that are supportive and comfortable. If cuts, scrapes, or burns occur, they should be treated promptly and monitored carefully. Wash the area and apply a nonabrasive or nonirritating antiseptic ointment. Cover the area with a dry, sterile pad. Patients should notify the health care provider immediately if the injury does not begin to heal within 24 hours or if signs of infection develop.

Medical Identification and Travel. Instruct the patient to carry medical identification at all times indicating that he or she has diabetes. Police, paramedics, and many private citizens are aware of the need to look for this identification when working with sick or unconscious persons. Every person with diabetes should wear a Medic Alert bracelet or necklace. An identification card (Fig. 49-10) can supply valuable information, such as the name of the health care provider; the type of diabetes; and the type and dosage of insulin, noninsulin injectable agents, or OAs.

Travel for a patient with diabetes requires planning. Being sedentary for long periods may raise the person's glucose level. Encourage the patient to get up and walk at least every 2 hours to lower the risk for deep vein thrombosis and to prevent elevation of glucose levels. The patient should have a full set of diabetes care supplies in the carry-on luggage when traveling by plane, train, or bus. This includes blood glucose monitoring equipment, insulin, noninsulin injectable agents, oral medications, and syringes or insulin pens.

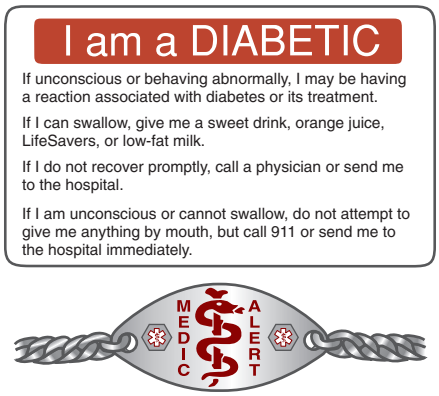

FIG. 49-10 Medical alerts. A patient with diabetes should carry a card and wear a bracelet or necklace that indicates diabetes. If the patient with diabetes is unconscious, these measures will ensure prompt and appropriate attention.

When equipment such as syringes, lancing devices, insulin vials or pens, and insulin pumps are taken onto a commercial airliner, the professional printed pharmaceutical labels should accompany them. A letter from the prescribing health care provider indicating medical necessity may prevent delays at security checkpoints. Notify screeners if an insulin pump is used so they can inspect it while it is on the body, rather than removing it.

For patients who use insulin or OAs that can cause hypoglycemia, snack items and a quick-acting carbohydrate source for treating hypoglycemia should be included in the carry-on luggage. Extra insulin should be available in case a bottle breaks or is lost. For longer trips, the patient should carry a full day's supply of food in the event of canceled flights, delayed meals, or closed restaurants. If the patient is planning a trip out of the country, it is wise to have a letter from the health care provider explaining that the patient has diabetes and requires all the materials, particularly syringes, for ongoing health care.

When travel involves time changes such as traveling coast to coast or across the International Date Line, the patient should contact the health care provider to plan an appropriate insulin schedule. During travel, most patients find it helpful to keep watches set to the time of the city of origin until they reach their destination. The key to travel when taking insulin is to know the type of insulin being taken, its onset of action, the anticipated peak time, and mealtimes.

Patient and Caregiver Teaching. The goals of diabetes self-management education are to match the level of self-management to the patient's individual ability so he or she can become the most active participant possible. Patients who actively manage their diabetes care have better outcomes than those who do not. For this reason, an educational approach that facilitates informed decision making by the patient is advocated. Sometimes this is referred to as the *empowerment approach* to education.

Unfortunately, patients can encounter a variety of physical, psychologic, and emotional barriers when it comes to effectively managing their diabetes. These barriers may include feelings of inadequacy about one's own abilities, unwillingness to make the necessary behavioral changes, ineffective coping strategies, and cognitive deficits. If the patient is not able to manage the disease, a family member may be able to assume part of this role. If the patient or the caregiver cannot make decisions related to diabe-

COMPLEMENTARY & ALTERNATIVE THERAPIES

Herbs and Supplements That May Affect Blood Glucose

Scientific Evidence*

- Herbs and supplements that may lower blood glucose include aloe, α-lipoic acid, cinnamon, chromium, garlic, and ginseng.
- However, many studies have been small and not well designed. Further research is needed.

Nursing Implications

- Teach patients to use herbs and supplements with caution, since they may affect blood glucose.
- Patients with diabetes mellitus should consult their health care provider before using herbs or nutritional supplements.
- Patients who use herbs should monitor their blood glucose levels carefully and regularly.

*Based on a systematic review of scientific literature. Retrieved from *www.naturalstandard.com.*

INFORMATICS IN PRACTICE

Patient Teaching Using Gaming

- Teaching is a critical part of nursing care for patients with diabetes. Put some fun into patient teaching by using gaming applications.
- Try an application with a quiz-show format. The patient answers questions about diabetes and then compares his or her answers in real time to those of other players. The questions (e.g., How does exercise affect insulin?) are written to help the patient learn to manage diabetes on a daily basis.
- Players in online simulations become either a caregiver to or a patient with type 1 diabetes. Players earn rewards by properly managing blood glucose levels.

tes management, consider a referral to a CDE, social worker, or other resources within the community. These resources can assist the patient and the family in outlining a feasible treatment program that meets their capabilities. Patient and health care provider resources are listed at the end of this chapter.

An assessment of the patient's knowledge of diabetes and lifestyle preferences is useful in planning a teaching program. Tables 49-14 and 49-15 present guidelines to use for patient and caregiver teaching. Assess the patient's knowledge base frequently so that gaps in knowledge or incorrect or inaccurate ideas can be corrected.

The ADA offers resources for patients in the form of pamphlets, booklets, books, and a monthly magazine called *Diabetes Forecast.* Affiliates of the ADA are located in all states, and most can be reached by dialing 1-800-DIABETES (800-342-2383). The ADA publishes materials and sponsors conferences for health care professionals concerned with diabetes education, research, and management of patients. The ADA website (*www.diabetes.org*) has extensive information for the public and health care professionals. This organization also recognizes education programs that meet the national standards of diabetes education and can provide a list of these programs. Drug companies manufacturing diabetes-related products also have free educational materials for patients and health care providers.

EVALUATION

The expected outcomes for the patient with diabetes mellitus are addressed in eNursing Care Plan 49-1.

TABLE 49-14 PATIENT & CAREGIVER TEACHING GUIDE

Management of Diabetes Mellitus

Include the following instructions when teaching the patient and caregiver how to manage diabetes mellitus.

Component	What to Teach
Disease Process	• Include an introduction about the pancreas and the islets of Langerhans. • Describe how insulin is made and what affects its production. • Discuss the relationship of insulin and glucose. • Explain the difference between type 1 and type 2 diabetes.
Physical Activity	• Discuss the effect of regular exercise on the management of blood glucose, improvement of cardiovascular function, and general health.
Menu Planning	• Stress the importance of a well-balanced diet as part of a diabetes management plan. • Explain the impact of carbohydrates on the glycemic index and blood glucose levels.
Medication Adherence	• Ensure that the patient understands the proper use of prescribed medication (e.g., insulin [see Table 49-5], OAs, and noninsulin injectables). • Account for a patient's physical limitations or inabilities for self-medication. If necessary, involve the family or the caregiver in proper use of medication. • Discuss all side effects and safety issues regarding medication.
Monitoring Blood glucose	• Teach correct blood glucose monitoring. • Include when blood glucose levels should be checked, how to record them, and how to adjust insulin levels if necessary.
Risk Reduction	• Ensure that the patient understands and appropriately responds to the signs and symptoms of hypoglycemia and hyperglycemia (see Table 49-16). • Stress the importance of proper foot care (see Table 49-21), regular eye examinations, and consistent glucose monitoring. • Inform the patient about the effect that stress can have on blood glucose.
Psychosocial	• Advise the patient of resources that are available to facilitate the adjustment and answer questions about living with a chronic condition such as diabetes (see Resources at end of chapter).

OAs, Oral agents.

ACUTE COMPLICATIONS OF DIABETES MELLITUS

The acute complications of diabetes mellitus arise from events associated with hyperglycemia and hypoglycemia. It is important for the health care provider to distinguish between hyperglycemia and hypoglycemia because hypoglycemia worsens rapidly and constitutes a serious threat if action is not immediately taken. Table 49-16 compares the manifestations, causes, management, and prevention of hyperglycemia and hypoglycemia.

TABLE 49-15 PATIENT & CAREGIVER TEACHING GUIDE

Instructions for Patients With Diabetes Mellitus

Include the following essential instructions for diabetes management.

Do	Do Not
Blood Glucose	
• Monitor your blood glucose at home and record results in a log. • Take your insulin. OA, and/or noninsulin injectable agent as prescribed. • Obtain A1C blood test every 3-6 mo as an indicator of your long-term blood glucose control. • Know the symptoms of hypoglycemia and hyperglycemia. • Carry some form of rapid-acting glucose at all times so you can treat hypoglycemia quickly. • Instruct family members how and when to use glucagon if patient becomes unresponsive because of hypoglycemia.	• Skip doses of your insulin, especially when you are sick. • Run out of insulin. • Ignore the symptoms of hypoglycemia and hyperglycemia.
Exercise	
• Learn how exercise and food affect your blood glucose levels. • Begin an exercise program after approval from health care provider.	• Forget that exercise will lower your blood glucose level.
Diet	
• Have an individualized meal plan created by a dietitian. • Follow your diet, eating regular meals at regular times. • Choose foods low in saturated and *trans* fat. • Limit the amount of alcohol you drink. • Know your cholesterol level.	• Drink excessive amounts of alcohol because this may lead to unpredictable low blood glucose reactions. • Use a fad diet. • Drink regular soda or lots of fruit juice.
Other Guidelines	
• Obtain an annual eye examination by an ophthalmologist. • Obtain annual urine testing for protein. • Examine your feet at home. • Wear comfortable, well-fitting shoes to help prevent foot injury. Break in new shoes gradually. • Always carry identification that says you have diabetes. • Have other medical problems treated, especially high blood pressure and high cholesterol. • Quit cigarette smoking. • Have a yearly influenza vaccination.	• Smoke cigarettes or use nicotine products. • Apply hot or cold directly to your feet. • Go barefoot. • Put oil or lotion between your toes.

A1C, Glycosylated hemoglobin; *OA,* oral agent.

TABLE 49-16 COMPARISON OF HYPERGLYCEMIA AND HYPOGLYCEMIA

Hyperglycemia	Hypoglycemia
Manifestations*	
Elevated blood glucose†	Blood glucose <70 mg/dL (3.9 mmol/L)
Increase in urination	Cold, clammy skin
Increase in appetite followed by lack of appetite	Numbness of fingers, toes, mouth
	Rapid heartbeat
	Emotional changes
Weakness, fatigue	Headache
Blurred vision	Nervousness, tremors
Headache	Faintness, dizziness
Glycosuria	Unsteady gait, slurred speech
Nausea and vomiting	Hunger
Abdominal cramps	Changes in vision
Progression to DKA or HHS	Seizures, coma
Causes	
Illness, infection	Alcohol intake without food
Corticosteroids	Too little food—delayed, omitted, inadequate intake
Too much food	
Too little or no diabetes medication	Too much diabetic medication
	Too much exercise without adequate food intake
Inactivity	
Emotional, physical stress	Diabetes medication or food taken at wrong time
Poor absorption of insulin	
	Loss of weight without change in medication
	Use of β-adrenergic blockers interfering with recognition of symptoms
Treatment	
Get medical care	Follow the Rule of 15 (see p. 1179).
Continue diabetes medication as ordered	See Table 49-19 for treatment of hypoglycemia.
Check blood glucose frequently and check urine for ketones record results	
Drink fluids at least on an hourly basis	
Contact health care provider regarding ketonuria	
Preventive Measures	
Take prescribed dose of medication at proper time	Take prescribed dose of medication at proper time.
Accurately administer insulin, noninsulin injectables, OA	Accurately administer insulin, noninsulin injectables, OA.
	Ingest all recommended foods at proper time.
Maintain diet	Provide adequate food intake needed for calories for exercise.
Adhere to sick-day rules when ill	Be able to recognize and know symptoms and treat them immediately.
Check blood for glucose as ordered	Carry simple carbohydrates.
	Educate family and caregiver about symptoms and treatment.
	Check blood glucose as ordered.
Wear diabetic identification	Wear Medic Alert (diabetic) identification.

*There is usually a gradual onset of symptoms in hyperglycemia and a rapid onset in hypoglycemia.
†Specific clinical manifestations related to elevated levels of blood glucose vary according to the patient.
DKA, Diabetic ketoacidosis; *HHS,* hyperosmolar hyperglycemic syndrome; *OA,* oral agent.

DIABETIC KETOACIDOSIS

Etiology and Pathophysiology

Diabetic ketoacidosis (DKA) is caused by a profound deficiency of insulin and is characterized by hyperglycemia, ketosis, acidosis, and dehydration. It is most likely to occur in people with type 1 diabetes but may be seen in people with type 2 diabetes in conditions of severe illness or stress when the pancreas cannot meet the extra demand for insulin. Precipitating factors include illness and infection, inadequate insulin dosage, undiagnosed type 1 diabetes, poor self-management, and neglect.

When the circulating supply of insulin is insufficient, glucose cannot be properly used for energy. The body compensates by breaking down fat stores as a secondary source of fuel (Fig. 49-11). Ketones are acidic by-products of fat metabolism that can cause serious problems when they become excessive in the blood. Ketosis alters the pH balance, causing metabolic acidosis to develop. Ketonuria is a process that occurs when ketone bodies are excreted in the urine. During this process, electrolytes become depleted as cations are eliminated along with the anionic ketones in an attempt to maintain electrical neutrality.

Insulin deficiency impairs protein synthesis and causes excessive protein degradation. This results in nitrogen losses from the tissues. Insulin deficiency also stimulates the production of glucose from amino acids (from proteins) in the liver and leads to further hyperglycemia. Because of the deficiency of insulin, the additional glucose cannot be used and the blood glucose level rises further, adding to the osmotic diuresis.

If not treated, the patient will develop severe depletion of sodium, potassium, chloride, magnesium, and phosphate. Vomiting caused by the acidosis results in more fluid and electrolyte losses. Eventually, hypovolemia followed by shock will ensue. Renal failure, which may eventually occur from hypovolemic shock, causes the retention of ketones and glucose, and the acidosis progresses. Untreated, the patient becomes comatose as a result of dehydration, electrolyte imbalance, and acidosis. If the condition is not treated, death is inevitable.

Clinical Manifestations

Dehydration occurs in DKA with manifestations of poor skin turgor, dry mucous membranes, tachycardia, and orthostatic hypotension. Early symptoms may include lethargy and weakness. As the patient becomes severely dehydrated, the skin becomes dry and loose, and the eyes become soft and sunken. Abdominal pain may be present and accompanied by anorexia, nausea, and vomiting. *Kussmaul respirations* (rapid, deep breathing associated with dyspnea) are the body's attempt to reverse metabolic acidosis through the exhalation of excess carbon dioxide. Acetone is noted on the breath as a sweet, fruity odor. (See Chapter 17 for a discussion of respiratory compensation of metabolic acidosis.) Laboratory findings include a blood glucose level greater than or equal to 250 mg/dL (13.9 mmol/L), arterial blood pH less than 7.30, serum bicarbonate level less than 16 mEq/L (16 mmol/L), and moderate to large ketones in the urine or serum.[10]

Collaborative Care

Before the advent of SMBG, patients with DKA required hospitalization for treatment. Today, hospitalization may not be required. If fluid and electrolyte imbalances are not severe and blood glucose levels can be safely monitored at home, DKA may be managed on an outpatient basis (Table 49-17). Other factors to consider when deciding where the patient is managed include the presence of fever, nausea, vomiting, and diarrhea; altered mental status; the cause of the ketoacidosis; and availability of frequent communication with the health care provider (every few hours). Patients with DKA who have an illness such as pneumonia or a urinary tract infection are usually admitted to the hospital.

TABLE 49-17 COLLABORATIVE CARE

Diabetic Ketoacidosis (DKA) and Hyperosmolar Hyperglycemic Syndrome (HHS)

Diagnostic
- History and physical examination
- Blood studies, including immediate blood glucose, complete blood count, pH, ketones, electrolytes, blood urea nitrogen, arterial or venous blood gases
- Urinalysis, including specific gravity, glucose, acetone

Collaborative Therapy
- Administration of IV fluids
- IV administration of short-acting insulin
- Electrolyte replacement
- Assessment of mental status
- Recording of intake and output
- Central venous pressure monitoring (if indicated)
- Assessment of blood glucose levels
- Assessment of blood and urine for ketones
- ECG monitoring
- Assessment of cardiovascular and respiratory status

DKA is a serious condition that proceeds rapidly and must be treated promptly. Refer to Table 49-18 for the emergency management of a patient with DKA. Because fluid imbalance is potentially life threatening, the initial goal of therapy is to establish IV access and begin fluid and electrolyte replacement. Typically, an infusion of 0.45% or 0.9% NaCl at a rate to restore urine output to 30 to 60 mL/hr and to raise BP constitutes the initial fluid therapy regimen. When blood glucose levels approach 250 mg/dL (13.9 mmol/L), 5% to 10% dextrose is added to the fluid regimen to prevent hypoglycemia and a sudden drop in glucose that can be associated with cerebral edema.[10] Overzealous rehydration, especially with hypotonic IV solutions, can result in cerebral edema.

The aim of fluid and electrolyte therapy is to replace extracellular and intracellular water and to correct deficits of sodium, chloride, bicarbonate, potassium, phosphate, magnesium, and nitrogen. Monitor patients with renal or cardiac compromise for fluid overload. Obtain a serum potassium level before starting insulin. If the patient is hypokalemic, insulin administration will further decrease the potassium levels, making early potassium replacement essential. Although initial serum potassium may be normal or high, levels can rapidly decrease once therapy starts as insulin drives potassium into the cells, leading to life-threatening hypokalemia.

IV insulin administration therapy is directed toward correcting hyperglycemia and hyperketonemia. Insulin is immediately started at 0.1 U/kg/hr by a continuous infusion. It is important to prevent rapid drops in serum glucose to avoid cerebral edema. A blood glucose reduction of 36 to 54 mg/dL/hr (2 to 3 mmol/L/hr) will avoid complications.[10] Insulin allows water and potassium to enter the cell along with glucose and can lead to a depletion of vascular volume and hypokalemia, so monitor the patient's fluid balance and potassium levels.

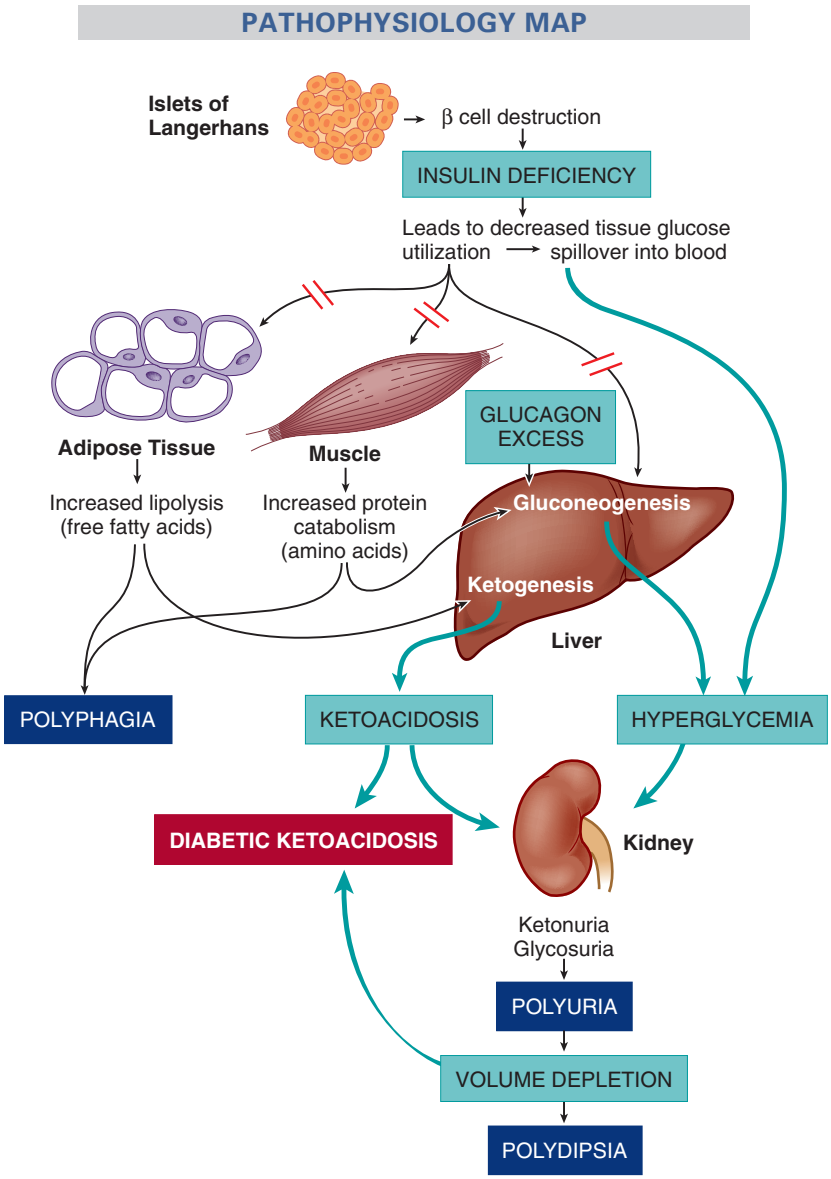

FIG. 49-11 Metabolic events leading to diabetic ketoacidosis.

TABLE 49-18 EMERGENCY MANAGEMENT

Diabetic Ketoacidosis

Etiology

- Undiagnosed diabetes mellitus
- Inadequate treatment of existing diabetes mellitus
- Insulin not taken as prescribed
- Infection
- Change in diet, insulin, or exercise regimen

Assessment Findings

- Dry mouth
- Thirst
- Abdominal pain
- Nausea and vomiting
- Gradually increasing restlessness, confusion, lethargy
- Flushed, dry skin
- Eyes appearing sunken
- Breath odor of ketones
- Rapid, weak pulse
- Labored breathing (Kussmaul respirations)
- Fever
- Urinary frequency
- Serum glucose >250 mg/dL (13.9 mmol/L)
- Glucosuria and ketonuria

Interventions

Initial

- Ensure patent airway.
- Administer O_2 via nasal cannula or non-rebreather mask.
- Establish IV access with large-bore catheter.
- Begin fluid resuscitation with 0.9% NaCl solution 1 L/hr until BP stabilized and urine output 30-60 mL/hr.
- Begin continuous regular insulin drip 0.1 U/kg/hr.
- Identify history of diabetes, time of last food, and time and amount of last insulin injection.

Ongoing Monitoring

- Monitor vital signs, level of consciousness, cardiac rhythm, O_2 saturation, and urine output.
- Assess breath sounds for fluid overload.
- Monitor serum glucose and serum potassium.
- Administer potassium to correct hypokalemia.
- Administer sodium bicarbonate if severe acidosis (pH <7.0).

SAFETY ALERT

- Too rapid administration of IV fluids and a rapid lowering of serum glucose can lead to cerebral edema.
- Incorrect fluid replacement, especially with hypotonic fluids, can cause a sudden fall in serum sodium that can cause cerebral edema.

HYPEROSMOLAR HYPERGLYCEMIC SYNDROME

Hyperosmolar hyperglycemic syndrome (HHS) is a life-threatening syndrome that can occur in the patient with diabetes who is able to produce enough insulin to prevent DKA but not enough to prevent severe hyperglycemia, osmotic diuresis, and extracellular fluid depletion (Fig. 49-12). HHS is less common than DKA. It often occurs in patients over 60 years of age with type 2 diabetes.

PATHOPHYSIOLOGY MAP

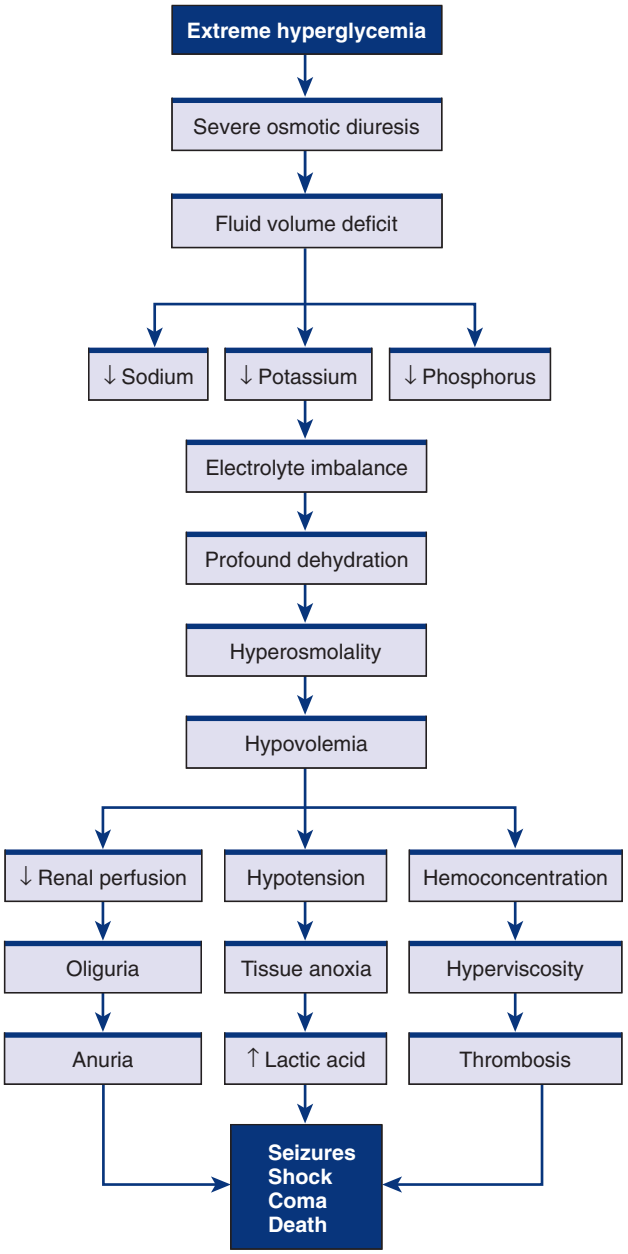

FIG. 49-12 Pathophysiology of hyperosmolar hyperglycemic syndrome.

Common causes of HHS are urinary tract infections, pneumonia, sepsis, any acute illness, and newly diagnosed type 2 diabetes. HHS is often related to impaired thirst sensation and/or a functional inability to replace fluids. There is usually a history of inadequate fluid intake, increasing mental depression, and polyuria.

The main difference between HHS and DKA is that the patient with HHS usually has enough circulating insulin so that ketoacidosis does not occur. Because HHS produces fewer symptoms in the earlier stages, blood glucose levels can climb quite high before the problem is recognized. The higher blood glucose levels increase serum osmolality and produce more severe neurologic manifestations, such as somnolence, coma, seizures, hemiparesis, and aphasia. Since these manifestations resemble a stroke, immediate determination of the glucose level is critical for correct diagnosis and treatment.

Laboratory values in HHS include a blood glucose level greater than 600 mg/dL (33.33 mmol/L) and a marked increase in serum osmolality. Ketone bodies are absent or minimal in both blood and urine.

Collaborative Care

HHS constitutes a medical emergency and has a high mortality rate. The management of DKA and HHS is similar and includes immediate IV administration insulin and either 0.9% or 0.45% NaCl. HHS usually requires greater volumes of fluid replacement (see Table 49-17). This should be accomplished slowly and carefully. Patients with HHS are commonly older and may have cardiac or renal compromise, requiring hemodynamic monitoring to avoid fluid overload during fluid replacement. When blood glucose levels fall to approximately 250 mg/dL (13.9 mmol/L), IV fluids containing glucose are administered to prevent hypoglycemia.

Electrolytes are monitored and replaced as needed. Hypokalemia is not as significant in HHS as it is in DKA, although fluid losses may result in milder potassium deficits that require replacement. Assess vital signs, intake and output, tissue turgor, laboratory values, and cardiac monitoring to check the efficacy of fluid and electrolyte replacement. This includes monitoring serum osmolality and frequently assessing cardiac, renal, and mental status.[10] Once the patient is stabilized, initiate attempts to detect and correct the underlying cause.

NURSING MANAGEMENT
DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC SYNDROME

Closely monitor the hospitalized patient with appropriate blood and urine tests. You are responsible for monitoring blood glucose and urine for output and ketones and using laboratory data to determine appropriate patient care.

Monitor the administration of (1) IV fluids to correct dehydration, (2) insulin therapy to reduce blood glucose and serum ketone levels, and (3) electrolytes given to correct electrolyte imbalance. Assess renal status and the cardiopulmonary status related to hydration and electrolyte levels. Monitor the level of consciousness.

Assess for signs of potassium imbalance resulting from hypoinsulinemia and osmotic diuresis (see Chapter 17). When insulin treatment is begun, serum potassium levels may decrease rapidly as potassium moves into the cells once insulin becomes available. This movement of potassium into and out of extracel-

lular fluid influences cardiac functioning. Cardiac monitoring is useful in detecting hyperkalemia and hypokalemia because characteristic changes indicating potassium excess or deficit are observable on electrocardiogram (ECG) tracings (see Fig. 17-14). Assess vital signs often to identify fever, hypovolemic shock, tachycardia, and Kussmaul respirations.

HYPOGLYCEMIA

Hypoglycemia, or low blood glucose, occurs when there is too much insulin in proportion to available glucose in the blood. This causes the blood glucose level to drop to less than 70 mg/dL (3.9 mmol/L). When plasma glucose drops below 70 mg/dL, counterregulatory hormones are released and the autonomic nervous system is activated. Suppression of insulin secretion and production of glucagon and epinephrine provide defense against hypoglycemia. Epinephrine release causes manifestations that include shakiness, palpitations, nervousness, diaphoresis, anxiety, hunger, and pallor. Because the brain requires a constant supply of glucose in sufficient quantities to function properly, hypoglycemia can affect mental functioning. These manifestations are difficulty speaking, visual disturbances, stupor, confusion, and coma. Manifestations of hypoglycemia can mimic alcohol intoxication. Untreated hypoglycemia can progress to loss of consciousness, seizures, coma, and death.

Hypoglycemic unawareness is a condition in which a person does not experience the warning signs and symptoms of hypoglycemia until the glucose levels reach a critical point. Then the person may become incoherent and combative or lose consciousness. This is often related to autonomic neuropathy of diabetes that interferes with the secretion of counterregulatory hormones that produce these symptoms. Patients at risk for hypoglycemic unawareness include those who have had repeated episodes of hypoglycemia, older patients, and patients who use β-adrenergic blockers. Using intensive treatment to get tight blood glucose control in patients who are at risk for hypoglycemic unawareness may not be an appropriate goal because a major drawback is hypoglycemia. These patients are usually managed with blood glucose goals that are somewhat higher than those of patients who are able to detect and manage the onset of hypoglycemia.

Causes of hypoglycemia are often related to a mismatch in the timing of food intake and the peak action of insulin or oral hypoglycemic agents that increase endogenous insulin secretion. The balance between blood glucose and insulin can be disrupted by administering too much insulin or medication, ingesting too little food, delaying the time of eating, and performing unusual amounts of exercise. Hypoglycemia can occur at any time, but most episodes occur when the OA or insulin is at its peak of action or when the patient's daily routine is disrupted without adequate adjustments in diet, medications, and activity. Although hypoglycemia is more common with insulin therapy, it can occur with noninsulin injectable agents and OAs, and it may be severe and persist for an extended time because of the longer duration of action.

Hypoglycemic symptoms may occur when a very high blood glucose level falls too rapidly (e.g., a blood glucose level of 300 mg/dL [16.7 mmol/L] falling quickly to 180 mg/dL [10 mmol/L]). Although the blood glucose level is above normal by definition and measurement, the sudden metabolic shift can evoke hypoglycemic symptoms. Too vigorous management of hyperglycemia with insulin can cause this type of situation.

NURSING AND COLLABORATIVE MANAGEMENT HYPOGLYCEMIA

Hypoglycemia can usually be quickly reversed with effective treatment. At the first sign of hypoglycemia, check the blood glucose if possible. If it is less than 70 mg/dL (3.9 mmol/L), immediately begin treatment for hypoglycemia. If the blood glucose is greater than 70 mg/dL, investigate other possible causes of the signs and symptoms. If the patient has manifestations of hypoglycemia and monitoring equipment is not available or the patient has a history of chronic poor glycemic control, hypoglycemia should be assumed and treatment initiated.

Follow the "Rule of 15" to treat hypoglycemia (Table 49-19). A blood glucose less than 70 mg/dL is treated by ingesting 15 g of a simple (fast-acting) carbohydrate, such as 4 to 6 oz of fruit juice or a regular soft drink. Commercial products such as gels or tablets containing specific amounts of glucose are convenient for carrying in a purse or pocket to be used in such situations. Recheck the blood glucose 15 minutes later. If the value is still less than 70 mg/dL, ingest 15 g more of carbohydrate and recheck the blood glucose in 15 minutes. If no significant improvement occurs after two or three doses of 15 g of simple carbohydrate, contact the health care provider. Because of the potential for rebound hypoglycemia after an acute episode, have the patient ingest a complex carbohydrate after recovery to prevent another hypoglycemic attack.

Avoid treatment with carbohydrates that contain fat, such as candy bars, cookies, whole milk, and ice cream. The fat in those foods will slow the absorption of the glucose and delay the response to treatment. Avoid overtreatment with large quantities of quick-acting carbohydrates so that a rapid fluctuation to hyperglycemia does not occur.

TABLE 49-19 COLLABORATIVE CARE

Hypoglycemia

Diagnostic
- History of hypoglycemic episodes and symptoms.
- Blood glucose—immediately.

Collaborative Therapy
- Determine cause of hypoglycemia (after correction of condition).

Conscious Patient
- Have patient eat or drink 15 g of quick-acting carbohydrate (4-6 oz of regular soda, 8-10 LifeSavers, 1 tbs syrup or honey, 4 tsp jelly, 4-6 oz orange juice, commercial dextrose products [per label instructions]).
- Wait 15 min. Then check blood glucose again.
- If blood glucose is still <70 mg/dL, have patient repeat treatment of 15 g of carbohydrate.
- Once the glucose level is stable and the next meal is more than 1 hr away, give patient additional food of longer-acting combination carbohydrate plus protein or fat (e.g., crackers with peanut butter or cheese) after symptoms subside.
- Immediately notify health care provider or emergency service (if patient outside hospital) if symptoms do not subside after two or three administrations of quick-acting carbohydrate.

Worsening Symptoms or Unconscious Patient
- Subcutaneous or IM injection of 1 mg glucagon. IV administration of 25-50 mL of 50% glucose.

In an acute care setting, patients with hypoglycemia may be treated with 20 to 50 mL of 50% dextrose IV push. Another option, if the patient is not alert enough to swallow and no IV access is available, is to administer 1 mg of glucagon by intramuscular (IM) or subcutaneous injection. An IM injection in a site such as the deltoid muscle will result in a quicker response. Glucagon stimulates a strong hepatic response to convert glycogen to glucose and therefore makes glucose rapidly available. Nausea is a common reaction after glucagon injection. Therefore, to prevent aspiration if vomiting occurs, turn the patient on the side until he or she becomes alert. Patients with minimal glycogen stores will not respond to glucagon. This includes patients with alcohol-related hepatic disease, starvation, and adrenal insufficiency. Teach family members and others likely to be present when a severe hypoglycemic episode occurs when to use and how to inject glucagon.

Once the acute hypoglycemia has been reversed, explore with the patient the reasons why the situation developed. This assessment may indicate the need for additional teaching of the patient and the family to avoid future episodes of hypoglycemia.

CHRONIC COMPLICATIONS OF DIABETES MELLITUS

ANGIOPATHY

Chronic complications of diabetes are primarily those of end-organ disease from damage to blood vessels *(angiopathy)* secondary to chronic hyperglycemia (Fig. 49-13). Angiopathy is one of the leading causes of diabetes-related deaths, with about 68% of deaths caused by CVD and 16% caused by strokes for those ages 65 or older.[2] These chronic blood vessel dysfunctions are divided into two categories: macrovascular complications and microvascular complications.

Several theories exist as to how and why chronic hyperglycemia damages cells and tissues. Possible causes include (1) the accumulation of damaging by-products of glucose metabolism, such as sorbitol, which is associated with damage to nerve cells; (2) the formation of abnormal glucose molecules in the basement membrane of small blood vessels such as those that circulate to the eye and kidney; and (3) a derangement in red blood cell function that leads to a decrease in oxygenation to the tissues.

The Diabetes Control and Complications Trial (DCCT), a landmark study in diabetes management, demonstrated that in patients with type 1 diabetes the risk for microvascular complications could be significantly reduced by keeping blood glucose levels as near to normal as possible for as much of the time as possible *(tight glucose control)*.[20] Subjects who maintained tight glucose control reduced their risk of developing retinopathy and nephropathy, some of the most common microvascular complications. Based on these findings, the ADA issued recommendations for the management of diabetes that included treatment goals to maintain blood glucose levels as near to normal as possible. Specific targets for individual patients must take into account the risk for severe or undetected hypoglycemia as a side effect of tight glucose control.

The United Kingdom Prospective Diabetes Study (UKPDS) demonstrated that intensive treatment of type 2 diabetes significantly lowered the risk for developing diabetes-related eye, kidney, and neurologic problems. The findings from this study included a 25% reduction of microvascular disease and a 16%

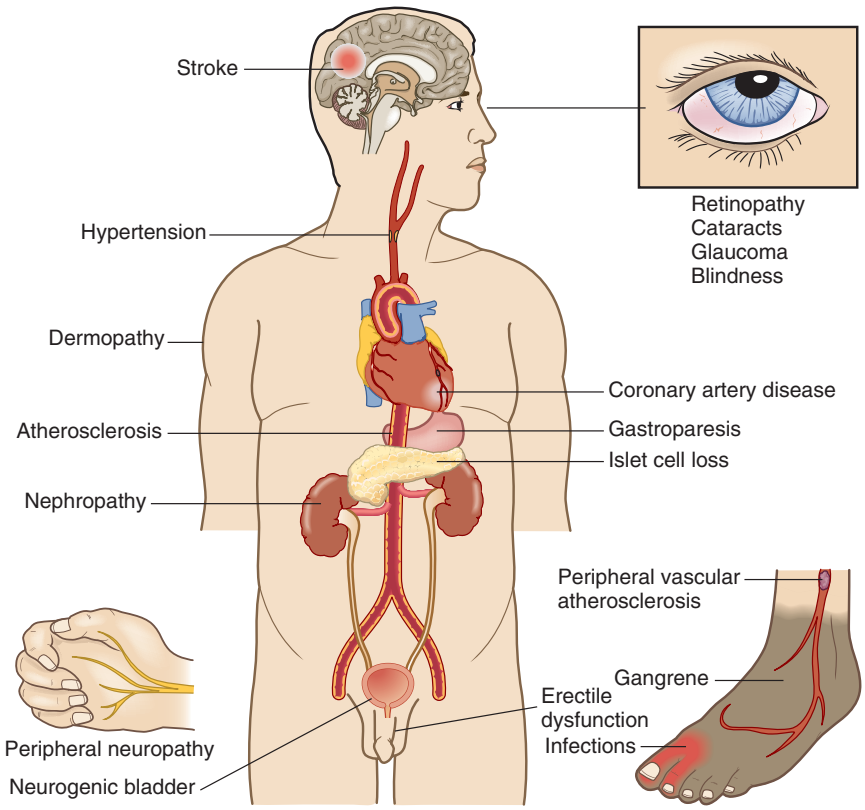

FIG. 49-13 Long-term complications of diabetes mellitus.

reduction in the risk for myocardial infarction in subjects who maintained long-term glycemic control.[21]

Because of the devastating effects of long-term complications, patients with diabetes require scheduled and ongoing monitoring for the detection and prevention of chronic complications. The ADA recommendations for ongoing evaluation are listed in Table 49-20. It is imperative that patients understand the importance of participating in regular follow-up examinations.

Macrovascular Complications

Macrovascular complications are diseases of the large and medium-size blood vessels that occur with greater frequency and with an earlier onset in people with diabetes. Macrovascular diseases include cerebrovascular, cardiovascular, and peripheral vascular disease. Women with diabetes have a four to six times increased risk for CVD, and men with diabetes have a two to three times increased risk for CVD compared with those without diabetes.[4] Patients with diabetes can decrease several risk factors associated with macrovascular complications, such as obesity, smoking, hypertension, high fat intake, and sedentary lifestyle. Smoking, which is detrimental to health in general, is especially injurious to people with diabetes and significantly increases their risk for blood vessel and cardiovascular disease, stroke, and lower extremity amputation. The ADA recommends yearly screening of diabetic patients for CVD risk factors.[10]

Optimizing BP control in patients with diabetes is significant for the prevention of cardiovascular and renal disease. Treating hypertension in diabetic patients results in a decrease in macrovascular and microvascular complications. Hypertension in people with diabetes causes an increase in mortality greater than for those with hypertension without diabetes.[2] A target BP of less than 130/80 mm Hg is recommended for most patients with diabetes.[22]

Patients with diabetes have an increase in lipid abnormalities. This contributes to the increase in CVD seen in this population. The ADA recommends target values of LDL cholesterol less than 100 mg/dL (2.6 mmol/L), triglycerides less than 150 mg/dL (1.7 mmol/L), and HDL cholesterol greater than 40 mg/dL (1.0 mmol/L) in men and greater than 50 mg/dL (1.3 mmol/L) in women.[10] The ADA advocates lifestyle interventions, including nutritional therapy, exercise, weight loss, and smoking cessation to treat hyperlipidemia. Medications (primarily statins) are recommended for those who do not reach lipid goals with lifestyle modifications and for people over 40 years of age with other CVD risk factors regardless of their baseline lipid levels. (Hypertension is discussed in Chapter 33, and coronary artery disease is discussed in Chapter 34.)

Insulin resistance has an important role in the development of CVD and is implicated in the pathogenesis of essential hypertension and dyslipidemia. The role of insulin resistance in the pathogenesis of CVD is not well understood, but it seems to combine with dyslipidemia in contributing to greater risk of CVD in patients with diabetes mellitus. All patients with diabetes should be screened for dyslipidemia at the time diabetes is diagnosed.

Microvascular Complications

Microvascular complications result from thickening of the vessel membranes in the capillaries and arterioles in response to conditions of chronic hyperglycemia. They differ from the macrovascular complications in that they are specific to diabetes. Although microangiopathy can be found throughout the body, the areas most noticeably affected are the eyes (retinopathy), the kidneys (nephropathy), and the skin (dermopathy). Microvascular changes are present in some patients with type 2 diabetes at the time of diagnosis.

TABLE 49-20 MONITORING FOR LONG-TERM COMPLICATIONS OF DIABETES MELLITUS

Complication	Type of Examination	Frequency
Retinopathy	• Funduscopic—dilated eye examination • Fundus photography	• Annually
Nephropathy	• Urine for microalbuminuria • Serum creatinine	• Annually
Neuropathy (foot and lower extremities)	• Visual examination of foot	• Daily by patient • Every visit to health care provider
	• Comprehensive foot: • Visual examination • Sensory examination with monofilament and tuning fork • Palpation (pulses, temperature, callus formation)	• Annually
Cardiovascular disease	• Risk factor assessment: hypertension, dyslipidemia, smoking, family history of premature coronary artery disease, and presence of microalbuminuria or macroalbuminuria	• At least annually
	• Exercise stress testing (may include stress ECG, stress echocardiogram, stress nuclear imaging)	• As needed based on risk factors

DIABETIC RETINOPATHY

Etiology and Pathophysiology

Diabetic retinopathy refers to the process of microvascular damage to the retina as a result of chronic hyperglycemia, nephropathy, and hypertension in patients with diabetes. Diabetic retinopathy is estimated to be the most common cause of new cases of adult blindness.[2]

Retinopathy can be classified as nonproliferative or proliferative. In *nonproliferative retinopathy,* the most common form, partial occlusion of the small blood vessels in the retina causes microaneurysms to develop in the capillary walls. The walls of these microaneurysms are so weak that capillary fluid leaks out, causing retinal edema and eventually hard exudates or intraretinal hemorrhages. Vision may be affected if the macula is involved.

Proliferative retinopathy, the most severe form, involves the retina and the vitreous. When retinal capillaries become occluded, the body compensates by forming new blood vessels to supply the retina with blood, a pathologic process known as *neovascularization.* These new vessels are extremely fragile and hemorrhage easily, producing vitreous contraction. Eventually light is prevented from reaching the retina as the vessels become

torn and bleed into the vitreous cavity. The patient sees black or red spots or lines. If these new blood vessels pull the retina while the vitreous contracts, causing a tear, partial or complete retinal detachment will occur. If the macula is involved, vision is lost. Without treatment, more than half of patients with proliferative diabetic retinopathy will be blind.

Persons with diabetes are also prone to other visual problems. Glaucoma occurs as a result of the occlusion of the outflow channels secondary to neovascularization. This type of glaucoma is difficult to treat and often results in blindness. Cataracts develop at an earlier age and progress more rapidly in people with diabetes.

Collaborative Care

The earliest and most treatable stages of diabetic retinopathy often produce no changes in the vision. Therefore patients with type 2 diabetes should have a dilated eye examination by an ophthalmologist or a specially trained optometrist at the time of diagnosis and annually thereafter for early detection and treatment. A person with type 1 diabetes should have a dilated eye examination within 5 years after the onset of diabetes and then repeated annually.[10]

The best approach to the management of diabetic eye disease is to prevent it by maintaining good glycemic control and managing hypertension. Laser photocoagulation therapy is indicated to reduce the risk of vision loss in patients with proliferative retinopathy or macular edema and in some cases of nonproliferative retinopathy.[23] Laser photocoagulation destroys the ischemic areas of the retina that produce growth factors that encourage neovascularization. A patient who develops vitreous hemorrhage and retinal detachment of the macula may need to undergo vitrectomy. *Vitrectomy* is the aspiration of blood, membrane, and fibers from the inside of the eye through a small incision just behind the cornea. (Photocoagulation and vitrectomy are discussed in Chapter 22.)

Recent research has identified the importance of vascular endothelial growth factor (VEFG) in the development of diabetic retinopathy. Drugs injected into the eye that block the action of VEGF and reduce inflammation are currently being studied for their effectiveness in treating retinopathy.[23]

NEPHROPATHY

Diabetic nephropathy is a microvascular complication associated with damage to the small blood vessels that supply the glomeruli of the kidney. It is the leading cause of end-stage kidney disease in the United States and is seen in 20% to 40% of people with diabetes. Risk factors for diabetic nephropathy include hypertension, genetic predisposition, smoking, and chronic hyperglycemia. Results of the DCCT and UKPDS research have demonstrated that kidney disease can be significantly reduced when near-normal blood glucose control is maintained.[20,21]

Patients with diabetes are screened for nephropathy annually with a random spot urine collection to assess for albuminuria and measure the albumin-to-creatinine ratio. Serum creatinine is also measured to provide an estimation of the glomerular filtration rate and thus the degree of kidney function.

Patients with diabetes who have microalbuminuria or macroalbuminuria should receive either angiotensin-converting enzyme (ACE) inhibitor drugs (e.g., lisinopril [Prinivil, Zestril]) or angiotensin II receptor antagonists (e.g., losartan [Cozaar]). Both classifications of these drugs are used to treat hypertension and have been found to delay the progression of nephropathy in patients with diabetes.[10] Hypertension significantly accelerates the progression of nephropathy. Therefore aggressive BP management is indicated for all patients with diabetes. Tight blood glucose control is also critical in the prevention and delay of diabetic nephropathy. (See Chapter 33 for a discussion of hypertension and Chapter 47 for a discussion of renal failure.)

NEUROPATHY

Diabetic neuropathy is nerve damage that occurs because of the metabolic derangements associated with diabetes mellitus. About 60% to 70% of patients with diabetes have some degree of neuropathy.[2] The most common type of neuropathy affecting persons with diabetes is sensory neuropathy. This can lead to the loss of protective sensation in the lower extremities, and, coupled with other factors, significantly increases the risk for complications that result in a lower limb amputation. More than 60% of nontraumatic amputations in the United States occur in people with diabetes.[2] Screening for neuropathy should begin at the time of diagnosis in patients with type 2 diabetes and 5 years after diagnosis in patients with type 1 diabetes.[10]

Etiology and Pathophysiology

The pathophysiologic processes of diabetic neuropathy are not well understood. Several theories exist, including metabolic, vascular, and autoimmune factors. The prevailing theory is that persistent hyperglycemia leads to an accumulation of sorbitol and fructose in the nerves that causes damage by an unknown mechanism. The result is reduced nerve conduction and demyelinization. Ischemic damage by chronic hyperglycemia in blood vessels that supply the peripheral nerves is also implicated in the development of diabetic neuropathy. Neuropathy can precede, accompany, or follow the diagnosis of diabetes.

Classification

The two major categories of diabetic neuropathy are *sensory neuropathy,* which affects the peripheral nervous system, and *autonomic neuropathy.* Each of these types can take on several forms.

Sensory Neuropathy. The most common form of sensory neuropathy is distal symmetric polyneuropathy, which affects the hands and/or feet bilaterally. This is sometimes referred to as *stocking-glove neuropathy.* Characteristics of distal symmetric polyneuropathy include loss of sensation, abnormal sensations, pain, and paresthesias. The pain, which is often described as burning, cramping, crushing, or tearing, is usually worse at night and may occur only at that time. The paresthesias may be associated with tingling, burning, and itching sensations. The patient may report a feeling of walking on pillows or numb feet. At times the skin becomes so sensitive (hyperesthesia) that even light pressure from bed sheets cannot be tolerated. Complete or partial loss of sensitivity to touch and temperature is common. Foot injury and ulcerations can occur without the patient ever having pain (Fig. 49-14). Neuropathy can also cause atrophy of the small muscles of the hands and feet, causing deformity and limiting fine movement.

Control of blood glucose is the only treatment for diabetic neuropathy. It is effective in many, but not all, cases. Drug therapy may be used to treat neuropathic symptoms, particu-

FIG. 49-14 Neuropathy: neurotrophic ulceration.

larly pain. Medications commonly used include topical creams (e.g., capsaicin [Zostrix]), tricyclic antidepressants (e.g., amitriptyline [Elavil]), selective serotonin and norepinephrine reuptake inhibitors (e.g., duloxetine [Cymbalta]), and antiseizure medications (e.g., gabapentin [Neurontin], pregabalin [Lyrica]). Capsaicin is a moderately effective topical cream made from chili peppers. It depletes the accumulation of pain-mediating chemicals in the peripheral sensory neurons. The cream is applied three or four times a day. At the start of therapy, symptoms usually increase, followed by relief of pain in 2 to 3 weeks. Tricyclic antidepressants are moderately effective in treating the symptoms of diabetic neuropathy. They work by inhibiting the reuptake of norepinephrine and serotonin, which are neurotransmitters believed to play a role in the transmission of pain through the spinal cord. Duloxetine is thought to relieve pain by increasing the levels of serotonin and norepinephrine, which improves the body's ability to regulate pain. Antiseizure medications decrease the release of neurotransmitters that transmit pain.[24]

Autonomic Neuropathy. Autonomic neuropathy can affect nearly all body systems and lead to hypoglycemic unawareness, bowel incontinence and diarrhea, and urinary retention. *Gastroparesis* (delayed gastric emptying) is a complication of autonomic neuropathy that can produce anorexia, nausea, vomiting, gastroesophageal reflux, and persistent feelings of fullness. Gastroparesis can trigger hypoglycemia by delaying food absorption. Cardiovascular abnormalities associated with autonomic neuropathy are postural hypotension, resting tachycardia, and painless myocardial infarction. Assess patients with diabetes for postural hypotension to determine if they are at risk for falls. Instruct the patient with postural hypotension to change from a lying or sitting position slowly.

Diabetes can affect sexual function in men and women. Erectile dysfunction (ED) in diabetic men is well recognized and common, often being the first manifestation of autonomic neuropathy. ED in diabetes is also associated with other factors, including vascular disease, poor metabolic control, endocrine disorders, psychogenic factors, and medications. Decreased libido is a problem for some women with diabetes. Candidal and nonspecific vaginitis is also common. ED or sexual dysfunction requires sensitive therapeutic counseling for both the patient and the patient's partner. (See Chapter 55 for a further discussion of ED.)

A neurogenic bladder may develop as the sensation in the inner bladder wall decreases, causing urinary retention. A patient with retention has infrequent voiding, difficulty voiding, and a weak stream of urine. Emptying the bladder every 3 hours in a sitting position helps prevent stasis and subsequent infection. Tightening the abdominal muscles during voiding and using the Credé maneuver (mild massage downward over the lower abdomen and bladder) may also help with complete bladder emptying. Cholinergic agonist drugs such as bethanechol (Urecholine) may be used. The patient may also need to learn self-catheterization (see Chapter 46).

FIG. 49-15 The necrotic toe developed as a complication of diabetes. **A,** Before amputation. **B,** After amputation.

COMPLICATIONS OF FEET AND LOWER EXTREMITIES

People with diabetes are at high risk for foot ulcerations and lower extremity amputations.[25] The development of diabetic foot complications can be the result of a combination of microvascular and macrovascular diseases that place the patient at risk for injury and serious infection (Fig. 49-15). Sensory neuropathy and peripheral artery disease (PAD) are risk factors for foot complications. In addition, clotting abnormalities, impaired immune function, and autonomic neuropathy also have a role. Smoking is deleterious to the health of lower extremity blood vessels and increases the risk for amputation.

Sensory neuropathy is a major risk factor for lower extremity amputation in the person with diabetes. *Loss of protective sensation* (LOPS) often prevents the patient from being aware that a foot injury has occurred. Improper footwear and injury from stepping on foreign objects while barefoot are common causes of undetected foot injury in the person with LOPS.[26] Because the primary risk factor for lower extremity amputation is LOPS, annual screening using a *monofilament* is important. This is done by applying a thin, flexible filament to several spots on the plantar surface of the foot and asking the patient to report if it is felt. Insensitivity to a monofilament has been shown to greatly increase the risk for diabetic foot ulcers that can lead to amputation.

PAD increases the risk for amputation by causing a reduction in blood flow to the lower extremities. When blood flow is decreased, oxygen, white blood cells, and vital nutrients are not available to the tissues. Wounds take longer to heal, and the risk for infection increases. Signs of PAD include intermittent claudication, pain at rest, cold feet, loss of hair, delayed capillary filling, and dependent rubor (redness of the skin that occurs when the extremity is in a dependent position). The disease is diagnosed by history, ankle-brachial index (ABI) (see Table 38-3), and angiography. Management includes control or reduction of risk factors, particularly smoking, high cholesterol intake, and hypertension. Bypass or graft surgery is indicated in some patients. (PAD is discussed in Chapter 38.)

If the patient has LOPS or PAD, aggressive measures must be taken to teach the patient how to prevent foot ulcers. These measures include the selection of proper footwear, including prescription shoes. The patient also must carefully avoid injury to the foot, practice diligent skin and nail care, inspect the foot thoroughly each day, and treat small problems promptly.[26] Guidelines for patient teaching are listed in Table 49-21.

Proper care of a diabetic foot ulcer is critical for wound healing. Several forms of treatment can be used. Casting can be done to redistribute the weight on the plantar surface of the foot. Wound control for the ulcer can include debridement, dressings, advanced wound healing products (becaplermin [Regranex]), vacuum-assisted closure, ultrasound, hyperbaric oxygen, and skin grafting.[26]

TABLE 49-21 PATIENT & CAREGIVER TEACHING GUIDE*

Foot Care

Include the following instructions when teaching the patient and caregiver about diabetic foot care.

1. Wash feet daily with a mild soap and warm water. First test water temperature with hands.
2. Pat feet dry gently, especially between toes.
3. Examine feet daily for cuts, blisters, swelling, and red, tender areas. Do not depend on feeling sores. If eyesight is poor, have others inspect feet.
4. Use lanolin on feet to prevent skin from drying and cracking. Do not apply between toes.
5. Use mild foot powder on sweaty feet.
6. Do not use commercial remedies to remove calluses or corns.
7. Cleanse cuts with warm water and mild soap, covering with clean dressing. Do not use iodine, rubbing alcohol, or strong adhesives.
8. Report skin infections or nonhealing sores to health care provider immediately.
9. Cut toenails evenly with rounded contour of toes. Do not cut down corners. The best time to trim nails is after a shower or bath.
10. Separate overlapping toes with cotton or lamb's wool.
11. Avoid open-toe, open-heel, and high-heel shoes. Leather shoes are preferred to plastic ones. Wear slippers with soles. Do not go barefoot. Shake out shoes before putting on.
12. Wear clean, absorbent (cotton or wool) socks or stockings that have not been mended. Colored socks must be colorfast.
13. Do not wear clothing that leaves impressions, hindering circulation.
14. Do not use hot water bottles or heating pads to warm feet. Wear socks for warmth.
15. Guard against frostbite.
16. Exercise feet daily either by walking or by flexing and extending feet in suspended position. Avoid prolonged sitting, standing, and crossing of legs.

*This teaching guide is also appropriate for patients with peripheral vascular problems.

Neuropathic arthropathy, or *Charcot's foot,* results in ankle and foot changes that ultimately lead to joint dysfunction and footdrop. These changes occur gradually and promote an abnormal distribution of weight over the foot, further increasing the chances of developing a foot ulcer as new pressure points emerge. Foot deformity should be recognized early and proper footwear fitted before ulceration occurs.

INTEGUMENTARY COMPLICATIONS

Up to two thirds of persons with diabetes develop skin problems.[10] Diabetic dermopathy, the most common diabetic skin lesion, is characterized by reddish brown, round or oval patches. They initially are scaly, then they flatten out and become indented. The lesions appear most frequently on the shins, but can also be found on the front of the thighs, forearm, side of the foot, scalp, and trunk.

Acanthosis nigricans is a velvety light brown to black skin thickening, predominantly seen on flexures, axillae, and the neck. *Necrobiosis lipoidica diabeticorum* usually appears as red-yellow lesions, with atrophic skin that becomes shiny and transparent revealing tiny blood vessels under the surface (Fig. 49-16). This condition is uncommon and occurs more frequently in young women. It may appear before other clinical signs or symptoms of diabetes. Because the thin skin is prone to injury, special care must be taken to protect affected areas from injury and ulceration.

INFECTION

A person with diabetes is more susceptible to infections because of a defect in the mobilization of white blood cells and an impaired phagocytosis by neutrophils and monocytes. Recurring or persistent infections such as *Candida albicans,* as well as boils and furuncles, in the undiagnosed patient often lead the health care provider to suspect diabetes. Loss of sensation (neuropathy) may delay the detection of an infection.

Persistent glycosuria may predispose patients to bladder infections, especially patients with a neurogenic bladder.

FIG. 49-16 Necrobiosis lipoidica diabeticorum.

Decreased circulation resulting from angiopathy can prevent or delay the immune response. Antibiotic therapy has prevented infection from being a major cause of death in diabetic patients. The treatment of infections must be prompt and vigorous. Teach diabetic patients measures to prevent infection: practicing good hand hygiene, avoiding exposure to individuals who have a communicable illness, and getting an annual influenza vaccine and pneumococcal vaccine (Pneumovax) every 5 years.

PSYCHOLOGIC CONSIDERATIONS

Patients with diabetes have high rates of depression, anxiety, and eating disorders. Depression contributes to poor adherence to diabetes self-care, feelings of helplessness related to chronic illness, and poor outcomes.[10] Assess patients for manifestations of depression.

Persons with type 1 diabetes have an increased risk of developing disordered eating behaviors (DEB).[27] The greatest incidence of eating disorders is seen in females. Adolescent girls with diabetes are more than twice as likely to develop DEB than those who do not have diabetes.[28] DEBs include anorexia, bulimia, binge eating, excessive restriction of calories, and intense exercise. Patients may intentionally decrease their dose of insulin or omit the dose. This leads to weight loss, hyperglycemia, and glycosuria because the food ingested cannot be used for energy without adequate insulin. Insulin omission and DEBs can have serious consequences, including retinopathy, neuropathy, lipid abnormalities, DKA, and death.[28] Open com-

DELEGATION DECISIONS

Caring for the Patient With Diabetes Mellitus

Oral agents (OAs), noninsulin injectable agents, and insulin can be administered by licensed practical/vocational nurses (LPN/LVNs) (and in some states and settings by unlicensed assistive personnel [UAP]) to stable patients. In patients experiencing acute complications of diabetes mellitus (DM), actions such as insulin administration and infusion of IV fluids should be done or directly supervised by a registered nurse (RN).

Role of Registered Nurse (RN)

- Assess for risk factors for prediabetes and type 1 and type 2 DM.
- Teach the patient and caregiver about self-management of DM, including self-monitoring of blood glucose (SMBG), insulin, noninsulin injectables, OAs, nutrition, physical activity, and recognition and management of hypoglycemia.
- Develop a plan to avoid hypoglycemia or hyperglycemia in the patient with DM who is acutely ill or having surgery.
- Assess for acute complications and implement appropriate actions: hypoglycemia, diabetic ketoacidosis (DKA), and hyperosmolar hyperglycemic syndrome (HHS).
- Assess for chronic complications of diabetes, including cardiovascular disease, retinopathy, nephropathy, neuropathy, and diabetic foot complications.
- Teach patient and caregiver about prevention and management of chronic complications of diabetes.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- Administer OAs and routinely scheduled insulin regimens.
- Monitor the diabetic patient for symptoms of hypoglycemia, DKA, and HHS.
- In the ambulatory or home setting, monitor patient self-management of insulin, OAs, nutrition, and physical activity.
- Report concerns with patient self-management in the home setting to the RN.

Role of Unlicensed Assistive Personnel (UAP)

- Check capillary blood glucose (CBG) levels (after being trained and evaluated in this procedure) and report values to the RN.
- Report changes in patient vital signs, urine output, behavior, or level of consciousness to the RN.
- In a community or home care setting, administer OAs and insulin to the stable diabetic patient (consider state nurse practice act and agency policy).

ETHICAL/LEGAL DILEMMAS

Durable Power of Attorney for Health Care

Situation

G.V., a 64-yr-old white woman, is admitted to the intensive care unit with heart failure. She has many complications from a long-term history of type 1 diabetes and hypertension, including a right leg above-the-knee amputation and blindness related to diabetic retinopathy. She severed ties with her family 30 yr ago. She has a life partner of 35 yr whom she designated as her proxy in her signed Durable Power of Attorney. She has stated many times that she would rather die than have renal dialysis. She has been sedated and intubated for 3 days. The physician plans to extubate her and resuscitate her so that dialysis can be initiated. Her brother shows up at the hospital and supports the physician's decision. Her partner disagrees with the decision. The physician refuses to recognize her partner as proxy because she is not a blood relative.

Ethical/Legal Points for Consideration

- The Patient Self-Determination Act (1990) requires all health care facilities receiving Medicare and Medicaid funding to make available advance directives allowing individuals to state their preferences or refusals of health care in the event that they are incapable of consenting for themselves.
- Durable Power of Attorney for health care is one type of advance directive in which people, when they are competent, identify someone else to make decisions for them, should they lose their decision-making ability in the future.
- The Living Will, another type of advance directive, permits individuals to state their own preferences and refusals.
- Many health care providers mistakenly think that proxies must be family members or blood relatives. Lesbian, gay, bisexual, and transgender individuals often have difficulty having their partnership recognized as valid, especially if the patient's family disputes their rights.
- Some families are deeply divided on decisions for their loved ones, and sometimes difficulties occur when money and property are also disputed. The passage of time may be an issue where the original documents were executed and then changes occurred (e.g., divorce, death or disability of the proxy, inability to contact the proxy, inability to find a valid original of the advance directive).
- Within your scope of nursing practice, you need to be informed as to decision-making laws and regulations in your own state and make advance directive documents available to patients. In addition, you need to (1) teach patients and their families about advance directives, (2) make sure that health care providers are aware of the presence of advance directives, (3) assist the patient and family in communicating with the health care providers when a "No Code" order is requested, and (4) assist a conflicted family in obtaining appropriate counseling whenever necessary.

Discussion Questions

1. How would you handle a situation in which the family and surrogate decision maker disagree?
2. How can you assess the patient and family's understanding of durable power of attorney and assist them in understanding their role in decision making?
3. What should you do when a physician orders dialysis to be initiated when you know that this goes against the patient's advance directive?

munication is critical to identify these behaviors early. Patients with eating disorders need to be seen by a mental health professional with expertise in eating disorders and an understanding of diabetes management.

GERONTOLOGIC CONSIDERATIONS

DIABETES MELLITUS

Diabetes is present in more than 25% of persons over 65 years of age, with this age-group being the fastest growing segment of the population developing diabetes.[2] Older people with diabetes have higher rates of premature death, functional disability, and coexisting illnesses such as hypertension and stroke than those without diabetes. The prevalence of diabetes increases with age. A major reason for this is that the process of aging is associated with a reduction in β-cell function, decreased insulin sensitivity, and altered carbohydrate metabolism. Aging is also associated with a number of conditions that are more likely to be treated with medications that impair insulin action (e.g., corticosteroids, antihypertensives, phenothiazines). Undiagnosed and untreated diabetes is more common in older adults, partly because many of the normal physiologic changes of aging resemble those of diabetes, such as low energy levels, falls, dizziness, confusion, and chronic urinary tract infections.

Several factors are taken into account when determining glycemic goals for an older adult. One is that hypoglycemic unawareness is more common in older adults, making these patients more likely to suffer adverse consequences from blood glucose–lowering therapy. They may have delayed psychomotor function that could interfere with the ability to treat hypoglycemia. Other factors to consider in establishing glycemic goals for the older patient include the patient's own desire for treatment and coexisting medical problems such as cognitive impairment. Compounding the challenge, diabetes has been found to contribute to a greater rate of decline of cognitive function. Although it is generally agreed that treatment is indicated to prevent acute complications and avoid unpleasant symptoms, strict glycemic control may be difficult to achieve.

Diet and exercise are recommended as therapy for older adult patients with diabetes. This should take into account functional limitations that may interfere with physical activity and the ability to prepare meals. Because of the physiologic changes that occur with aging, the therapeutic outcome for the older adult with diabetes who receives OAs may be altered. Assess renal function and creatinine clearance in patients over 80 years of age taking metformin. Monitor those taking sulfonylurea drugs (e.g., glipizide) for hypoglycemia and renal and liver dysfunction. Insulin therapy may be instituted if OAs are not effective. However, it is important to recognize that older adults are more likely to have limitations in the manual dexterity and visual acuity necessary for accurate insulin administration. Insulin pens may be a safer alternative for older adults.

Base patient teaching on the individual's needs, using a slower pace with simple printed or audio materials in patients with cognitive and functional limitations. Include the family or caregivers in the teaching. The patient education issues for the older patient include those related to altered vision, mobility, cognitive status, and functional ability. Consider the patient's financial and social situation and the effect of multiple medications, eating habits, and quality-of-life issues.

CASE STUDY

Diabetic Ketoacidosis

iStockphoto/Thinkstock

Patient Profile

N.B., a 34-yr-old Native American man, was admitted to the emergency department after he was found unconscious by his wife in their home.

Subjective Data (Provided by Wife)

- Was diagnosed with type 1 diabetes mellitus 12 mo ago
- Was taking 50 U/day of insulin: 5 U of lispro insulin with breakfast, 5 U with lunch, and 10 U with dinner plus 30 U of glargine insulin at bedtime
- Has history of gastroenteritis for 1 wk with vomiting and anorexia
- Stopped taking insulin 2 days ago when he was unable to eat

Objective Data

Physical Examination

- Breathing is deep and rapid
- Fruity acetone smell on breath
- Skin flushed and dry

Diagnostic Studies

- Blood glucose level 730 mg/dL (40.5 mmol/L)
- Blood pH 7.26

Discussion Questions

1. Briefly explain the pathophysiology of the development of diabetic ketoacidosis (DKA) in this patient.
2. What clinical manifestations of DKA does this patient exhibit?
3. What factors precipitated this patient's DKA?
4. ***Priority Decision:*** What is the priority nursing intervention for N.B.?
5. What distinguishes this case history from one of hyperosmolar hyperglycemic syndrome (HHS) or hypoglycemia?
6. ***Priority Decision:*** What is the priority teaching that should be done with this patient and his family?
7. What role should N.B.'s wife have in the management of his diabetes?
8. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
9. ***Evidence-Based Practice:*** N.B.'s wife asks you if she should have given her husband insulin when he got sick. How would you respond?

evolve Answers and a corresponding concept map are available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Polydipsia and polyuria related to diabetes mellitus are primarily due to
   a. the release of ketones from cells during fat metabolism.
   b. fluid shifts resulting from the osmotic effect of hyperglycemia.
   c. damage to the kidneys from exposure to high levels of glucose.
   d. changes in RBCs resulting from attachment of excessive glucose to hemoglobin.
2. Which statement would be correct for a patient with type 2 diabetes who was admitted to the hospital with pneumonia?
   a. The patient must receive insulin therapy to prevent ketoacidosis.
   b. The patient has islet cell antibodies that have destroyed the pancreas's ability to produce insulin.
   c. The patient has minimal or absent endogenous insulin secretion and requires daily insulin injections.
   d. The patient may have sufficient endogenous insulin to prevent ketosis but is at risk for hyperosmolar hyperglycemic syndrome.
3. Analyze the following diagnostic findings for your patient with type 2 diabetes. Which result will need further assessment?
   a. A1C 9%
   b. BP 126/80 mm Hg
   c. FBG 130 mg/dL (7.2 mmol/L)
   d. LDL cholesterol 100 mg/dL (2.6 mmol/L)
4. Which statement by the patient with type 2 diabetes is accurate?
   a. "I am supposed to have a meal or snack if I drink alcohol."
   b. "I am not allowed to eat any sweets because of my diabetes."
   c. "I do not need to watch what I eat because my diabetes is not the bad kind."
   d. "The amount of fat in my diet is not important. Only carbohydrates raise my blood sugar."
5. You are caring for a patient with newly diagnosed type 1 diabetes. What information is essential to include in your patient teaching before discharge from the hospital *(select all that apply)?*
   a. Insulin administration
   b. Elimination of sugar from diet
   c. Need to reduce physical activity
   d. Use of a portable blood glucose monitor
   e. Hypoglycemia prevention, symptoms, and treatment
6. What is the priority action for the nurse to take if the patient with type 2 diabetes complains of blurred vision and irritability?
   a. Call the physician.
   b. Administer insulin as ordered.
   c. Check the patient's blood glucose level.
   d. Assess for other neurologic symptoms.
7. A diabetic patient has a serum glucose level of 824 mg/dL (45.7 mmol/L) and is unresponsive. After assessing the patient, the nurse suspects diabetic ketoacidosis rather than hyperosmolar hyperglycemic syndrome based on the finding of
   a. polyuria.
   b. severe dehydration.
   c. rapid, deep respirations.
   d. decreased serum potassium.
8. Which are appropriate therapies for patients with diabetes mellitus *(select all that apply)?*
   a. Use of statins to treat dyslipidemia
   b. Use of diuretics to treat nephropathy
   c. Use of ACE inhibitors to treat nephropathy
   d. Use of serotonin agonists to decrease appetite
   e. Use of laser photocoagulation to treat retinopathy

1. b, 2. d, 3. a, 4. a, 5. a, d, e, 6. c, 7. c, 8. a, c, e

LEARNING OUTCOMES

1. Explain the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with an imbalance of hormones produced by the anterior pituitary gland.
2. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with an imbalance of hormones produced by the posterior pituitary gland.
3. Explain the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with thyroid dysfunction.
4. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with an imbalance of the hormone produced by the parathyroid glands.
5. Identify the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with an imbalance of hormones produced by the adrenal cortex.
6. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of the patient with an excess of hormones produced by the adrenal medulla.
7. List the side effects of corticosteroid therapy.
8. Describe common nursing assessments, interventions, rationales, and expected outcomes related to patient teaching for management of chronic endocrine problems.

The endocrine system is made up of a number of organs and glands that are involved in the synthesis and secretion of hormones that affect every body system. Because these hormones have such a wide range of action, endocrine problems are associated with a variety of clinical manifestations. Many aspects of a person's life are affected when an endocrine problem is present.

DISORDERS OF ANTERIOR PITUITARY GLAND

ACROMEGALY

Acromegaly is a rare condition characterized by an overproduction of growth hormone (GH). Approximately six out of every 1 million adults in the United States are diagnosed annually.[1] Both genders are affected equally. The mean age at the time of diagnosis is 40 to 45 years old.

Etiology and Pathophysiology

Acromegaly most often occurs as a result of a benign pituitary tumor (adenoma). The excessive secretion of GH results in an overgrowth of soft tissues and bones in the hands, feet, and face. Because the problem develops after epiphyseal closure, the bones of the arms and legs do not grow longer.

Clinical Manifestations

The changes resulting from excess GH can occur over a number of years and may go unnoticed by family and friends. Patients experience enlargement of hands and feet with joint pain that can range from mild to crippling. Carpal tunnel syndrome may be present. Thickening and enlargement of the bony and soft tissues on the face, feet, and head occur (Fig. 50-1).

Enlargement of the tongue results in speech difficulties, and the voice deepens because of hypertrophy of the vocal cords. Sleep apnea may occur because of upper airway narrowing and obstruction from increased amounts of pharyngeal soft tissues. The skin becomes thick, leathery, and oily. Persons with acromegaly may experience peripheral neuropathy and proximal muscle weakness. Women may develop menstrual disturbances.

Visual changes may occur due to pressure on the optic nerve from a pituitary adenoma. Headaches are common. Since GH antagonizes the action of insulin leading to hyperglycemia, glucose intolerance and manifestations of diabetes mellitus may occur, including *polydipsia* (increased thirst) and *polyuria* (increased urination).[2] Because GH mobilizes stored fat for energy, it increases free fatty acid levels in the blood and predisposes the patient to atherosclerosis.

The life expectancy of patients with acromegaly is reduced by 5 to 10 years. They are more likely to succumb to cardiac and respiratory diseases, diabetes mellitus, and colorectal cancer.[3] Even when patients are cured or acromegaly is well controlled, manifestations such as joint pain and deformities often remain.

FIG. 50-1 Progressive development of facial changes associated with acromegaly.

GENDER DIFFERENCES

Endocrine Problems

Men	Women
• Ectopic ACTH production is more common in men.	• Hyperthyroidism and hypothyroidism are more common in women than in men. • Graves' disease affects four to eight times more women than men. • Hyperaldosteronism affects twice as many women as men. • Thyroid nodules and thyroid cancer affect up to four times as many women as men.

ACTH, Adrenocorticotropic hormone.

Diagnostic Studies

In addition to the history and physical examination, a diagnosis of acromegaly requires evaluation of plasma insulin-like growth factor 1 (IGF-1) levels and GH response to an oral glucose tolerance test (OGTT). The peripheral actions of GH are mediated by IGF-1. As GH levels rise, so do IGF-1 levels. However, GH is released in a pulsatile fashion, requiring several samples to obtain an accurate measure. Serum IGF-1 levels are more constant, providing a more reliable diagnostic measure of acromegaly.

OGTT is a specific test for acromegaly. Because GH secretion is normally inhibited by glucose, measurement of glucose nonsuppressibility is useful. Two baseline GH levels are obtained before ingestion of 75 or 100 g of oral glucose, and additional GH measurements are made at 30, 60, 90, and 120 minutes. Normally, GH concentration falls during an OGTT. In acromegaly GH levels do not fall, and in some cases GH concentration rises.

Magnetic resonance imaging (MRI) and a high-resolution computed tomography (CT) scan with contrast media are used to detect pituitary tumors. A complete ophthalmologic examination, including visual fields, is done because a tumor may cause pressure on the optic chiasm or optic nerves.

Collaborative Care

The patient's prognosis depends on the age at onset, age when treatment started, and tumor size. The overall goal is to return the patient's GH levels to normal. Treatment consists of surgery, radiation therapy, drug therapy, or a combination of these therapies. With treatment, bone growth can be stopped and tissue hypertrophy reversed. However, sleep apnea and diabetic and cardiac complications may persist.

Surgical Therapy. Surgery (hypophysectomy) is the treatment of choice because it offers the best chance for a cure, especially for smaller pituitary adenomas. Most surgeries are done by an endoscopic *transsphenoidal* approach (Fig. 50-2).

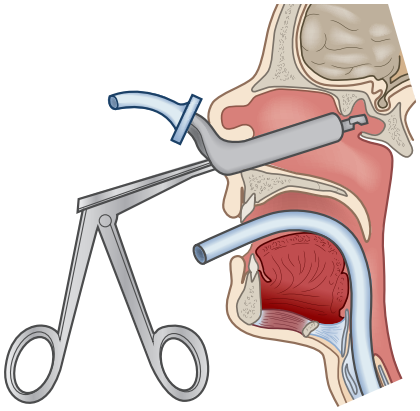

FIG. 50-2 Surgery on the pituitary gland is most commonly performed with the transsphenoidal approach. An incision is made in the inner aspect of the upper lip and gingiva. The sella turcica is entered through the floor of the nose and sphenoid sinuses.

Surgery produces an immediate reduction in GH levels followed by a drop in IGF-1 levels within a few weeks. When the entire pituitary gland is removed, there is permanent loss of all pituitary hormones. Rather than replacing the pituitary (tropic) hormones, which requires parenteral administration, the essential hormones produced by target organs (glucocorticoids, thyroid hormone, and sex hormones) are given. Hormone therapy continues throughout life. Patients with larger tumors or those with GH levels greater than 45 ng/mL may require adjuvant radiation or drug therapy.

Radiation Therapy. Radiation therapy is used when surgery has failed to produce a cure or when patients are poor candidates for surgery. Radiation therapy is usually offered in combination with drugs that reduce GH levels. However, the full effects may not be noted for months to years. Radiation can also be used to reduce the size of a tumor before surgery. Radiation therapy may lead to hypopituitarism, which then requires lifelong hormone replacement therapy.

Stereotactic radiosurgery (gamma knife surgery, proton beam, linear accelerator) may be used for small, surgically inaccessible pituitary tumors or in place of conventional radiation (see Chapter 57). This procedure consists of radiation delivered to one site from multiple angles.

Drug Therapy. Drugs are most commonly used in patients who have had an inadequate response to surgery and/or in combination with radiation therapy. The primary drug used for acromegaly is octreotide (Sandostatin), a somatostatin analog that reduces GH levels to normal in many patients. Octreotide is given by subcutaneous injection three times a week. Two long-acting analogs, octreotide (Sandostatin LAR) and lanreotide SR (Somatuline Depot), are available as intramuscular (IM) injections given every 4 weeks. GH levels are measured every 2 weeks to guide drug dosing, and then every 6 months until the desired response is obtained.

Dopamine agonists (e.g., bromocriptine [Parlodel], pergolide [Permax], cabergoline [Dostinex]) may be given alone or added to somatostatin analogs if complete remission has not been achieved after surgery. These drugs reduce the secretion of GH from the tumor.

GH antagonists (e.g., pegvisomant [Somavert]) reduce the effect of GH in the body by blocking the hepatic production of IGF-1. With the use of drug therapy, most patients achieve normal IGF-1 levels with symptom improvement.[2]

NURSING MANAGEMENT ACROMEGALY

NURSING ASSESSMENT

Assess the patient for signs and symptoms of abnormal tissue growth and evaluate changes in physical size. It is important to question patients about increases in hat, glove, and shoe sizes. Older photographs are helpful to evaluate any changes (see Fig. 50-1). Because physical changes occur slowly and over a long period, the individual may not even be aware of any changes.

NURSING IMPLEMENTATION

Postoperative care after a transsphenoidal hypophysectomy includes elevating the head of the patient's bed at all times to a 30-degree angle. This elevation avoids pressure on the sella turcica and decreases headaches, a frequent postoperative problem. Monitor the pupillary response, speech patterns, and extremity strength to detect neurologic complications. Perform mouth care every 4 hours to keep the surgical area clean and free of debris. Avoid tooth brushing for at least 10 days to protect the suture line. Observe the patient for any signs of bleeding, since hemorrhage may be a complication, particularly when larger tumors are removed by this approach.

Instruct the patient to avoid vigorous coughing, sneezing, and straining at stool (Valsalva maneuver) to prevent cerebrospinal fluid (CSF) leakage. Notify the surgeon, and send any clear nasal drainage to the laboratory to be tested for glucose. A glucose level greater than 30 mg/dL (1.67 mmol/L) indicates CSF leakage from an open connection to the brain. If this happens, the patient is at increased risk for meningitis. Complaints of persistent and severe generalized or supraorbital headache may indicate CSF leakage into the sinuses. A CSF leak usually resolves within 72 hours when treated with head elevation and bed rest. If the leak persists, daily spinal taps may be done to reduce pressure to below-normal levels.

If stereotactic radiosurgery is used, the patient is usually moved from the specialized radiation center to the neurosurgical nursing unit for overnight observation. The patient will be in a stereotactic head frame. Carefully monitor vital signs, neurologic status, and fluid volume status. Possible complications of sterotactic surgery include increased headaches, seizures, nausea, and vomiting. Perform pin-site care according to institutional policy. Instruct family members on pin-site care if the patient is discharged with pins in place.

Observe the patient for transient diabetes insipidus (DI). This may occur because of the loss of antidiuretic hormone (ADH), which is stored in the posterior lobe of the pituitary gland, or cerebral edema related to manipulation of the pituitary during surgery. To assess for DI, closely monitor urine output and serum and urine osmolarity. Clinical manifestations and treatment of DI are discussed in more detail later in this chapter.

If a hypophysectomy is performed or the pituitary gland is damaged, hormone therapy will be necessary. ADH, cortisol, and thyroid hormone replacement will be needed. Surgery may result in permanent loss or deficiencies in follicle-stimulating hormone (FSH) and luteinizing hormone (LH). This can lead to decreased fertility. Assist the patient in working through the grieving process associated with these losses.

If hormones are prescribed, teach the patient about the need for lifelong therapy. Serial photographs to show improvement may be helpful. Patients with acromegaly are at higher risk for

colon polyps and colorectal cancer and should have a screening colonoscopy every 3 to 4 years.

EXCESSES OF OTHER TROPIC HORMONES

In addition to GH, the pituitary also secretes prolactin, adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), and ADH. An excess of any of these hormones (discussed later in the chapter) can cause significant disturbances in metabolism and general health.

Prolactinomas are among the most common type of pituitary adenomas.[4] Women with prolactinomas frequently experience galactorrhea, anovulation, infertility, oligomenorrhea or amenorrhea, decreased libido, and hirsutism. In men, impotence and decreased sperm density and libido may result. Compression of the optic chiasm can cause visual problems and signs of increased intracranial pressure, including headache, nausea, and vomiting. Because prolactinomas do not typically progress in size, drug therapy is usually the first-line treatment. The dopamine agonists cabergoline and bromocriptine have successfully been used to treat prolactinomas. Surgery may be done depending on the extent and size of the tumor. Radiation therapy may be used to reduce the risk of tumor recurrence for patients with large tumors.

HYPOFUNCTION OF PITUITARY GLAND

Hypopituitarism is a rare disorder that involves a decrease in one or more of the pituitary hormones. The anterior pituitary gland secretes ACTH, TSH, FSH, LH, GH, and prolactin. The posterior pituitary gland secretes ADH and oxytocin. A deficiency of only one pituitary hormone is referred to as *selective hypopituitarism.* Total failure of the pituitary gland results in deficiency of all pituitary hormones—a condition referred to as *panhypopituitarism.* The most common hormone deficiencies associated with hypopituitarism involve GH and gonadotropins (i.e., LH, FSH).

Etiology and Pathophysiology

The usual cause of pituitary hypofunction is a pituitary tumor. Autoimmune disorders, infections, pituitary infarction (Sheehan syndrome), or destruction of the pituitary gland (from trauma, radiation, or surgical procedures) can also cause hypopituitarism. African Americans have a higher incidence of pituitary adenomas than other ethnic groups.[5]

Anterior pituitary hormone deficiencies can lead to end-organ failure. Deficiencies of TSH and ACTH are life threatening. ACTH deficiency can lead to acute adrenal insufficiency and shock. Hypovolemic shock is due to sodium and water depletion. (Acute adrenal insufficiency is discussed later in this chapter on pp. 1211-1212.)

Clinical Manifestations and Diagnostic Studies

The manifestations associated with pituitary hypofunction vary with the type and degree of dysfunction. Early manifestations associated with a space-occupying lesion include headaches, visual changes (decreased visual acuity or decreased peripheral vision), loss of smell, nausea and vomiting, and seizures. Manifestations associated with hyposecretion of the target glands vary widely (Table 50-1).

In addition to a history and physical examination, diagnostic studies such as MRI and CT are used to identify a pituitary tumor. Laboratory tests for diagnosing hypopituitarism vary widely, but generally involve the direct measurement of pituitary hormones (e.g., TSH) or an indirect determination of the target organ hormones (e.g., triiodothyronine [T_3], thyroxine [T_4]). (See Chapter 48 for more information regarding diagnostic studies.)

TABLE 50-1 CLINICAL MANIFESTATIONS OF HYPOPITUITARISM

Hormone Deficiency	Manifestations
Growth hormone (GH)	Subtle, nonspecific findings. Truncal obesity, decreased muscle mass and strength, weakness, fatigue, depression or flat affect.
Follicle-stimulating hormone (FSH) and luteinizing hormone (LH)	*Women:* Menstrual irregularities, loss of libido, changes in secondary sex characteristics such as decreased breast size. *Men:* Testicular atrophy, diminished spermatogenesis, loss of libido, impotence, decreased facial hair and muscle mass.
Thyroid-stimulating hormone (TSH)	Mild form of primary hypothyroidism: fatigue, cold intolerance, constipation, lethargy, weight gain.
Adrenocorticotropic hormone (ACTH)	Involves a deficiency of cortisol: weakness, fatigue, headache, dry and pale skin, diminished axillary and pubic hair, lowered resistance to infection, fasting hypoglycemia.

NURSING AND COLLABORATIVE MANAGEMENT HYPOPITUITARISM

The treatment for hypopituitarism often consists of surgery or radiation therapy followed by lifelong hormone therapy. Surgery and radiation therapy for pituitary tumors are discussed earlier in this chapter on pp. 1190 and 1191. Appropriate hormone therapy is used (e.g., GH, corticosteroids, thyroid hormone, sex hormones). Hormone therapies for thyroid hormone and corticosteroids are discussed later in this chapter on pp. 1202 and 1213.

Somatropin (Omnitrope, Genotropin, Humatrope), which is recombinant human GH, is used for long-term hormone therapy in adults with GH deficiency. These patients respond well to GH replacement and experience increased energy, increased lean body mass, a feeling of well-being, and improved body image. Mild to moderate side effects of GH include fluid retention with swelling in the feet and hands, myalgia, joint pain, and headache. GH is given daily as a subcutaneous injection (preferably in the evening). The dosing is variable because it is adjusted based on symptoms, IGF-1 levels, and the development of adverse effects.

Although gonadal deficiency is not life threatening, hormone therapy is offered to improve sexual function and general well-being. This therapy is contraindicated in individuals with certain medical conditions, such as breast cancer, phlebitis, and pulmonary embolism in women and prostate cancer in men. Estrogen and progesterone replacement therapy may be indicated for hypogonadal women to treat hot flashes, vaginal dryness, and decreased libido. Hormone therapy for women is discussed in Chapter 54. Testosterone is used to treat men with gonadotropin deficiency. The benefits achieved with testoster-

PATHOPHYSIOLOGY MAP

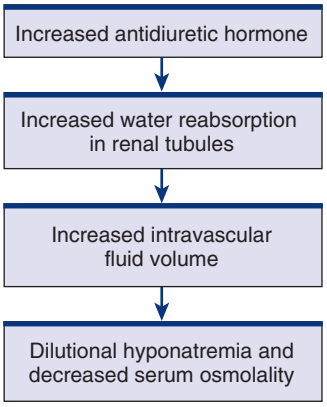

FIG. 50-3 Pathophysiology of syndrome of inappropriate antidiuretic hormone (SIADH).

one therapy include a return of male secondary sex characteristics; improvement in libido; and increased muscle mass, bone mass, and bone density. Hormone therapy for men is discussed in Chapter 55.

DISORDERS OF POSTERIOR PITUITARY GLAND

The hormones secreted by the posterior pituitary, antidiuretic hormone (ADH) and oxytocin, are produced in the hypothalamus and then transported and stored in the posterior pituitary gland. ADH, also referred to as *arginine vasopressin* (AVP) or vasopressin, plays a major role in the regulation of water balance and osmolarity (see Chapter 48).

The two primary problems associated with ADH secretion are a result of either overproduction or underproduction of ADH. Overproduction or oversecretion of ADH results in a condition known as **syndrome of inappropriate antidiuretic hormone (SIADH).** Underproduction or undersecretion of ADH results in a condition referred to as *diabetes insipidus* (DI).

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Etiology and Pathophysiology

SIADH results from abnormally high production or sustained secretion of ADH. In SIADH, ADH is released despite normal or low plasma osmolarity (Fig. 50-3). This disorder is characterized by fluid retention, serum hypoosmolality, dilutional hyponatremia, hypochloremia, concentrated urine in the presence of normal or increased intravascular volume, and normal renal function.

This syndrome occurs more commonly in older adults. SIADH has various causes (Table 50-2). The most common cause is malignancy, especially small cell lung cancer. Although SIADH tends to be self-limiting when it is caused by head trauma or drugs, it is chronic when associated with tumors or metabolic diseases.

Clinical Manifestations and Diagnostic Studies

ADH increases the permeability of the renal distal tubule and collecting duct, which leads to the reabsorption of water into the circulation. Consequently, extracellular fluid volume expands, plasma osmolality declines, glomerular filtration rate increases, and sodium levels decline (dilutional hyponatremia).[6] Hyponatremia causes muscle cramping, pain, and weakness. Initially, the patient displays thirst, dyspnea on exertion, and fatigue.

The patient with SIADH experiences low urine output and increased body weight. As the serum sodium level falls (usually below 120 mEq/L [120 mmol/L]), manifestations become more severe and include vomiting, abdominal cramps, muscle twitching, and seizures. As plasma osmolality and serum sodium levels continue to decline, cerebral edema may occur, which leads to lethargy, confusion, headache, seizures, and coma.

The diagnosis of SIADH is made by simultaneous measurements of urine and serum osmolality. Dilutional hyponatremia is indicated by a serum sodium less than 134 mEq/L, serum osmolality less than 280 mOsm/kg (280 mmol/kg), and a urine specific gravity greater than 1.025. A serum osmolality much lower than the urine osmolality indicates the inappropriate excretion of concentrated urine in the presence of dilute serum.

TABLE 50-2 CAUSES OF SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Malignant Tumors
- Small cell lung cancer
- Pancreatic cancer
- Lymphoid cancers (Hodgkin's lymphoma, non-Hodgkin's lymphoma, lymphocytic leukemia)
- Thymus cancer
- Prostate cancer
- Colorectal cancer

Central Nervous System Disorders
- Head injury (skull fracture, subdural hematoma, subarachnoid hemorrhage)
- Stroke
- Brain tumors
- Infection (encephalitis, meningitis)
- Cerebral atrophy
- Guillain-Barré syndrome
- Systemic lupus erythematosus

Drug Therapy
- carbamazepine (Tegretol)
- chlorpropamide (Diabinese)
- General anesthesia agents
- Opioids
- oxytocin
- Thiazide diuretics
- SSRI antidepressants
- Tricyclic antidepressants
- Chemotherapy drugs (vincristine [Oncovin], vinblastine [Velban], cyclophosphamide [Cytoxan])

Miscellaneous Conditions
- Hypothyroidism
- Lung infection (pneumonia, tuberculosis, lung abscess)
- Chronic obstructive pulmonary disease
- Positive pressure mechanical ventilation
- HIV
- Adrenal insufficiency

SIADH, Syndrome of inappropriate antidiuretic hormone; *SSRI,* selective serotonin reuptake inhibitor.

NURSING AND COLLABORATIVE MANAGEMENT SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

In your assessment of individuals at risk and those who have confirmed SIADH, be alert for low urine output with a high specific gravity, a sudden weight gain without edema, or a decreased serum sodium level. Monitor intake and output, vital signs, and heart and lung sounds. Observe for signs of hyponatremia, including seizures, nausea and vomiting, muscle cramping, and decreased neurologic function.

Once SIADH is diagnosed, treatment is directed at the underlying cause. Medications that stimulate the release of

ADH should be avoided or discontinued (see Table 50-2). If symptoms are mild and serum sodium is greater than 125 mEq/L (125 mmol/L), the only treatment may be a fluid restriction of 800 to 1000 mL/day. This restriction should result in gradual reductions in weight, a progressive rise in serum sodium concentration and osmolality, and symptomatic improvement.

In the acute care setting restrict the patient's total fluid intake to no more than 1000 mL/day (including that taken with medications) and obtain daily weights. Position the head of the bed flat or elevated no more than 10 degrees to enhance venous return to the heart and increase left atrial filling pressure, thereby reducing the release of ADH. Frequent turning, positioning, and range-of-motion exercise (if patient is bedridden) are important to maintain skin integrity and joint mobility. Protect the patient from injury (e.g., assist with ambulation, bed alarm) because of the potential for alterations in mental status. Implement seizure precautions. Provide the patient with frequent oral care and distractions to decrease discomfort related to thirst from the fluid restrictions.

In cases of severe hyponatremia (less than 120 mEq/L), especially in the presence of neurologic manifestations such as seizures, IV hypertonic saline solution (3% to 5%) may be slowly administered. A loop diuretic such as furosemide (Lasix) may be used to promote diuresis, but only if the serum sodium is at least 125 mEq/L (125 mmol/L) because it may promote a further loss of sodium. Because furosemide increases potassium, calcium, and magnesium losses, supplements may be needed. A fluid restriction of 500 mL/day may be indicated for those with severe hyponatremia.

Vasopressin receptor antagonists, tolvaptan (Samsca) and conivaptan (Vaprisol), are used to treat euvolemia-hyponatremia in hospitalized patients. These medications should be initiated in a closely monitored setting to prevent rapid correction of serum sodium.

Assist the patient with chronic SIADH in self-management of the treatment regimen. In chronic SIADH, a fluid restriction of 800 to 1000 mL/day is recommended. Because this degree of restriction may be difficult, demeclocycline (Declomycin) may be administered. This drug blocks the effect of ADH on the renal tubules, resulting in a more dilute urine. The use of ice chips or sugarless chewing gum helps to decrease thirst. Have the patient weigh daily to monitor changes in fluid balance. Teach the patient to supplement the diet with sodium and potassium, especially if loop diuretics are also prescribed. Solutions of these electrolytes must be well diluted to prevent gastrointestinal (GI) irritation or damage. They are best taken at mealtime to allow mixing with and dilution by food. Teach the patient the symptoms of fluid and electrolyte imbalances, especially those involving sodium and potassium (see Chapter 17).

DIABETES INSIPIDUS

Etiology and Pathophysiology

Diabetes insipidus (DI) is caused by a deficiency of production or secretion of ADH or a decreased renal response to ADH. The decrease in ADH results in fluid and electrolyte imbalances caused by increased urine output and increased plasma osmolality (Fig. 50-4). Depending on the cause, DI may be transient or a chronic, lifelong condition.

There are several types of DI (Table 50-3). Central DI is the most common form.

PATHOPHYSIOLOGY MAP

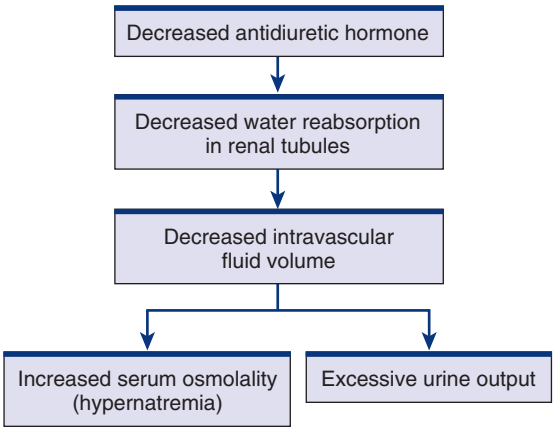

FIG. 50-4 Pathophysiology of diabetes insipidus (DI).

TABLE 50-3 TYPES OF DIABETES INSIPIDUS

Type	Etiology
Central (neurogenic) DI	Results from an interference with ADH synthesis, transport, or release *Examples:* Brain tumor, head injury, brain surgery, CNS infections
Nephrogenic DI	Results from inadequate renal response to ADH despite presence of adequate ADH *Examples:* Drug therapy (especially lithium), renal damage, hereditary renal disease
Primary DI	Results from excessive water intake *Examples:* Structural lesion in thirst center, psychologic disorder

Clinical Manifestations

DI is characterized by polydipsia and polyuria.[6] The primary characteristic is the excretion of large quantities of urine (2 to 20 L/day) with a very low specific gravity (less than 1.005) and urine osmolality of less than 100 mOsm/kg (100 mmol/kg). Serum osmolality is elevated (usually greater than 295 mOsm/kg [295 mmol/kg]) because of hypernatremia caused by pure water loss in the kidneys. Most patients compensate for fluid loss by drinking large amounts of water so that serum osmolality remains normal or is moderately elevated. The patient may be fatigued from nocturia and experience generalized weakness.

The onset of central DI is usually acute and accompanied by excessive fluid loss. After intracranial surgery, central DI has a triphasic pattern: the acute phase with an abrupt onset of polyuria, an interphase in which urine volume normalizes, and a third phase in which central DI is permanent. The third phase occurs within 10 to 14 days postoperatively. Central DI that results from head trauma is often self-limiting and improves with treatment of the underlying problem. DI following cranial surgery is more likely to be permanent. Although the clinical manifestations of nephrogenic DI are similar to those of central DI, the onset and amount of fluid loss are less dramatic.

If oral fluid intake cannot keep up with urinary losses, severe dehydration results. This is manifested by poor tissue turgor, hypotension, tachycardia, and hypovolemic shock. In addition, the patient may show central nervous system (CNS) manifesta-

tions, ranging from irritability and mental dullness to coma, related to increasing serum osmolality and hypernatremia.

Diagnostic Studies

Patients with DI excrete dilute urine at a rate greater than 200 mL/hr with a specific gravity of less than 1.005. Identification of central DI requires a water deprivation test. Before the test, body weight, and urine osmolality, volume, and specific gravity are measured. The patient is deprived of water for 8 to 12 hours, and then given desmopressin acetate (DDAVP) subcutaneously or nasally. Patients with central DI exhibit a dramatic increase in urine osmolality, from 100 to 600 mOsm/kg, and a significant decrease in urine volume. The patient with nephrogenic DI will not be able to increase urine osmolality to greater than 300 mOsm/kg.

Another test to differentiate central DI from nephrogenic DI is to measure the level of ADH after an analog of ADH (e.g., desmopressin) is given. If the cause is central DI, the kidneys will respond to the hormone by concentrating urine. If the kidneys do not respond in this way, then the cause is nephrogenic.

NURSING AND COLLABORATIVE MANAGEMENT
DIABETES INSIPIDUS

Nursing management of the patient with DI includes early detection, maintenance of adequate hydration, and patient teaching for long-term management. A therapeutic goal is maintenance of fluid and electrolyte balance.

For central DI, fluid and hormone therapy is the cornerstone of treatment. Fluids are replaced orally or IV, depending on the patient's condition and ability to drink copious amounts of fluids. In acute DI, IV hypotonic saline or dextrose 5% in water (D_5W) is given and titrated to replace urine output. If IV glucose solutions are used, monitor serum glucose levels because hyperglycemia and glycosuria can lead to osmotic diuresis, which increases the fluid volume deficit. Monitoring of blood pressure (BP), heart rate, and urine output and specific gravity is essential and may be required hourly in the patient who is acutely ill. Monitor the level of consciousness and for signs of acute dehydration by assessing alertness, response to stimuli, mucous membranes, tachycardia, and skin turgor. Maintain an accurate record of intake and output and daily weights to determine fluid volume status. Adjustments in fluid replacement should be made accordingly.

DDAVP, an analog of ADH, is the hormone replacement of choice for central DI. Other ADH replacement drugs include aqueous vasopressin (Pitressin) or lysine vasopressin (Diapid). DDAVP can be given orally, IV, subcutaneously, or as a nasal spray. Assess the response to DDAVP (e.g., weight gain, headache, depression, restlessness, hyponatremia). Monitor pulse, BP, level of consciousness, fluid intake and output, and urine specific gravity. Teach the patient about the need for close follow-up. Chlorpropamide (Diabinese) and carbamazepine (Tegretol) are used to help decrease thirst associated with central DI.

Because the kidney is unable to respond to ADH in nephrogenic DI, hormone therapy has little effect. Instead, the treatment includes dietary measures (low-sodium diet) and thiazide diuretics (e.g., hydrochlorothiazide [HydroDIURIL], chlorothiazide [Diuril]), which may reduce flow to the ADH-sensitive distal nephrons. Limiting sodium intake to no more than 3 g/day often helps decrease urine output. When a low-sodium diet and thiazide drugs are not effective, indomethacin (Indocin) may be prescribed. Indomethacin, a nonsteroidal antiinflammatory drug (NSAID), helps increase renal responsiveness to ADH.

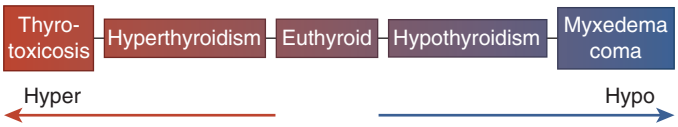

FIG. 50-5 Continuum of thyroid dysfunction.

DISORDERS OF THYROID GLAND

Alterations in thyroid function are among the most common endocrine disorders. The thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3), regulate energy metabolism and growth and development. Disorders of the thyroid gland include goiter, benign and malignant nodules, inflammation, hyperthyroidism, and hypothyroidism (Fig. 50-5).

GOITER

A **goiter** is an enlarged thyroid gland. In a person with a goiter the thyroid cells are stimulated to grow, which may result in an overactive thyroid (hyperthyroidism) or an underactive thyroid (hypothyroidism). The most common cause of goiter worldwide is a lack of iodine in the diet. In the United States, where most people use iodized salt, goiter is more often due to the overproduction or underproduction of thyroid hormones or to nodules that develop in the gland itself. *Goitrogens* (foods or drugs that contain thyroid-inhibiting substances) can cause goiter[7] (Table 50-4).

A nontoxic goiter is a diffuse enlargement of the thyroid gland that does not result from a malignancy or inflammatory process. Normal levels of thyroid hormone are associated with this type of goiter. *Nodular goiters* are thyroid hormone–secreting nodules that function independent of TSH stimulation. There may be multiple nodules (multinodular goiter) or a single nodule (solitary autonomous nodule). The nodules are usually benign follicular adenomas. If these nodules are associated with hyperthyroidism, they are termed *toxic nodular goiters*. This type of goiter is commonly found in patients with Graves' disease (Fig. 50-6). Toxic nodular goiters occur equally in men and women. Although they can appear at any age, the frequency is greatest in people over 40 years of age.

TABLE 50-4 GOITROGENS

Thyroid Inhibitors
- propylthiouracil (PTU)
- methimazole (Tapazole)
- Iodine in large doses

Other Drugs
- Sulfonamides
- Salicylates
- *p*-Aminosalicylic acid
- lithium
- amiodarone (Cordarone)

Foods*
- Broccoli
- Brussels sprouts
- Cabbage
- Cauliflower
- Kale
- Mustard
- Peanuts
- Turnips

*List is not all-inclusive.

FIG. 50-6 Exophthalmos and goiter of Graves' disease.

In a person with a goiter, TSH and T_4 levels are measured to determine whether a goiter is associated with normal thyroid function, hyperthyroidism, or hypothyroidism. Thyroid antibodies (e.g., thyroid peroxidase [TPO] antibody) are measured to assess for *thyroiditis* (inflammation of the thyroid). Treatment with thyroid hormone may prevent further thyroid enlargement. Surgery is used to remove large goiters. Goiter as a clinical manifestation of thyroid disorders is further discussed in the following sections.

THYROIDITIS

Thyroiditis, an inflammation of the thyroid gland, is a frequent cause of goiter. *Subacute granulomatous thyroiditis* is thought to be caused by a viral infection. *Acute thyroiditis* is due to bacterial or fungal infection. Subacute and acute forms of thyroiditis have an abrupt onset. The patient complains of pain localized in the thyroid or radiating to the throat, ears, or jaw.[8] Other systemic manifestations include fever, chills, sweats, and fatigue.

Hashimoto's thyroiditis (chronic autoimmune thyroiditis) results in hypothyroidism caused by the destruction of thyroid tissue by antibodies. It is the most common cause of hypothyroid goiters in the United States. Factors placing an individual at higher risk include female gender, a positive family history, older age, and white ethnicity. The goiter, which is the hallmark of Hashimoto's thyroiditis, may develop gradually or rapidly (see eFig. 50-1 available on the website for this chapter). If the thyroid gland enlarges rapidly, structures in the neck (e.g., trachea and laryngeal nerves) may become compressed, thus changing the voice and affecting breathing.

Silent, painless thyroiditis, which may be early Hashimoto's thyroiditis, can occur in postpartum women. This condition, which is usually seen in the first 6 months after delivery, may be due to an autoimmune reaction to fetal cells in the mother's thyroid gland.

T_4 and T_3 levels are initially elevated in subacute, acute, and silent thyroiditis but become depressed with time. In chronic Hashimoto's thyroiditis, thyroid hormone levels are usually low and the TSH level is high. Suppression of radioactive iodine uptake (RAIU) is seen in subacute and silent thyroiditis. Antithyroid antibodies are present in Hashimoto's thyroiditis.

Recovery from acute or subacute thyroiditis may be complete in weeks or months without any treatment. If the thyroiditis is bacterial in origin, treatment may include specific antibiotics or surgical drainage. In the subacute and acute forms, NSAIDs (aspirin or naproxen [Aleve]) are used to relieve symptoms. With more severe pain, corticosteroids (e.g., prednisone up to 40 mg/day) are used to relieve discomfort. This treatment may be required for several months and then should be withdrawn gradually.[9] Propranolol (Inderal) or atenolol (Tenormin) may be used to treat the cardiovascular symptoms related to a hyperthyroid condition. Thyroid hormone therapy is indicated if the patient is hypothyroid.

Nursing care of the patient with thyroiditis includes patient teaching regarding the disease process and course of treatment. Stress the importance of not abruptly discontinuing medications. Instruct the patient to remain under close health care supervision so that progress can be monitored. In addition, teach the patient to report to the health care provider any change in symptoms, such as difficulty breathing or swallowing, swelling to face and extremities, or rapid weight gain or loss.

The patient with Hashimoto's thyroiditis is at risk for other autoimmune diseases such as Addison's disease, pernicious anemia, or Graves' disease. Teach the patient the signs and symptoms of these disorders, particularly Addison's disease. Instruct the patient receiving thyroid hormone about the expected side effects of these drugs and measures to manage them (see p. 1202).

HYPERTHYROIDISM

Hyperthyroidism is hyperactivity of the thyroid gland with sustained increase in synthesis and release of thyroid hormones. Hyperthyroidism occurs in women more than men, with the highest frequency in persons 20 to 40 years old. The most common form of hyperthyroidism is Graves' disease. Other causes include toxic nodular goiter, thyroiditis, excess iodine intake, pituitary tumors, and thyroid cancer.

The term *thyrotoxicosis* refers to the physiologic effects or clinical syndrome of hypermetabolism that results from excess circulating levels of T_4, T_3, or both.[10] Hyperthyroidism and thyrotoxicosis usually occur together, as seen in Graves' disease.

Etiology and Pathophysiology

Graves' Disease. **Graves' disease** is an autoimmune disease of unknown etiology characterized by diffuse thyroid enlargement and excessive thyroid hormone secretion. Graves' disease accounts for up to 80% of the cases of hyperthyroidism. Women are five times more likely than men to develop Graves' disease. Precipitating factors such as insufficient iodine supply, infection, and stressful life events may interact with genetic factors to cause Graves' disease. Cigarette smoking increases the risk of Graves' disease and the development of eye problems associated with the disease.[11]

In Graves' disease the patient develops antibodies to the TSH receptor. These antibodies attach to the receptors and stimulate the thyroid gland to release T_3, T_4, or both. The excessive release of thyroid hormones leads to the clinical manifestations associated with thyrotoxicosis. The disease is characterized by remissions and exacerbations, with or without treatment. It may progress to destruction of the thyroid tissue, causing hypothyroidism.

TABLE 50-5 CLINICAL MANIFESTATIONS OF THYROID DYSFUNCTION

Hyperfunction	Hypofunction
Cardiovascular System	
• Systolic hypertension	• Increased capillary fragility
• Increased rate and force of cardiac contractions	• Decreased rate and force of contractions
• Bounding, rapid pulse	• Varied changes in blood pressure
• Increased cardiac output	• Cardiac hypertrophy
• Cardiac hypertrophy	• Distant heart sounds
• Systolic murmurs	• Anemia
• Dysrhythmias	• Tendency to develop heart failure, angina, myocardial infarction
• Palpitations	
• Atrial fibrillation (more common in the older adult)	
• Angina	
Respiratory System	
• Increased respiratory rate	• Dyspnea
• Dyspnea on mild exertion	• Decreased breathing capacity
Gastrointestinal System	
• Increased appetite, thirst	• Decreased appetite
• Weight loss	• Nausea and vomiting
• Increased peristalsis	• Weight gain
• Diarrhea, frequent defecation	• Constipation
• Increased bowel sounds	• Distended abdomen
• Splenomegaly	• Enlarged, scaly tongue
• Hepatomegaly	• Celiac disease
Integumentary System	
• Warm, smooth, moist skin	• Dry, thick, inelastic, cold skin
• Thin, brittle nails detached from nail bed (onycholysis)	• Thick, brittle nails
• Hair loss (may be patchy)	• Dry, sparse, coarse hair
• Clubbing of fingers (thyroid acropachy) (see Fig. 50-7)	• Poor turgor of mucosa
• Palmar erythema	• Generalized interstitial edema
• Fine silky hair	• Puffy face
• Premature graying (in men)	• Decreased sweating
• Diaphoresis	• Pallor
• Vitiligo	
• Pretibial myxedema (infiltrative dermopathy)	

Hyperfunction	Hypofunction
Musculoskeletal System	
• Fatigue	• Fatigue
• Muscle weakness	• Weakness
• Proximal muscle wasting	• Muscular aches and pains
• Dependent edema	• Slow movements
• Osteoporosis	• Arthralgia
Nervous System	
• Difficulty focusing eyes	• Apathy
• Nervousness	• Lethargy
• Fine tremor (of fingers and tongue)	• Fatigue
• Insomnia	• Forgetfulness
• Lability of mood, delirium	• Slowed mental processes
• Restlessness	• Hoarseness
• Personality changes of irritability, agitation	• Slow, slurred speech
• Exhaustion	• Prolonged relaxation of deep tendon muscles
• Hyperactive deep-tendon reflexes	• Stupor, coma
• Depression, fatigue, apathy (in the older adult)	• Paresthesias
• Lack of ability to concentrate	• Anxiety, depression
• Stupor, coma	
Reproductive System	
• Menstrual irregularities	• Prolonged menstrual periods or amenorrhea
• Amenorrhea	• Decreased libido
• Decreased libido	• Infertility
• Impotence in men	
• Gynecomastia in men	
• Decreased fertility	
Other	
• Intolerance to heat	• Increased susceptibility to infection
• Elevated basal temperature	• Increased sensitivity to opioids, barbiturates, anesthesia
• Lid lag, stare	• Intolerance to cold
• Eyelid retraction	• Decreased hearing
• Exophthalmos	• Sleepiness
• Goiter (see Fig. 50-6)	• Goiter
• Rapid speech	

Clinical Manifestations

Clinical manifestations of hyperthyroidism are related to the effect of excess circulating thyroid hormone. It directly increases metabolism and tissue sensitivity to stimulation by the sympathetic nervous system.

Palpation of the thyroid gland may reveal a goiter. When the thyroid gland is excessively large, a goiter may be noted on inspection. Auscultation of the thyroid gland may reveal bruits, a reflection of increased blood supply. Another common finding is *ophthalmopathy,* a term used to describe abnormal eye appearance or function. A classic finding in Graves' disease is **exophthalmos,** a protrusion of the eyeballs from the orbits that is usually bilateral (see Fig. 50-6). Exophthalmos results from increased fat deposits and fluid (edema) in the orbital tissues and ocular muscles. The increased pressure forces the eyeballs outward. The upper lids are usually retracted and elevated, with the sclera visible above the iris. When the eyelids do not close completely, the exposed corneal surfaces become dry and irritated. Serious consequences, such as corneal ulcers and eventual loss of vision, can occur. The changes in the ocular muscles result in muscle weakness, causing diplopia.

Other manifestations of thyroid hyperfunction are summarized in Table 50-5. Abnormal laboratory findings are listed in Table 50-6. A patient in the early stages of hyperthyroidism may exhibit only weight loss and increased nervousness. *Acropachy* (clubbing of the digits) may occur with advanced disease (Fig. 50-7). Manifestations (e.g., palpitations, tremors, weight loss) in older adults with hyperthyroidism do not differ significantly from those of younger adults (Table 50-7). In older patients with reports of confusion and agitation, dementia may be suspected and delay the diagnosis.

Complications

Thyrotoxicosis (also called *thyrotoxic crisis* or *thyroid storm*) is an acute, severe, and rare condition that occurs when excessive amounts of thyroid hormones are released into the circulation. Although it is considered a life-threatening emergency, death is rare when treatment is initiated early. Thyrotoxicosis is thought to result from stressors (e.g., infection, trauma, surgery) in a patient with preexisting hyperthyroidism, either diagnosed or undiagnosed. Patients particularly prone to thyrotoxicosis are those having a thyroidectomy, since manipulation of the

TABLE 50-6 LABORATORY RESULTS FOR HYPERTHYROID AND HYPOTHYROID PATIENTS

N, Normal; +, positive.

hyperactive thyroid gland results in an increase in hormones released.[11]

In thyrotoxicosis, all the symptoms of hyperthyroidism are prominent and severe. Manifestations include severe tachycardia, heart failure, shock, hyperthermia (up to 105.3° F [40.7° C]), restlessness, irritability, seizures, abdominal pain, vomiting, diarrhea, delirium, and coma. Treatment is aimed at reducing circulating thyroid hormone levels and the clinical manifestations with appropriate drug therapy. Supportive therapy is directed at managing respiratory distress, reducing fever, replacing fluid, and eliminating or managing the initiating stressor(s).

Diagnostic Studies

The two primary laboratory findings used to confirm the diagnosis of hyperthyroidism are decreased TSH levels and elevated free thyroxine (free T_4) levels. Total T_3 and T_4 levels may also be assessed, but they are not as definitive. Total T_3 and T_4 determine both free and bound (to protein) hormone levels. The free hormone is the only biologically active form of these hormones.

The RAIU test is used to differentiate Graves' disease from other forms of thyroiditis. The patient with Graves' disease shows a diffuse, homogeneous uptake of 35% to 95%, whereas the patient with thyroiditis shows an uptake of less than 2%. The person with a nodular goiter has an uptake in the high normal range.

TABLE 50-7 COMPARISON OF HYPERTHYROIDISM IN YOUNGER AND OLDER ADULTS

	Younger Adult	Older Adult
Common causes	Graves' disease in >90% of cases	Graves' disease or toxic nodular goiter
Common symptoms	Nervousness, irritability, weight loss, heat intolerance, warm moist skin	Anorexia, weight loss, apathy, lassitude, depression, confusion
Goiter	Present in >90% of cases	Present in about 50% of cases
Ophthalmopathy	Exophthalmos (see Fig. 50-6) present in 20%-40% of cases	Exophthalmos less common
Cardiac features	Tachycardia and palpitations common, but without heart failure	Angina, dysrhythmia (especially atrial fibrillation), heart failure may occur

FIG. 50-7 Thyroid acropachy. Digital clubbing and swelling of fingers.

Collaborative Care

The goal of management of hyperthyroidism is to block the adverse effects of excessive thyroid hormone, suppress oversecretion of thyroid hormone, and prevent complications. There are several treatment options, including antithyroid medications, radioactive iodine therapy, and surgical intervention (Table 50-8). The choice of treatment is influenced by the patient's age and preferences, coexistence of other diseases, and pregnancy status.

Drug Therapy. Drugs used in the treatment of hyperthyroidism include antithyroid drugs, iodine, and β-adrenergic blockers. These drugs are useful in the treatment of thyrotoxic states, but they are not considered curative. Radiation therapy or surgery may ultimately be required.

Antithyroid Drugs. The first-line antithyroid drugs are propylthiouracil (PTU) and methimazole (Tapazole).[12] These drugs

  - methimazole (Tapazole)
  - propylthiouracil (PTU)
- Iodine (Lugol's solution, SSKI)
- β-Adrenergic receptor blockers
  - propranolol (Inderal)
  - atenolol (Tenormin) or metoprolol (Toprol)

Radiation Therapy
- Radioactive iodine

Surgical Therapy
- Subtotal thyroidectomy

Nutritional Therapy
- High-calorie, high-protein diet
- Frequent meals

SSKI, Saturated solution of potassium iodine; *TSH,* thyroid-stimulating hormone.

inhibit the synthesis of thyroid hormones. Indications for the use of antithyroid drugs include Graves' disease in the young patient, hyperthyroidism during pregnancy, and the need to achieve a euthyroid state before surgery or radiation therapy. PTU is generally used for patients who are in their first trimester of pregnancy, have an adverse reaction to methimazole, or require a rapid reduction in symptoms. PTU is also considered first line in thyrotoxicosis, since it also blocks the peripheral conversion of T_4 to T_3. The advantage of PTU is that it achieves the therapeutic goal of being euthyroid more quickly, but it must be taken three times per day. In contrast, methimazole is given in a single daily dose.

Individuals vary, but improvement usually begins 1 to 2 weeks after the start of drug therapy. Good results are usually seen within 4 to 8 weeks. Therapy is usually continued for 6 to 15 months to allow for spontaneous remission, which occurs in 20% to 40% of patients. Emphasize to the patient the importance of adherence to the drug regimen. Abrupt discontinuation of drug therapy can result in a return of hyperthyroidism.

Iodine. Iodine is used with other antithyroid drugs to prepare the patient for thyroidectomy or for treatment of thyrotoxicosis. The administration of iodine in large doses rapidly inhibits synthesis of T_3 and T_4 and blocks the release of these hormones into circulation. It also decreases the vascularity of the thyroid gland, making surgery safer and easier. The maximal effect of iodine is usually seen within 1 to 2 weeks. Because of a reduction in the therapeutic effect, long-term iodine therapy is not effective in controlling hyperthyroidism. Iodine is available in the form of saturated solution of potassium iodine (SSKI) and Lugol's solution.

β-Adrenergic Blockers. β-Adrenergic blockers are used for symptomatic relief of thyrotoxicosis. These drugs block the effects of sympathetic nervous stimulation, thereby decreasing tachycardia, nervousness, irritability, and tremors. Propranolol is usually administered with other antithyroid agents. Atenolol is the preferred β-adrenergic blocker for use in the hyperthyroid patient with asthma or heart disease.

Radioactive Iodine Therapy. Radioactive iodine (RAI) therapy is the treatment of choice for most nonpregnant adults. RAI damages or destroys thyroid tissue, thus limiting thyroid hormone secretion. RAI has a delayed response, and the maximum effect may not be seen for up to 3 months. For this reason, the patient is usually treated with antithyroid drugs and propranolol before and for 3 months after the initiation of RAI until the effects of radiation become apparent. Although RAI is usually effective, it has a high incidence of posttreatment hypothyroidism (80% of adequately treated persons), resulting in the need for lifelong thyroid hormone therapy. Teach the patient and the family about the symptoms of hypothyroidism and to seek medical help if these symptoms occur.

RAI therapy is usually administered on an outpatient basis. A pregnancy test is done before initiation of therapy on all women who experience menstrual cycles. Instruct the patient that radiation thyroiditis and parotiditis are possible and may cause dryness and irritation of the mouth and throat. Relief may be obtained with frequent sips of water, ice chips, or a salt and soda gargle three or four times per day. This gargle is made by dissolving 1 tsp of salt and 1 tsp of baking soda in 2 cups of warm water. The discomfort should subside in 3 to 4 days. A mixture of antacid (Mylanta or Maalox), diphenhydramine (Benadryl), and viscous lidocaine can be used to swish and spit, increasing patient comfort when eating. To limit radiation exposure to others, instruct the patient receiving RAI on the importance of home precautions, including (1) using private toilet facilities if possible and flushing two or three times after each use; (2) separately laundering towels, bed linens, and clothes daily at home; (3) not preparing food for others that requires prolonged handling with bare hands; and (4) avoiding being close to pregnant women or children for 7 days after therapy.

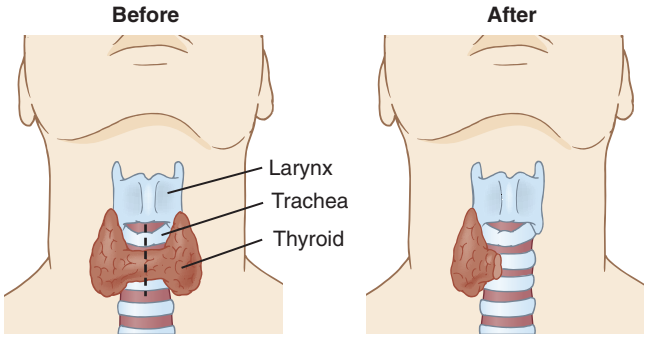

FIG. 50-8 Subtotal thyroidectomy. Part of the thyroid gland is removed.

Surgical Therapy. Thyroidectomy is indicated for individuals who have (1) a large goiter causing tracheal compression, (2) been unresponsive to antithyroid therapy, or (3) thyroid cancer (Fig. 50-8). Additionally, surgery may be done when an individual is not a candidate for RAI. One advantage that thyroidectomy has over RAI is a more rapid reduction in T_3 and T_4 levels. A *subtotal thyroidectomy* is often the preferred surgical procedure and involves the removal of a significant portion (90%) of the thyroid gland.

An endoscopic thyroidectomy is a minimally invasive procedure. Several small incisions are made, and a scope is inserted. Instruments are passed through the scope to remove thyroid tissue or nodules. Endoscopic thyroidectomy is an appropriate procedure for patients with small nodules (less than 3 cm) and no evidence of malignancy. Advantages of endoscopic thyroidectomy over open thyroidectomy include less scarring, less pain, and a faster return to normal activity.

Nutritional Therapy. With the increased metabolic rate in hyperthyroid patients, there is a high potential for the patient to have a nutritional deficit. A high-calorie diet (4000 to 5000 cal/day) may be ordered to satisfy hunger, prevent tissue breakdown, and decrease weight loss. This can be accomplished with six full meals a day and snacks high in protein, carbohydrates, minerals, and vitamins. The protein content should be 1 to 2 g/kg of ideal body weight. Increase carbohydrate intake to compensate for increased metabolism. Carbohydrates provide energy and decrease the use of body-stored protein. Teach the patient to avoid highly seasoned and high-fiber foods because these foods can further stimulate the already hyperactive GI tract. Instruct the patient to avoid caffeine-containing liquids such as coffee, tea, and cola to decrease the restlessness and sleep disturbances associated with these fluids. Refer the patient to a dietitian for help in meeting individual nutritional needs.

NURSING MANAGEMENT HYPERTHYROIDISM

NURSING ASSESSMENT

Subjective and objective data that should be obtained from an individual with hyperthyroidism are presented in Table 50-9.

TABLE 50-9 NURSING ASSESSMENT

Hyperthyroidism

Subjective Data

Important Health Information

Past health history: Preexisting goiter; recent infection or trauma, immigration from iodine-deficient area, autoimmune disease

Medications: Thyroid hormones, herbal therapies that may contain thyroid hormone

Functional Health Patterns

Health perception–health management: Positive family history of thyroid or autoimmune disorders

Nutritional-metabolic: Iodine intake; weight loss; increased appetite, thirst; nausea, vomiting

Elimination: Diarrhea; polyuria; sweating

Activity-exercise: Dyspnea on exertion; palpitations; muscle weakness, fatigue

Sleep-rest: Insomnia

Cognitive-perceptual: Chest pain; nervousness; heat intolerance; pruritus

Sexuality-reproductive: Decreased libido; impotence; gynecomastia (in men); amenorrhea (in women)

Coping–stress tolerance: Emotional lability, irritability, restlessness, personality changes, delirium

Objective Data

General Observation

Agitation, rapid speech and body movements; anxiety, restlessness, hyperthermia, enlarged or nodular thyroid gland

Eyes

Exophthalmos, eyelid retraction; infrequent blinking

Integumentary

Warm, diaphoretic, velvety skin; thin, loose nails; fine, silky hair and hair loss; palmar erythema; clubbing; white pigmentation of skin (vitiligo), diffuse edema of legs and feet

Respiratory

Tachypnea, dyspnea on exertion

Cardiovascular

Tachycardia, bounding pulse, systolic murmurs, dysrhythmias, hypertension, bruit over the thyroid gland

Gastrointestinal

Increased bowel sounds; increased appetite, diarrhea, weight loss, hepatosplenomegaly

Neurologic

Hyperreflexia; diplopia; fine tremors of hands, tongue, eyelids

Musculoskeletal

Muscle wasting

Reproductive

Menstrual irregularities, infertility; impotence, gynecomastia in men

Possible Diagnostic Findings

↑ T_3, ↑ T_4; ↑ T_3 resin uptake; ↓ or undetectable TSH; chest x-ray showing enlarged heart; ECG findings of tachycardia, atrial fibrillation

TSH, Thyroid-stimulating hormone.

NURSING DIAGNOSES

Nursing diagnoses for the patient with hyperthyroidism include, but are not limited to, the following:

- Activity intolerance *related to* fatigue and heat intolerance
- Imbalanced nutrition: less than body requirements *related to* hypermetabolism and inadequate food intake

Additional information on nursing diagnoses is presented in eNursing Care Plan 50-1 for the patient with hyperthyroidism (available on the website for this chapter).

PLANNING

The overall goals are that the patient with hyperthyroidism will (1) experience relief of symptoms, (2) have no serious complications related to the disease or treatment, (3) maintain nutritional balance, and (4) cooperate with the therapeutic plan.

NURSING IMPLEMENTATION

ACUTE INTERVENTION. Individuals who have hyperthyroidism are usually treated in an outpatient setting. However, patients who develop acute thyrotoxicosis or those who undergo thyroidectomy require hospitalization and acute care.

Acute Thyrotoxicosis. Acute thyrotoxicosis is a systemic syndrome that requires aggressive treatment, often in an intensive care unit. Administer medications (previously discussed) that block thyroid hormone production and the sympathetic nervous system. Provide supportive therapy, including monitoring for cardiac dysrhythmias and decompensation, ensuring adequate oxygenation, and administering IV fluids to replace fluid and electrolyte losses. This is especially important in the patient who experiences fluid losses due to vomiting and diarrhea.

Ensuring adequate rest may be a challenge because of the patient's irritability and restlessness. Provide a calm, quiet room because increased metabolism and sensitivity of the sympathetic nervous system causes sleep disturbances. Other interventions may include (1) placing the patient in a cool room away from very ill patients and noisy, high-traffic areas; (2) using light bed coverings and changing the linen frequently if the patient is diaphoretic; and (3) encouraging and assisting with exercise involving large muscle groups (tremors can interfere with small-muscle coordination) to allow the release of nervous tension and restlessness. It is important to establish a supportive, trusting relationship to facilitate coping by a patient who is irritable, restless, and anxious.

If exophthalmos is present, there is a potential for corneal injury related to irritation and dryness. The patient may have orbital pain. Nursing interventions to relieve eye discomfort and prevent corneal ulceration include applying artificial tears to soothe and moisten conjunctival membranes. Salt restriction may help reduce periorbital edema. Elevate the patient's head to promote fluid drainage from the periorbital area. The patient should sit upright as much as possible.

Dark glasses reduce glare and prevent irritation from smoke, air currents, dust, and dirt. If the eyelids cannot be closed, lightly tape them shut for sleep. To maintain flexibility, teach the patient to exercise the intraocular muscles several times a day by turning the eyes in the complete range of motion. Good grooming can help reduce the loss of self-esteem from an altered body image. If the exophthalmos is severe, treatment options include corticosteroids, radiation of retroorbital tissues, orbital decompression, or corrective lid or muscle surgery.

Thyroid Surgery. When subtotal thyroidectomy is the treatment of choice, the patient must be adequately prepared to avoid postoperative complications. Before surgery, antithyroid drugs, iodine, and β-adrenergic blockers may be administered to achieve a euthyroid state. Iodine reduces vascularization of the thyroid gland, reducing the risk of hemorrhage. Iodine is mixed with water or juice, sipped through a straw, and administered after meals. Assess the patient for signs of iodine toxicity such as swelling of the buccal mucosa and other mucous mem-

branes, excessive salivation, nausea and vomiting, and skin reactions. If toxicity occurs, discontinue iodine administration and notify the health care provider.

Preoperatively, teach the patient about comfort and safety measures. Teach the patient the importance of performing leg exercises. Instruct the patient in how to support the head manually while turning in bed, since this maneuver minimizes stress on the suture line after surgery. The patient should practice range-of-motion exercises of the neck. Explain routine postoperative care such as IV infusions. Tell the patient that talking is likely to be difficult for a short time after surgery.

Postoperative Care. Postoperative complications include hypothyroidism, damage to or inadvertent removal of parathyroid glands causing hypoparathyroidism and hypocalcemia, hemorrhage, injury to the recurrent or superior laryngeal nerve, thyrotoxicosis, and infection.[13] Recurrent laryngeal nerve damage leads to vocal cord paralysis. If both cords are paralyzed, spastic airway obstruction will occur, requiring an immediate tracheostomy.

SAFETY ALERT

- Although not common, airway obstruction after thyroid surgery is an emergency situation.
- Oxygen, suction equipment, and a tracheostomy tray should be readily available in the patient's room.

Respiration may also become difficult because of excess swelling of the neck tissues, hemorrhage, and hematoma formation. *Laryngeal stridor* (harsh, vibratory sound) may occur during inspiration and expiration as a result of edema of the laryngeal nerve. Laryngeal stridor may also be related to tetany, which occurs if the parathyroid glands are removed or damaged during surgery, leading to hypocalcemia. To treat tetany, IV calcium salts (e.g., calcium gluconate, calcium gluceptate) should be available.

Important nursing interventions after a thyroidectomy include the following:

- Assess the patient every 2 hours for 24 hours for signs of hemorrhage or tracheal compression such as irregular breathing, neck swelling, frequent swallowing, sensations of fullness at the incision site, choking, and blood on the anterior or posterior dressings.
- Place the patient in a semi-Fowler's position and support the patient's head with pillows. Avoid flexion of the neck and any tension on the suture lines.[13]
- Monitor vital signs and calcium levels. Complete the initial assessment by checking for signs of tetany secondary to hypoparathyroidism (e.g., tingling in toes, fingers, around the mouth; muscular twitching; apprehension) and by evaluating difficulty in speaking and hoarseness. Monitor Trousseau's sign and Chvostek's sign (see Chapter 17, Fig. 17-15). Expect some hoarseness for 3 or 4 days after surgery because of edema.
- Control postoperative pain by giving medication.

If postoperative recovery is uneventful, the patient ambulates within hours after surgery, is permitted to take fluid as soon as tolerated, and eats a soft diet the day after surgery.

The appearance of the incision may be distressing to the patient. Reassure the patient that the scar will fade in color and eventually look like a normal neck wrinkle. A scarf, jewelry, a high collar, or other covering can effectively camouflage the scar.

AMBULATORY AND HOME CARE. The patient, caregiver, and family need to be aware that thyroid hormone balance should be monitored periodically. Most patients experience a period of relative hypothyroidism soon after surgery because of the substantial reduction in the size of the thyroid. However, the remaining tissue usually hypertrophies over time and recovers the capacity to produce hormones. The administration of thyroid hormone is avoided because the exogenous hormone inhibits pituitary production of TSH and delays or prevents the restoration of normal gland function and tissue regeneration.

To prevent weight gain, caloric intake must be reduced substantially below the amount that was required before surgery. Adequate iodine is necessary to promote thyroid function, but excesses can inhibit the thyroid gland. Seafood once or twice a week or normal use of iodized salt should provide sufficient iodine intake. Encourage regular exercise to stimulate the thyroid gland. Teach the patient to avoid high environmental temperatures because they inhibit thyroid regeneration.

Regular follow-up care is necessary. The patient should see the health care provider biweekly for a month and then at least semiannually to assess thyroid function. If a complete thyroidectomy has been performed, instruct the patient about the need for lifelong thyroid hormone replacement. Teach the patient the signs and symptoms of progressive thyroid failure and to seek medical care if these develop. Hypothyroidism is relatively easy to manage with oral administration of thyroid replacement.

EVALUATION

The expected outcomes are that the patient with hyperthyroidism will

- Experience relief of symptoms
- Have no serious complications related to the disease or treatment
- Cooperate with the therapeutic plan

Additional information on expected outcomes is presented in eNursing Care Plan 50-1 for the patient with hyperthyroidism (available on the website for this chapter).

HYPOTHYROIDISM

Hypothyroidism is a deficiency of thyroid hormone that causes a general slowing of the metabolic rate. About 4% of the U.S. population has mild hypothyroidism, with about 0.3% having more severe disease.[14] Hypothyroidism is more common in women than men.

Etiology and Pathophysiology

Hypothyroidism can be classified as primary or secondary. *Primary hypothyroidism* is caused by destruction of thyroid tissue or defective hormone synthesis. *Secondary hypothyroidism* is caused by pituitary disease with decreased TSH secretion or hypothalamic dysfunction with decreased thyrotropin-releasing hormone (TRH) secretion. Hypothyroidism may also be transient and related to thyroiditis or discontinuance of thyroid hormone therapy.

Iodine deficiency is the most common cause of hypothyroidism worldwide. In the United States, the most common cause of primary hypothyroidism is atrophy of the thyroid gland. This atrophy is the end result of Hashimoto's thyroiditis or Graves' disease. These autoimmune diseases destroy the thyroid gland. Hypothyroidism may also develop due to treatment for hyperthyroidism, specifically the surgical removal of the thyroid gland or RAI therapy. Drugs such as amiodarone (Cordarone) (contains iodine) and lithium (blocks hormone production) can cause hypothyroidism.

Hypothyroidism that develops in infancy *(cretinism)* is caused by thyroid hormone deficiencies during fetal or early

neonatal life. All infants in the United States are screened for decreased thyroid function at birth.

Clinical Manifestations

Regardless of the cause, hypothyroidism has common features. It has systemic effects characterized by a slowing of body processes. Manifestations vary depending on the severity and the duration of thyroid deficiency, as well as the patient's age at the onset of the deficiency. The onset of symptoms may occur over months to years unless hypothyroidism occurs after a thyroidectomy, after thyroid ablation, or during treatment with antithyroid drugs.

The patient is often fatigued and lethargic and experiences personality and mental changes, including impaired memory, slowed speech, decreased initiative, and somnolence. Many individuals with hypothyroidism appear depressed. Weight gain is most likely a result of a decreased metabolic rate.

Hypothyroidism is associated with decreased cardiac contractility and decreased cardiac output. Thus the patient may experience low exercise tolerance and shortness of breath on exertion. Hypothyroidism may cause significant cardiovascular problems, especially in a person with previous cardiovascular disorders.

Anemia is a common feature of hypothyroidism. Erythropoietin levels may be low or normal. Because the metabolic rate is lower, oxygen demand is reduced. Other hematologic problems are related to cobalamin, iron, and folate deficiencies. The patient may bruise easily. Increased serum cholesterol and triglyceride levels and the accumulation of mucopolysaccharides in the intima of small blood vessels can result in coronary atherosclerosis.

Patients with severe, long-standing hypothyroidism may display **myxedema,** which alters the physical appearance of the skin and subcutaneous tissues with puffiness, facial and periorbital edema, and a masklike affect. Myxedema occurs due to the accumulation of hydrophilic mucopolysaccharides in the dermis and other tissues (Fig. 50-9). Individuals with hypothyroidism may describe an altered self-image related to their disabilities and altered appearance. Other manifestations of hypothyroidism are summarized in Table 50-5.

In the older adult the typical manifestations of hypothyroidism (including fatigue, cold and dry skin, hoarseness, hair loss, constipation, and cold intolerance) may be attributed to normal aging. For this reason, the patient's symptoms may not raise suspicion of an underlying condition. Older adults who have confusion, lethargy, and depression should be evaluated for thyroid disease.

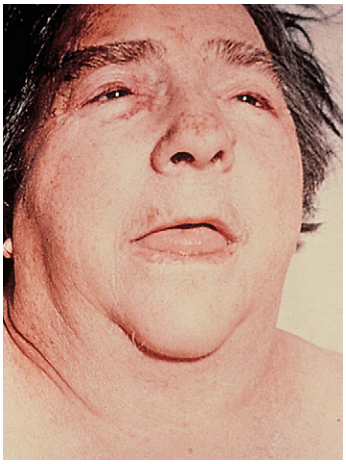

FIG. 50-9 Common features of myxedema. Dull, puffy skin; coarse, sparse hair; periorbital edema; and prominent tongue.

TABLE 50-10 COLLABORATIVE CARE

Hypothyroidism

Diagnostic	Collaborative Therapy
• History and physical examination • Serum TSH and free T_4 • Total serum T_3 and T_4 • Thyroid peroxidase (TPO) antibodies	• Thyroid hormone replacement (e.g., levothyroxine) • Monitor thyroid hormone levels and adjust dosage (if needed) • Nutritional therapy to promote weight loss • Patient and caregiver teaching (see Table 50-11)

TSH, Thyroid-stimulating hormone.

Complications

The mental sluggishness, drowsiness, and lethargy of hypothyroidism may progress gradually or suddenly to a notable impairment of consciousness or coma. This situation, termed *myxedema coma,* is a medical emergency. Myxedema coma can be precipitated by infection, drugs (especially opioids, tranquilizers, and barbiturates), exposure to cold, and trauma.[14] It is characterized by subnormal temperature, hypotension, and hypoventilation. Cardiovascular collapse can result from hypoventilation, hyponatremia, hypoglycemia, and lactic acidosis. For the patient to survive a myxedema coma, vital functions must be supported and IV thyroid hormone replacement administered.

Diagnostic Studies

The most common and reliable laboratory tests for thyroid function are TSH and free T_4. These values, correlated with symptoms gathered from the history and physical examination, confirm the diagnosis of hypothyroidism. Serum TSH levels help determine the cause of hypothyroidism. Serum TSH is high when the defect is in the thyroid and low when it is in the pituitary or the hypothalamus. The presence of thyroid antibodies suggests an autoimmune origin of the hypothyroidism. Other abnormal laboratory findings are elevated cholesterol and triglycerides, anemia, and increased creatine kinase (see Table 50-6).

Collaborative Care

The treatment goal for a patient with hypothyroidism is restoration of a euthyroid state as safely and rapidly as possible with hormone therapy (Table 50-10). A low-calorie diet is also indicated to promote weight loss or prevent weight gain.

Levothyroxine (Synthroid) is the drug of choice to treat hypothyroidism. In the young and otherwise healthy patient, the maintenance replacement dosage is adjusted according to the patient's response and laboratory findings. When thyroid hormone therapy is initiated, the initial dosages are low to avoid increases in resting heart rate and BP. In the patient with compromised cardiac status, careful monitoring is needed when starting and adjusting the dosage because the usual dose may increase myocardial oxygen demand.[15] The increased oxygen demand may cause angina and cardiac dysrhythmias.

DRUG ALERT: Levothyroxine (Synthroid)

- Carefully monitor patients with cardiovascular disease who take this drug.
- Monitor heart rate and report pulse greater than 100 beats/min or an irregular heartbeat.
- Promptly report chest pain, weight loss, nervousness, tremors, and/or insomnia.

In a patient without side effects, the dose is increased at 4- to 6-week intervals. It may take up to 8 weeks before the full effect of hormone therapy is seen, It is important that the patient regularly take replacement medication. Lifelong thyroid therapy is usually required.

Liotrix is a synthetic mix of levothyroxine (T_4) and liothyronine (T_3) in a 4:1 combination. Levothyroxine has a peak of action of 1 to 3 weeks. In contrast, liotrix has a faster onset of action with a peak of 2 to 3 days. Liotrix can be used in acutely ill individuals with hypothyroidism.

NURSING MANAGEMENT HYPOTHYROIDISM

NURSING ASSESSMENT

Careful assessment may reveal early and subtle changes in a patient suspected of having hypothyroidism. Note any previous history of hyperthyroidism and treatment with antithyroid medications, radioactive iodine, or surgery. Ask the patient about prescribed iodine-containing medications (see Table 50-4) and any changes in appetite, weight, activity level, speech, memory, and skin such as increased dryness or thickening. Assess for cold intolerance, constipation, and signs of depression. Further assessment should focus on heart rate, tenderness over the thyroid gland, and edema in the extremities and face.

NURSING DIAGNOSES

Nursing diagnoses for the patient with hypothyroidism may include, but are not limited to, the following:

- Imbalanced nutrition: more than body requirements *related to* calorie intake in excess of metabolic rate
- Constipation *related to* GI hypomotility
- Impaired memory *related to* hypometabolism

Additional information on nursing diagnoses is presented in the eNursing Care Plan 50-2 for the patient with hypothyroidism (available on the website for this chapter).

PLANNING

The overall goals are that the patient with hypothyroidism will (1) experience relief of symptoms, (2) maintain a euthyroid state, (3) maintain a positive self-image, and (4) comply with lifelong thyroid therapy.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Currently no consensus exists regarding thyroid function screening. Although hypothyroidism is relatively common, particularly among women over age 50, there does not appear to be strong justification for screening the general population.[16] High-risk populations should be screened for subclinical (asymptomatic) thyroid disease. High-risk individuals include those with a family history of thyroid disease, those with a history of neck radiation, women over 50 years old, and postpartum women.

ACUTE INTERVENTION. Most individuals with hypothyroidism are treated on an outpatient basis. The patient who develops myxedema coma requires acute nursing care, often in an intensive care setting. Mechanical respiratory support and cardiac monitoring are frequently necessary.

Administer thyroid hormone therapy and all other medications IV because paralytic ileus may be present in myxedema coma. Monitor the core temperature because hypothermia often occurs in myxedema coma. Use soap gently and moisturize frequently to prevent skin breakdown. Frequent changes in patient positioning and a low-pressure mattress can also assist in maintaining skin integrity.

Monitor the patient's progress by assessing vital signs, body weight, fluid intake and output, and visible edema. Cardiac assessment is especially important because the cardiovascular response to hormone therapy determines the medication regimen. Note energy level and mental alertness, which should increase within 2 to 14 days and continue to improve steadily to normal levels. The patient's neurologic status and free T_4 levels are used to determine continuing treatment.

AMBULATORY AND HOME CARE. Patient teaching is essential for the patient with hypothyroidism and the caregiver (Table 50-11). Initially the hypothyroid patient may have difficulty processing complex instructions. It is important to provide written instructions, repeat the information often, and assess the patient's comprehension level.

Stress the need for receiving lifelong drug therapy and avoiding abrupt discontinuation of drugs. Instruct the patient in expected and unexpected side effects. In the teaching plan include the signs and symptoms of hypothyroidism or hyperthyroidism that indicate hormone imbalance. Clearly define toxic symptoms. Table 50-5 lists manifestations of hyperthyroidism, which are the same as the toxic manifestations of thyroid hormone replacement.

Teach the patient to immediately contact a health care provider if manifestations of overdose occur, such as orthopnea, dyspnea, rapid pulse, palpitations, chest pain, nervousness, or insomnia. The patient with diabetes mellitus should test his or

TABLE 50-11 PATIENT & CAREGIVER TEACHING GUIDE

Hypothyroidism

Include the following instructions when teaching the patient and caregiver about management of hypothyroidism.

1. Discuss the importance of thyroid hormone therapy.
   - Need for lifelong therapy
   - Taking thyroid hormone in the morning before food
   - Need for regular follow-up care
2. Caution the patient not to switch brands of the hormone unless prescribed, since the bioavailability of thyroid hormones may differ.
3. Emphasize the need for a comfortable, warm environment because of intolerance to cold.
4. Teach measures to prevent skin breakdown. Soap should be used sparingly and lotion applied to skin.
5. Caution the patient, especially if an older adult, to avoid sedatives. If they must be used, suggest that the lowest dose be used. Caregiver should closely monitor mental status, level of consciousness, and respirations.
6. Discuss with the patient and the caregiver measures to minimize constipation, including
   - Gradual increase in activity and exercise
   - Increased fiber in diet
   - Use of stool softeners
   - Regular bowel elimination time
7. Tell patient to avoid using enemas because they produce vagal stimulation, which can be hazardous if cardiac disease is present.

her capillary blood glucose at least daily because the return to the euthyroid state frequently increases insulin requirements. In addition, thyroid drugs potentiate the effects of anticoagulants and decrease the effect of digitalis compounds. Instruct the patient about the toxic signs and symptoms of these medications and the need to remain under close medical observation until stable.

With treatment, striking transformations occur in both appearance and mental function. Most adults return to a normal state. Cardiovascular conditions and (occasionally) psychosis may persist despite corrections of the hormonal imbalance. Relapses occur if treatment is interrupted.

EVALUATION

The expected outcomes are that the patient with hypothyroidism will

- Have relief from symptoms
- Maintain a euthyroid state as evidenced by normal thyroid hormone and TSH levels
- Avoid complications of therapy
- Adhere to lifelong therapy

Additional information on expected outcomes is presented in the eNursing Care Plan 50-2 for the patient with hypothyroidism (available on the website for this chapter).

THYROID NODULES AND CANCER

A *thyroid nodule* (growth in the thyroid gland) may be benign or malignant (thyroid cancer). More than 95% of all thyroid gland nodules are benign. A person's chance of getting a thyroid nodule increases with age. Benign nodules are usually not dangerous, but they can cause tracheal compression if they become too large.

Thyroid cancer is the most common form of an endocrine system cancer. An estimated 56,460 new cases of thyroid cancer are diagnosed annually.[17] The incidence of thyroid cancer has risen significantly in the past 25 years. Thyroid cancer affects more women, and the incidence is higher in Asian Americans.[18]

Radiation exposure significantly increases the risk for thyroid cancer. Adults at higher risk for thyroid cancer include those who were given radiation treatment during childhood for lymphoma, Wilms' tumor, and neuroblastoma. Having a personal or family history of goiter also increases a person's risk.

Types of Thyroid Cancer

The four main types of thyroid cancer are papillary, follicular, medullary, and anaplastic. *Papillary* thyroid cancer is the most common type, accounting for about 70% to 80% of all thyroid cancers. Papillary cancer tends to grow slowly and spreads initially to lymph nodes in the neck.

Follicular thyroid cancer makes up about 15% of all thyroid cancers. It tends to occur in older patients. Follicular cancer first metastasizes into the cervical lymph nodes, then spreads to the neck, lungs, and bones.

Medullary thyroid cancer, which accounts for up to 10% of all thyroid cancers, is more likely to occur in families and to be associated with other endocrine problems. It is diagnosed by genetic testing for a proto-oncogene called *RET*. Medullary thyroid cancer is a type of multiple endocrine neoplasia (see discussion at right). This type of cancer is often poorly differentiated and associated with early metastasis.

Anaplastic thyroid cancer, which is found in less than 2% of patients with thyroid cancer, is the most advanced and aggressive thyroid cancer. It is the least likely to respond to treatment and has a poor prognosis.

Clinical Manifestations and Diagnostic Studies

The primary manifestation of thyroid cancer is a painless, palpable nodule or nodules in an enlarged thyroid gland. Patients or health care providers discover most of these nodules during a routine palpation of the neck. Physical examination may reveal firm, palpable, cervical masses that are suggestive of lymph node metastasis. Hemoptysis and airway obstruction may occur if the trachea is involved.

Nodular enlargement of the thyroid gland or palpation of a mass requires further evaluation. Ultrasound is often the first test used. Follow-up testing may involve CT, MRI, positron emission tomography (PET), and ultrasound-guided fine-needle aspiration (FNA). FNA is indicated when a tissue sample for pathologic examination is necessary. A thyroid scan may also be done to evaluate for possible malignancy. The scan shows whether nodules on the thyroid are "hot" or "cold." Tumors that take up radioactive iodine are called "hot" nodules and are nearly always benign. If the nodule does not take up the radioactive iodine, it appears as "cold" and has a higher risk of being malignant (see eFig. 50-2, available on the website for this chapter).

Elevations in serum calcitonin are associated with medullary thyroid cancer. In papillary and follicular cancers, serum thyroglobulin is elevated. In families with a history of medullary thyroid cancer, encourage family members to get genetic testing done and have thyroid screening on a regular basis.

NURSING AND COLLABORATIVE MANAGEMENT THYROID CANCER

Surgical removal of the tumor is usually indicated for thyroid cancer.[19] Surgical procedures may range from unilateral total lobectomy to near-total thyroidectomy with bilateral lobectomy. Lymph nodes in the neck may be removed with surgery to determine if the cancer has spread. RAI may be given to some patients to destroy any remaining cancer cells after surgery. RAI therapy has been shown to improve survival rates in patients with papillary and follicular thyroid cancer. External beam radiation may be given as palliative treatment for patients with metastatic thyroid cancer.

Many thyroid cancers are TSH dependent, and thyroid hormone therapy in high doses is often prescribed to inhibit pituitary secretion of TSH. Chemotherapy including doxorubicin (Adriamycin), and cyclophosphamide (Cytoxan) may be used for advanced disease. Vandetanib (Caprelsa) and cabozantinib (Cometriq) are targeted therapies used for medullary thyroid cancer that has metastasized. These drugs inhibit tyrosine kinases, which are enzymes that are involved in growth of cancer cells.

Nursing care for the patient with thyroid cancer is similar to that of a patient undergoing thyroidectomy (see p. 1199). Because of the surgical site location and the potential for hypocalcemia, the patient requires frequent postoperative assessment. Assess the patient for airway obstruction, bleeding, and tetany, since the parathyroid gland may have been disturbed or removed during surgery.

MULTIPLE ENDOCRINE NEOPLASIA

Multiple endocrine neoplasia is an inherited condition characterized by hormone-secreting tumors.[20] Multiple endocrine

neoplasia is caused by the mutation of one of two genes, *MEN1* or *RET,* that normally control cell growth. Tumors may develop in childhood or later in life.

The two major types of multiple endocrine neoplasia are type 1 and type 2. Both types are commonly inherited as autosomal dominant disorders. Persons with type 1 commonly show signs of parathyroid gland hyperactivity (hyperparathyroidism). Other signs may include hyperactivity of the pituitary gland (prolactinoma) and pancreas (gastrinomas). In most cases the tumors are initially benign, and some tumors later become malignant. Persons with type 2 neoplasia often have clinical manifestations of medullary thyroid carcinoma. They may also develop pheochromocytoma (tumor of the adrenal glands). (Pheochromocytoma is discussed later in this chapter on pp. 1214-1215.)

Treatment of the tumor(s) may include conservative management (watchful waiting), medication to block the effects of excess hormone, and surgical removal of the gland and/or tumor. It is important for patients to have regular screening visits with their health care provider so that new tumors may be detected early and existing tumors carefully monitored.

DISORDERS OF PARATHYROID GLANDS

HYPERPARATHYROIDISM

Etiology and Pathophysiology

Hyperparathyroidism is a condition involving an increased secretion of parathyroid hormone (PTH). PTH helps regulate serum calcium and phosphate levels by stimulating bone resorption of calcium, renal tubular reabsorption of calcium, and activation of vitamin D. Thus oversecretion of PTH is associated with increased serum calcium levels. Hyperparathyroidism affects approximately 1% of the U.S. population and is more common in women than in men.

Hyperparathyroidism is classified as primary, secondary, or tertiary. *Primary hyperparathyroidism* is due to an increased secretion of PTH leading to disorders of calcium, phosphate, and bone metabolism. The most common cause is a benign tumor (adenoma) in the parathyroid gland. Patients who have previously undergone head and neck radiation may have an increased risk of developing a parathyroid adenoma. Long-term lithium therapy has also been associated with primary hyperparathyroidism. The peak incidence of primary hyperparathyroidism is in the 40s and 50s.

Secondary hyperparathyroidism appears to be a compensatory response to conditions that induce or cause hypocalcemia, the main stimulus of PTH secretion. These conditions include vitamin D deficiencies, malabsorption, chronic kidney disease, and hyperphosphatemia.

Tertiary hyperparathyroidism occurs when there is hyperplasia of the parathyroid glands and a loss of negative feedback from circulating calcium levels. Thus there is autonomous secretion of PTH, even with normal calcium levels. This condition is seen in patients who have had a kidney transplant after a long period of dialysis treatment for chronic kidney disease (see Chapter 47).

Excessive levels of circulating PTH usually lead to hypercalcemia and hypophosphatemia. Multiple body systems are affected (Table 50-12). Decreased bone density can occur

TABLE 50-12 CLINICAL MANIFESTATIONS OF PARATHYROID DYSFUNCTION

Hyperfunction	Hypofunction
Cardiovascular	
• Dysrhythmias • Shortened QT interval on ECG • Hypertension	• Decreased contractility of heart muscle • Decreased cardiac output • Prolongation of QT and ST intervals on ECG • Dysrhythmias
Neurologic	
• Personality disturbances • Emotional irritability • Memory impairment • Psychosis, depression • Delirium, confusion, coma • Poor coordination • Hyperactive deep-tendon reflexes • Abnormalities of gait • Psychomotor retardation • Headache • Paresthesias	• Personality changes • Psychiatric manifestations of depression, anxiety, psychosis • Irritability • Memory impairment • Headache, increased intracranial pressure • Seizures • Positive Chvostek's sign or Trousseau's phenomenon (see Fig. 17-15) • Tremor • Paresthesias of lips, hands, feet • Hyperactive deep-tendon reflexes • Disorientation, confusion (in older adult)
Renal	
• Hypercalciuria • Kidney stones (nephrolithiasis) • Urinary tract infections • Polyuria	• Urinary frequency • Urinary incontinence
Visual	
• Corneal calcification on slit-lamp examination	• Eye changes, including lenticular opacities, cataracts, papilledema
Gastrointestinal	
• Vague abdominal pain • Anorexia • Nausea and vomiting • Constipation • Pancreatitis • Peptic ulcer disease • Cholelithiasis • Weight loss	• Abdominal cramps • Fecal incontinence (in older adult) • Malabsorption
Integumentary	
• Skin necrosis • Moist skin	• Dry, scaly skin • Hair loss on scalp and body • Brittle nails, transverse ridging • Changes in developing teeth, lack of tooth enamel
Musculoskeletal	
• Skeletal pain • Backache • Weakness, fatigue • Pain on weight bearing • Osteoporosis • Pathologic fractures of long bones • Compression fractures of spine • Decreased muscle tone, muscle atrophy	• Fatigue • Weakness • Painful muscle cramps • Skeletal x-ray changes, osteosclerosis • Soft tissue calcification • Difficulty walking

because of the effect of PTH on osteoclastic (bone resorption) and osteoblastic (bone formation) activity. In the kidneys the excess calcium cannot be reabsorbed, leading to increased levels of calcium in the urine (hypercalciuria). This urinary calcium, along with a large amount of urinary phosphate, can lead to calculi formation.

Clinical Manifestations and Complications

Clinical manifestations range from the asymptomatic individual (diagnosed through testing for unrelated problems) to the patient with overt symptoms.[21] The manifestations are associated with hypercalcemia (see Table 50-12). Muscle weakness, loss of appetite, constipation, fatigue, emotional disorders, and shortened attention span are often noted. Other signs of hyperparathyroidism include osteoporosis, fractures, and kidney stones (nephrolithiasis). Neuromuscular abnormalities are characterized by muscle weakness, particularly in the proximal muscles of the lower extremities. Serious complications of hyperparathyroidism are renal failure; pancreatitis; cardiac changes; and long bone, rib, and vertebral fractures.

Diagnostic Studies

PTH levels are elevated in patients with hyperparathyroidism. Serum calcium levels usually exceed 10 mg/dL (2.50 mmol/L). Because of its inverse relation with calcium, the serum phosphorus level is usually less than 3 mg/dL (0.1 mmol/L). Hypercalcemia in asymptomatic cases is often identified through a routine chemistry panel.

Elevations in other laboratory tests include urine calcium, serum chloride, uric acid, creatinine, amylase (if pancreatitis is present), and alkaline phosphatase (in the presence of bone disease). Bone density measurements may be used to detect bone loss. Conversely, individuals found to have bone loss on a screening dual-energy x-ray absorptiometry (DEXA) scan should be tested for hypercalcemia. MRI, CT, and/or ultrasound may be used for localization of an adenoma.

Collaborative Care

The goal of treatment is to relieve symptoms and prevent complications caused by excess PTH. The choice of therapy depends on the urgency of the clinical situation, the degree of hypercalcemia, and the underlying cause of the disorder.

Surgical Therapy. The most effective treatment of primary and secondary hyperparathyroidism is surgical intervention. Surgery involves partial or complete removal of the parathyroid glands. The most commonly used procedure involves endoscopy and is done on an outpatient basis. Criteria for surgery include elevated serum calcium levels (more than 1 mg/dL above the upper limit of normal), hypercalciuria (greater than 400 mg/day), markedly reduced bone mineral density, overt symptoms (e.g., neuromuscular effects, nephrolithiasis), or those under age 50. Parathyroidectomy leads to a rapid reduction of high calcium levels.

Patients who have multiple parathyroid glands removed may undergo autotransplantation of normal parathyroid tissue in the forearm or near the sternocleidomastoid muscle. This allows PTH secretion to continue with normalization of calcium levels. If autotransplantation is not possible or if it fails, the patient will need to take calcium supplements for life.

Nonsurgical Therapy. A conservative approach is often used in patients who are asymptomatic or have mild symptoms of hyperparathyroidism. Ongoing care includes an annual examination with measurements of serum PTH, calcium, phosphorus, alkaline phosphatase, creatinine and blood urea nitrogen (BUN) (to assess renal function), and urinary calcium excretion. X-rays and DEXA are done to assess for metabolic bone loss. Continued ambulation and the avoidance of immobility are important aspects of management. Dietary measures include high fluid and moderate calcium intake.

Several drugs help lower calcium levels, but they do not treat the underlying problem. Bisphosphonates (e.g., alendronate [Fosamax]) inhibit osteoclastic bone resorption, normalizing serum calcium levels and improving bone mineral density. IV bisphosphonates (e.g., pamidronate [Aredia]) can rapidly lower serum calcium in patients with dangerously elevated levels. Phosphorus is usually supplemented unless contraindicated in a person with an increased risk for urinary calculi formation. Phosphates should be used only if the patient has normal renal function and low serum phosphate levels. Loop diuretics may be given to increase the urinary excretion of calcium.

Calcimimetic agents (e.g., cinacalcet [Sensipar]) increase the sensitivity of the calcium receptor on the parathyroid gland, resulting in decreased PTH secretion and calcium blood levels. Drugs in this class are given for secondary hyperparathyroidism in individuals with chronic kidney disease on dialysis and for patients with parathyroid cancer. Cinacalcet remains under investigation for use in primary hyperparathyroidism.

NURSING MANAGEMENT HYPERPARATHYROIDISM

Nursing care for the patient after a parathyroidectomy is similar to that for a patient after thyroidectomy. The major postoperative complications are associated with hemorrhage and fluid and electrolyte disturbances. *Tetany,* a condition of neuromuscular hyperexcitability associated with sudden decrease in calcium levels, is another concern. It is usually apparent early in the postoperative period but may develop over several days. Mild tetany, characterized by unpleasant tingling of the hands and around the mouth, may be present but should decrease over time. If tetany becomes more severe (e.g., muscular spasms or laryngospasms), IV calcium may be given. IV calcium gluconate or gluceptate should be readily available for patients after parathyroidectomy in the event that acute tetany occurs.

Monitor intake and output to evaluate fluid status. Assess calcium, potassium, phosphate, and magnesium levels frequently, as well as Chvostek's and Trousseau's signs (see Fig. 17-15). Encourage mobility to promote bone calcification.

If surgery is not performed, treatment to relieve symptoms and prevent complications is initiated. Assist the patient with hyperparathyroidism to adapt the meal plan to his or her lifestyle. A referral to a dietitian may be useful. Because immobility can aggravate the bone loss, emphasize the importance of an exercise program. Encourage the patient to keep the regular follow-up appointments. Instruct the patient regarding the symptoms of hypocalcemia or hypercalcemia, and to report them should they occur. Hypocalcemia and hypercalcemia are discussed in Chapter 17.

HYPOPARATHYROIDISM

Hypoparathyroidism is an uncommon condition associated with inadequate circulating PTH. It is characterized by hypocalcemia resulting from a lack of PTH to maintain serum

calcium levels. PTH resistance at the cellular level may also occur *(pseudohypoparathyroidism)*. This is caused by a genetic defect resulting in hypocalcemia in spite of normal or high PTH levels and is often associated with hypothyroidism and hypogonadism.

The most common cause of hypoparathyroidism is iatrogenic. This may include accidental removal of the parathyroid glands or damage to the vascular supply of the glands during neck surgery (e.g., thyroidectomy).[22] Idiopathic hypoparathyroidism resulting from the absence, fatty replacement, or atrophy of the glands is a rare disease that usually occurs early in life and may be associated with other endocrine disorders. Affected patients may have antiparathyroid antibodies. Severe hypomagnesemia (e.g., malnutrition, chronic alcoholism, renal failure) also leads to a suppression of PTH secretion. Other causes of parathyroid deficiency include tumors and heavy metal poisoning.

The clinical features of acute hypoparathyroidism are due to hypocalcemia (see Table 50-12). Sudden decreases in calcium concentration cause tetany, characterized by tingling of the lips and stiffness in the extremities. Painful tonic spasms of smooth and skeletal muscles can cause dysphagia and laryngospasms, which compromise breathing. Lethargy, anxiety, and personality changes may occur. Abnormal laboratory findings include decreased serum calcium and PTH levels and increased serum phosphate levels.

NURSING AND COLLABORATIVE MANAGEMENT HYPOPARATHYROIDISM

Treatment goals for the patient with hypoparathyroidism are to treat acute complications such as tetany, maintain normal serum calcium levels, and prevent long-term complications. Emergency treatment of tetany after surgery requires the administration of IV calcium.

Give IV calcium chloride, calcium gluconate, or calcium gluceptate slowly. Use ECG monitoring during calcium administration because high serum calcium blood levels can cause hypotension, serious cardiac dysrhythmias, or cardiac arrest. The patient who takes digoxin is particularly vulnerable. IV calcium chloride can cause venous irritation and inflammation, and extravasation may cause cellulitis, necrosis, and tissue sloughing. It is important to assess IV patency before administering calcium chloride.

Rebreathing may partially alleviate acute neuromuscular symptoms associated with hypocalcemia such as generalized muscle cramps or mild tetany. Instruct the patient (if cooperative) to breathe in and out of a paper bag or breathing mask. This reduces carbon dioxide excretion from the lungs, increases carbonic acid levels in the blood, and lowers the pH. A lower pH (acidic environment) enhances calcium ionization, which causes more total body calcium to be available in the active form. This will temporarily relieve the manifestations of hypocalcemia.

The patient with hypoparathyroidism needs instruction in the management of long-term drug and nutritional therapy. PTH replacement is not recommended because of the expense and need for parenteral administration. Oral calcium supplements of at least 1.5 to 3 g/day in divided doses are usually prescribed. Hypomagnesemia needs to be corrected in some patients before the hypocalcemia can be treated.

Vitamin D is used in hypocalcemia to enhance intestinal calcium absorption. Vitamin D (e.g., dihydrotachysterol [Hytakerol], 1,25-dihydroxycholecalciferol, or calcitriol [Rocaltrol]) raises calcium levels rapidly and is quickly metabolized. Rapid metabolism is desired because vitamin D is a fat-soluble vitamin and toxicity can cause irreversible renal impairment. A high-calcium meal plan includes foods such as dark green vegetables, soybeans, and tofu. Tell the patient to avoid foods containing oxalic acid (e.g., spinach, rhubarb) because they inhibit the absorption of calcium. Instruct the patient about the need for follow-up care, including monitoring of calcium levels three or four times a year.

DISORDERS OF ADRENAL CORTEX

Adrenal cortex steroid hormones have three main classifications: glucocorticoids, mineralocorticoids, and androgens. Glucocorticoids regulate metabolism, increase blood glucose levels, and are critical in the physiologic stress response. The primary glucocorticoid is cortisol. Mineralocorticoids regulate sodium and potassium balance. The primary mineralocorticoid is aldosterone. Androgens contribute to growth and development in both genders and to sexual activity in adult women. The term *corticosteroid* refers to any one of these three types of hormones produced by the adrenal cortex.

CUSHING SYNDROME

Etiology and Pathophysiology

Cushing syndrome is a clinical condition that results from chronic exposure to excess corticosteroids, particularly glucocorticoids.[23] Several conditions can cause Cushing syndrome. The most common cause is iatrogenic administration of exogenous corticosteroids (e.g., prednisone). Approximately 85% of the cases of endogenous Cushing syndrome are due to an ACTH-secreting pituitary adenoma (Cushing disease). Other causes of Cushing syndrome include adrenal tumors and ectopic ACTH production by tumors (usually of the lung or pancreas) outside of the hypothalamic-pituitary-adrenal axis. Cushing disease and primary adrenal tumors are more common in women in the 20- to 40-year-old age-group. Ectopic ACTH production is more common in men.

Clinical Manifestations

Manifestations of Cushing syndrome can be seen in most body systems and are related to excess levels of corticosteroids (Table 50-13). Although signs of glucocorticoid excess usually predominate, symptoms of mineralocorticoid and androgen excess may also be seen.

Corticosteroid excess causes pronounced changes in physical appearance (Fig. 50-10). Weight gain, the most common feature, results from the accumulation of adipose tissue in the trunk, face, and cervical spine area (Fig. 50-11). Hyperglycemia occurs because of glucose intolerance (associated with cortisol-induced insulin resistance) and increased gluconeogenesis by the liver. Muscle wasting causes weakness, especially in the extremities. A loss of bone matrix leads to osteoporosis and back pain. The loss of collagen makes the skin weaker and thinner and more easily bruised. Catabolic processes lead to a delay in wound healing. Irritability, anxiety, euphoria, and occasionally psychosis may also occur.

Mineralocorticoid excess may cause hypertension (secondary to fluid retention), whereas adrenal androgen excess may cause severe acne, virilization in women, and feminization in

TABLE 50-13 CLINICAL MANIFESTATIONS OF ADRENOCORTICAL DYSFUNCTION

System	Hyperfunction (Cushing Syndrome)	Hypofunction (Addison's Disease)
Glucocorticoids		
General appearance	Truncal obesity, thin extremities, rounding of face (moon face), fat deposits on back of neck and shoulders (buffalo hump) (see Fig. 50-11).	Weight loss, emaciation.
Integumentary	Thin, fragile skin, purplish red striae (see Fig. 50-12). Petechial hemorrhages, bruises. Florid cheeks (plethora), acne, poor wound healing.	Bronzed or smoky hyperpigmentation of face, neck, hands (especially creases) (see Fig. 50-13), buccal membranes, nipples, genitalia, and scars (if pituitary function normal). Vitiligo, alopecia.
Cardiovascular	Hypervolemia, hypertension, edema of lower extremities.	Hypotension, tendency to develop refractory shock, vasodilation.
Gastrointestinal	Increase in secretion of pepsin and HCl acid, risk of peptic ulcer disease, anorexia.	Anorexia, nausea and vomiting, cramping abdominal pain, diarrhea.
Renal/urinary	Glycosuria, hypercalciuria, risk for kidney stones.	
Musculoskeletal	Muscle wasting in extremities, fatigue, osteoporosis, awkward gait, back pain, weakness, fractures.	Fatigue.
Immune	Inhibition of immune response, suppression of allergic response.	Tendency for coexisting autoimmune diseases.
Metabolic	Hyperglycemia, negative nitrogen balance, dyslipidemia.	Hyponatremia, insulin sensitivity, fever.
Emotional	Euphoria, irritability, depression, insomnia.	Depression, exhaustion or irritability, confusion, delusions.
Mineralocorticoids		
Fluid and electrolytes	Marked sodium and water retention, edema, marked hypokalemia, alkalosis.	Sodium loss, decreased volume of extracellular fluid, hyperkalemia, salt craving.
Cardiovascular	Hypertension, hypervolemia.	Hypovolemia, tendency toward shock, decreased cardiac output.
Androgens		
Integumentary	Hirsutism, acne, hyperpigmentation.	Decreased axillary and pubic hair (in women).
Reproductive	Menstrual irregularities and enlargement of clitoris (in women), gynecomastia and testicular atrophy (in men).	No effect in men, decreased libido in women.
Musculoskeletal	Muscle wasting and weakness.	Decrease in muscle size and tone.

FIG. 50-10 Cushing syndrome. Facies include a rounded face ("moon face") with thin, reddened skin. Hirsutism may also be present.

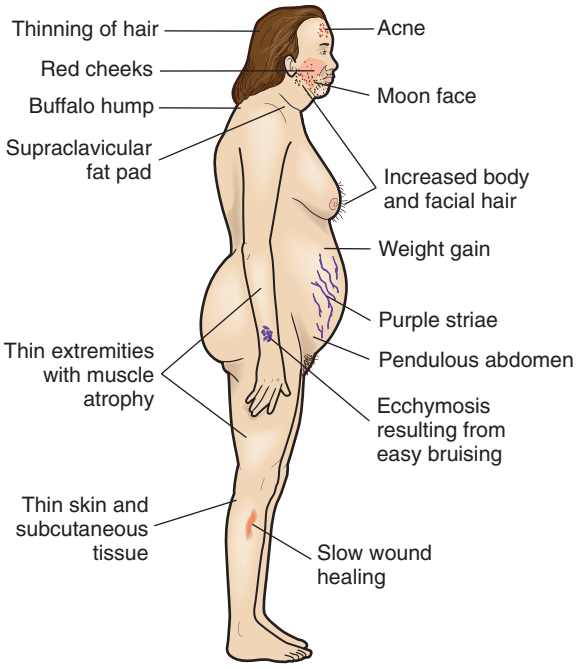

FIG. 50-11 Common characteristics of Cushing syndrome.

FIG. 50-12 Cushing syndrome. Truncal obesity; broad, purple striae; and easy bruising (left antecubital fossa).

men. Menstrual disorders and hirsutism in women and gynecomastia and impotence in men are seen more commonly in adrenal carcinomas.

The first indication of Cushing syndrome may be the clinical presentation, including (1) centripetal (truncal) obesity or generalized obesity; (2) *"moon face"* (fullness of the face) with facial plethora; (3) purplish red striae (usually depressed below the skin surface) on the abdomen, breast, or buttocks (Fig. 50-12); (4) hirsutism in women; (5) menstrual disorders in women; (6) hypertension; and (7) unexplained hypokalemia.

Diagnostic Studies

Plasma cortisol (the primary glucocorticoid) levels may be elevated, with loss of diurnal variation. When Cushing syndrome is suspected, a 24-hour urine collection for free cortisol is done. Urine cortisol levels higher than the normal range of 80 to 120 mcg/24 hr indicate Cushing syndrome. If results are borderline, a low-dose dexamethasone suppression test is done. False-positive results can occur in patients with depression and those taking certain medications, including phenytoin (Dilantin) and rifampicin (rifampin [Rifadin]). Urine levels of 17-ketosteroids may be elevated.[24] A CT scan and MRI of the pituitary and adrenal glands may be done.

Plasma ACTH levels may be low, normal, or elevated depending on the underlying cause of Cushing syndrome. High or normal ACTH levels indicate Cushing disease, whereas low or undetectable levels indicate an adrenal or medication etiology. Other findings on diagnostic tests associated with, but not diagnostic of, Cushing syndrome include leukocytosis, lymphopenia, eosinopenia, hyperglycemia, glycosuria, hypercalciuria, and osteoporosis. Hypokalemia and alkalosis are seen in ectopic ACTH syndrome and adrenal carcinoma.

Collaborative Care

The primary goal of treatment for Cushing syndrome is to normalize hormone secretion. The specific treatment depends on the underlying cause (Table 50-14). If the underlying cause is a pituitary adenoma, the standard treatment is surgical removal of the pituitary tumor using the transsphenoidal approach.[25] (The transsphenoidal approach is discussed earlier in this chapter on pp. 1190-1191.) Radiation therapy may also be used for patients who are not good surgical candidates.

Adrenalectomy is indicated for Cushing syndrome caused by adrenal tumors or hyperplasia. Occasionally, bilateral adrenalectomy is necessary. Laparoscopic adrenalectomy is used unless a malignant adrenal tumor is suspected. An open surgical adrenalectomy is usually performed for adrenal cancer.

Patients with ectopic ACTH-secreting tumors are best managed by locating and removing the tumor (usually lung or pancreas). This is usually possible when the tumor is benign. When a tumor is malignant and it has already metastasized, surgical removal may not be possible or successful.

When the patient is a poor candidate for surgery or prior surgery has failed, then drug therapy may be attempted. The goal of drug therapy is to suppress the synthesis and secretion of cortisol from the adrenal gland *(medical adrenalectomy).* Drugs used include ketoconazole (Nizoral), aminoglutethimide (Cytadren), and mitotane (Lysodren). These are used cautiously because they are often toxic at the dosages needed to reduce cortisol secretion. Hydrocortisone or prednisone may be needed to avoid adrenal insufficiency. Mifepristone (Korlym) may be used to control hyperglycemia in patients with endogenous Cushing syndrome who have type 2 diabetes.

TABLE 50-14 COLLABORATIVE CARE

Cushing Syndrome

Diagnostic
- History and physical examination
- Mental status examination
- Plasma cortisol levels for diurnal variations
- Plasma ACTH levels
- Complete blood count (CBC) with WBC differential
- Blood chemistries for sodium, potassium, glucose
- Dexamethasone suppression test
- 24-hr urine for free cortisol and 17-ketosteroids
- CT scan, MRI

Collaborative Therapy*

Pituitary Adenoma
- Transsphenoidal resection
- Radiation therapy

Adrenocortical Adenoma, Carcinoma, or Hyperplasia
- Adrenalectomy (open or laparoscopic)
- Drug therapy (e.g., ketoconazole [Nizoral], aminoglutethimide [Cytadren], mitotane [Lysodren], mifepristone [Korlym])

Ectopic ACTH-Secreting Tumor
- Treatment of the tumor (surgical removal or radiation)

Exogenous Corticosteroid Therapy
- Discontinue or alter the dose of exogenous corticosteroids

*Treatment is based on underlying cause.
ACTH, Adrenocorticotropic hormone.

If Cushing syndrome has developed during the course of prolonged administration of corticosteroids (e.g., prednisone), the following alternatives may be tried: (1) gradual discontinuance of corticosteroid therapy, (2) reduction of the corticosteroid dose, and (3) conversion to an alternate-day regimen. Gradual tapering of the corticosteroids is necessary to avoid potentially life-threatening adrenal insufficiency. In an alternate-day regimen, twice the daily dosage of a shorter-acting corticosteroid is given every other morning to minimize hypothalamic-pituitary-adrenal suppression, growth suppression, and altered appearance. This regimen is not used when the corticosteroids are given as hormone therapy.

NURSING MANAGEMENT CUSHING SYNDROME

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a patient with Cushing syndrome are presented in Table 50-15.

NURSING DIAGNOSES

Nursing diagnoses for the patient with Cushing syndrome may include, but are not limited to, the following:
- Risk for infection *related to* lowered resistance to stress and suppression of immune system
- Imbalanced nutrition: more than body requirements *related to* increased appetite, high caloric content of foods, and inactivity
- Disturbed body image *related to* change in appearance from disease process
- Impaired skin integrity *related to* excess corticosteroids, immobility, and altered skin fragility

Additional information on nursing diagnoses is presented in eNursing Care Plan 50-3 for the patient with Cushing syndrome (available on the website for this chapter).

TABLE 50-15 NURSING ASSESSMENT

Cushing Syndrome

Subjective Data

Important Health Information

Past health history: Pituitary tumor (Cushing disease); adrenal, pancreatic, or pulmonary neoplasms; GI bleeding; frequent infections
Medications: Corticosteroids

Functional Health Patterns

Health perception–health management: Malaise
Nutritional-metabolic: Weight gain, anorexia; prolonged wound healing, easy bruising
Elimination: Polyuria
Activity-exercise: Weakness, fatigue
Sleep: Insomnia, poor sleep quality
Cognitive-perceptual: Headache; back, joint, bone, and rib pain; poor concentration and memory
Self-perception–self-concept: Negative feelings regarding changes in personal appearance
Sexuality-reproductive: Amenorrhea, impotence, decreased libido
Coping–stress tolerance: Anxiety, mood disturbances, emotional lability, psychosis

Objective Data

General

Truncal obesity, supraclavicular fat pads, buffalo hump, moon face

Integumentary

Plethora; hirsutism of body and face, thinning of head hair; thin, friable skin; acne; petechiae; purpura; hyperpigmentation; purplish red striae on breasts, buttocks, and abdomen; edema of lower extremities

Cardiovascular

Hypertension

Musculoskeletal

Muscle wasting, thin extremities, awkward gait

Reproductive

Gynecomastia, testicular atrophy (in men), enlarged clitoris (in women)

Possible Diagnostic Findings

Hypokalemia, hyperglycemia, dyslipidemia; polycythemia, granulocytosis, lymphocytopenia, eosinopenia; ↑ plasma cortisol; high, low, or normal ACTH levels; abnormal dexamethasone suppression test; ↑ urine free cortisol, 17-ketosteroids; glycosuria, hypercalciuria; osteoporosis on x-ray

ACTH, Adrenocorticotropic hormone.

PLANNING

The overall goals are that the patient with Cushing syndrome will (1) experience relief of symptoms, (2) avoid serious complications, (3) maintain a positive self-image, and (4) actively participate in the therapeutic plan.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Health promotion is focused on identifying patients at risk for Cushing syndrome. Patients receiving long-term, exogenous corticosteroids for a variety of diseases are at risk. Patient teaching related to using medications and monitoring side effects is an important preventive measure.

ACUTE INTERVENTION. The patient with Cushing syndrome is seriously ill. Because the therapy has many side effects, assessment focuses on signs and symptoms of hormone and drug toxicity and complicating conditions (e.g., cardiovascular disease, diabetes mellitus, infection). Assess and monitor vital signs, daily weight, glucose, and possible infection. Because signs and symptoms of inflammation (e.g., fever, redness) may be minimal or absent, assess for pain, loss of function, and purulent drainage. Monitor for signs and symptoms of abnormal thromboembolic events such as pulmonary emboli (e.g., sudden chest pain, dyspnea, tachypnea).

Another important focus of nursing care is emotional support. Changes in appearance such as centripetal obesity, multiple bruises, hirsutism in women, and gynecomastia in men can be distressing. The patient may feel unattractive, repulsive, or unwanted. You can help by remaining sensitive to the patient's feelings and offering respect and unconditional acceptance. Reassure the patient that the physical changes and much of the emotional lability will resolve when hormone levels return to normal.

If treatment involves surgical removal of a pituitary adenoma, an adrenal tumor, or one or both adrenal glands, nursing care will also focus on preoperative and postoperative care.

Preoperative Care. Before surgery the patient should be brought to optimal physical condition. Hypertension and hyperglycemia must be controlled, and hypokalemia must be corrected with diet and potassium supplements. A high-protein diet helps correct the protein depletion. Preoperative teaching depends on the type of surgical approach planned (hypophysectomy or adrenalectomy) and should include information regarding the anticipated postoperative care. Preoperative management for the patient undergoing a hypophysectomy is discussed earlier in this chapter on pp. 1190-1191.

Postoperative Care. Surgery on the adrenal glands poses greater risks than other operations. Because the adrenal glands are vascular, the risk of hemorrhage is increased. In the postoperative period (for both laparoscopic and open adrenalectomy), patients may have a nasogastric tube, a urinary catheter, IV therapy, central venous pressure monitoring, and leg sequential compression devices to prevent emboli.

Manipulation of glandular tissue during surgery may release large amounts of hormones into the circulation, producing marked fluctuations in the metabolic processes affected by these hormones. Postoperatively, BP, fluid balance, and electrolyte levels may be unstable due to these hormone fluctuations.

High doses of corticosteroids (e.g., hydrocortisone [Solu-Cortef]) are administered IV during surgery and for several days afterward to ensure adequate responses to the stress of the procedure. If large amounts of endogenous hormone have been released into the systemic circulation during surgery, the patient is likely to develop hypertension, increasing the risk of hemorrhage. High levels of corticosteroids increase susceptibility to infection and delay wound healing.

The critical period for circulatory instability ranges from 24 to 48 hours after surgery. During this time you must constantly be alert for signs of corticosteroid imbalance. Report any rapid or significant changes in BP, respirations, or heart rate. Monitor fluid intake and output carefully and assess for potential imbalances. IV corticosteroids are given, and the dosage and flow rate are adjusted to the patient's clinical manifestations and fluid and electrolyte balance. Oral doses are given as tolerated. After IV corticosteroids are withdrawn, keep the IV line open for quick administration of corticosteroids or vasopressors. Obtain morning urine samples (collected at the same time each morning) for cortisol measurement to evaluate the surgery's effectiveness.

If corticosteroid dosage is tapered too rapidly after surgery, acute adrenal insufficiency may develop. Vomiting, increased weakness, dehydration, and hypotension may indicate hypocortisolism. In addition, the patient may complain of painful joints, pruritus, or peeling skin and may experience severe emotional disturbances. Report these signs and symptoms so that drug doses can be adjusted as necessary.

After surgery the patient is usually maintained on bed rest until the BP stabilizes. Be alert for subtle signs of postoperative infection because the usual inflammatory responses are suppressed. To prevent infection, provide meticulous care when changing the dressing and during any other procedures that involve access to body cavities, circulation, or areas under the skin. eNursing Care Plan 50-3 for the patient with Cushing syndrome is available on the website for this chapter.

AMBULATORY AND HOME CARE. Discharge instructions are based on the patient's lack of endogenous corticosteroids and resulting inability to physiologically react to stressors. Consider a home health nurse referral, especially for older adults, because of the need for ongoing evaluation and teaching. Instruct the patient to wear a Medic Alert bracelet at all times and carry medical identification and instructions in a wallet or purse. Teach the patient to avoid exposure to extreme temperatures, infections, and emotional disturbances. Stress may produce or precipitate acute adrenal insufficiency because the remaining adrenal tissue cannot meet an increased hormonal demand. Teach patients to adjust their corticosteroid replacement therapy in accordance with their stress levels. Consult with the patient's health care provider to determine the parameters for dosage changes if this plan is feasible. If the patient cannot adjust his or her own medication or if weakness, fainting, fever, or nausea and vomiting occur, the patient should contact the health care provider for a possible adjustment in corticosteroid dosage. Many patients require lifetime replacement therapy. However, patients should be prepared for it to take several months to adjust the hormone dose satisfactorily.

EVALUATION

The expected outcomes are that the patient with Cushing syndrome will

- Experience no signs or symptoms of infection
- Attain weight appropriate for height
- Verbalize acceptance of appearance and treatment regimen
- Demonstrate healing of skin and maintenance of intact skin

Additional information on expected outcomes is presented in eNursing Care Plan 50-3 for the patient with Cushing syndrome (available on the website for this chapter).

ADRENOCORTICAL INSUFFICIENCY

Etiology and Pathophysiology

Adrenocortical insufficiency (hypofunction of the adrenal cortex) may be from a primary cause **(Addison's disease)** or a secondary cause (lack of pituitary ACTH secretion). In Addison's disease, all three classes of adrenal corticosteroids (glucocorticoids, mineralocorticoids, and androgens) are reduced. In secondary adrenocortical insufficiency, corticosteroids and androgens are deficient but mineralocorticoids rarely are. ACTH deficiency may be caused by pituitary disease or suppression of the hypothalamic-pituitary axis because of the administration of exogenous corticosteroids.

The most common cause of Addison's disease in the United States is an autoimmune response.[26] Adrenal tissue is destroyed by antibodies against the patient's own adrenal cortex. Often, other endocrine conditions are present and Addison's disease is considered a component of *autoimmune polyglandular syndrome*. This rare syndrome is caused by a mutation in a gene that helps to regulate the immune system. The condition is inherited as an autosomal recessive trait. Addison's disease, if caused by an autoimmune response, is most common in white females.

Although tuberculosis causes Addison's disease worldwide, it is now an uncommon cause in the United States. Other causes include infarction, fungal infections (e.g., histoplasmosis), acquired immunodeficiency syndrome (AIDS), and metastatic cancer. Iatrogenic Addison's disease may be due to adrenal hemorrhage, often related to anticoagulant therapy, chemotherapy, ketoconazole therapy for AIDS, or bilateral adrenalectomy. Adrenal insufficiency most often occurs in adults younger than 60 years of age and affects both genders equally.

Clinical Manifestations

Because manifestations do not tend to become evident until 90% of the adrenal cortex is destroyed, the disease is often advanced before it is diagnosed. The manifestations have a slow (insidious) onset and include progressive weakness, fatigue, weight loss, and anorexia as primary features. Increased ACTH causes the striking feature of a bronze-colored skin hyperpigmentation. It is seen primarily in sun-exposed areas of the body; at pressure points; over joints; and in the creases, especially palmar creases (Fig. 50-13). The changes in the skin are most likely due to increased secretion of β-lipotropin (which contains melanocyte-stimulating hormone [MSH]). This tropic hormone is increased because of decreased negative feedback and subsequent low corticosteroid levels. Other manifestations of adrenal insufficiency are orthostatic hypotension, hyponatremia, salt craving, hyperkalemia, nausea and vomiting, and diarrhea. Irritability and depression may also occur in primary adrenal hypofunction.

Patients with secondary adrenocortical hypofunction may have many signs and symptoms similar to those of patients with Addison's disease. However, they usually do not have hyperpigmented skin because ACTH levels are low.

Complications

Patients with adrenocortical insufficiency are at risk for acute adrenal insufficiency *(addisonian crisis),* a life-threatening

FIG. 50-13 Hyperpigmentation typically seen in Addison's disease.

emergency caused by insufficient adrenocortical hormones or a sudden sharp decrease in these hormones. Addisonian crisis is triggered by (1) stress (e.g., from infection, surgery, psychologic distress), (2) the sudden withdrawal of corticosteroid hormone therapy (which is often done by a patient who lacks knowledge of the importance of this therapy), (3) adrenal surgery, or (4) sudden pituitary gland destruction.

During acute adrenal insufficiency, the patient exhibits severe manifestations of glucocorticoid and mineralocorticoid deficiencies, including hypotension (particularly postural), tachycardia, dehydration, hyponatremia, hyperkalemia, hypoglycemia, fever, weakness, and confusion. Hypotension may lead to shock. Circulatory collapse associated with adrenal insufficiency is often unresponsive to the usual treatment (vasopressors and fluid replacement). GI manifestations include severe vomiting, diarrhea, and pain in the abdomen. Pain may occur in the lower back or the legs.

Diagnostic Studies

Adrenal insufficiency is characterized by depressed serum and urinary cortisol levels. ACTH levels are increased in primary adrenal insufficiency and decreased in secondary disease. Primary adrenal insufficiency is confirmed when cortisol levels fail to rise over basal levels with an ACTH stimulation test. A positive response to ACTH stimulation test indicates a functioning adrenal gland and points to a probable diagnosis of secondary adrenocortical insufficiency related to the pituitary gland. Urine levels of free cortisol are low, as is the urine level of aldosterone.

Other abnormal laboratory findings in some cases include hyperkalemia, hypochloremia, hyponatremia, hypoglycemia, anemia, and increased BUN levels.[25] An ECG may show low voltage and peaked T waves caused by hyperkalemia. CT scans and MRI may be used to identify causes other than autoimmune, including tumors, fungal infections, tuberculosis, or adrenal calcification.

Collaborative Care

Treatment of adrenocortical insufficiency is focused on management of the underlying cause when possible. The mainstay of treatment for the adrenocortical insufficiency is hormone therapy (Table 50-16). Hydrocortisone, the most commonly used form of hormone therapy, has both glucocorticoid and mineralocorticoid properties. During stressful situations the glucocorticoid dosage is increased to prevent addisonian crisis. Mineralocorticoid replacement with fludrocortisone (Florinef) is administered daily. Increased salt needs to be added in the diet.

Addisonian crisis is a life-threatening emergency requiring aggressive management. Treatment must be directed toward shock management and high-dose hydrocortisone replacement. Large volumes of 0.9% saline solution and 5% dextrose are administered to reverse hypotension and electrolyte imbalances until BP returns to normal.

NURSING MANAGEMENT ADDISON'S DISEASE

NURSING IMPLEMENTATION

ACUTE INTERVENTION. When the patient with Addison's disease is hospitalized, nursing management focuses on monitoring the patient while correcting fluid and electrolyte balance.

TABLE 50-16 COLLABORATIVE CARE

Addison's Disease

Diagnostic
- History and physical examination
- Serum cortisol
- Serum ACTH
- Urine cortisol and aldosterone
- Serum electrolytes
- ACTH-stimulation test
- CT scan, MRI

Collaborative Therapy
- Daily glucocorticoid (e.g., hydrocortisone) replacement (two thirds on awakening in morning, one third in late afternoon)*
- Daily mineralocorticoid (fludrocortisone [Florinef]) in morning*
- Salt additives for excess heat or humidity
- Increased doses of cortisol for stress situations (e.g., surgery, hospitalization)

*For conditions of normal daily stress in individuals with usual daytime activity.
ACTH, Adrenocorticotropic hormone.

Assess vital signs and signs of fluid volume deficit and electrolyte imbalance. Monitor trends in serum glucose, sodium, and potassium. Establish baseline data regarding mental status, vital signs, and weight. Obtain a complete medication history to determine drugs that can potentially interact with corticosteroids. These drugs include oral hypoglycemics, cardiac glycosides, oral contraceptives, anticoagulants, and NSAIDs.

Note changes in BP, weight gain, weakness, or other manifestations of Cushing syndrome. In addition, protect against exposure to infection and assist with daily hygiene. Protect the patient from noise, light, and environmental temperature extremes. The patient cannot cope with these stresses because of the inability to produce corticosteroids.

AMBULATORY AND HOME CARE. You have an important role in the long-term management of Addison's disease. The serious nature of the disease and the need for lifelong hormone therapy necessitate a comprehensive teaching plan. Table 50-17 outlines the major areas to include in your teaching plan.

Glucocorticoids are usually given in divided doses, two thirds in the morning and one third in the afternoon. Mineralocorticoids are given once daily, preferably in the morning. This dosage schedule reflects normal circadian rhythm in endogenous hormone secretion and decreases the side effects associated with corticosteroid therapy. Help the patient maintain hormone balance while managing the medication regimen.

The patient with Addison's disease is unable to tolerate physical or emotional stress without additional exogenous corticosteroids. Long-term care revolves around recognizing the need for extra medication and techniques for stress management. Examples of situations requiring corticosteroid adjustment are fever, influenza, extraction of teeth, and rigorous physical activity such as playing tennis on a hot day or running a marathon. If vomiting or diarrhea occurs, as may happen with influenza, notify the health care provider immediately because electrolyte replacement and parenteral administration of cortisol may be necessary. Overall, patients who take their medications consistently can anticipate a normal life expectancy.

Teach the patient about the signs and symptoms of corticosteroid deficiency and excess (Cushing syndrome) and to report these signs to their health care provider so the dose can be adjusted. It is critical that the patient wear an identification

TABLE 50-17 PATIENT & CAREGIVER TEACHING GUIDE

Addison's Disease

Include the following information in the teaching plan for Addison's disease.

1. Names, dosages, and actions of drugs
2. Symptoms of overdosage and underdosage
3. Conditions requiring increased medication (e.g., trauma, infection, surgery, emotional crisis)
4. Course of action to take relative to changes in medication
   - Increase in dose of corticosteroid
   - Administration of large dose of corticosteroid intramuscularly, including demonstration and return demonstration
   - Consultation with health care provider
5. Prevention of infection and need for prompt and vigorous treatment of existing infections
6. Need for lifelong replacement therapy
7. Need for lifelong medical supervision
8. Need for medical identification device
9. Prevention of falls
10. Adverse effects of corticosteroid therapy and prevention techniques
11. Special instruction for patients who are diabetics and management of blood glucose when taking corticosteroids

bracelet (Medic Alert) and carry a wallet card stating the patient has Addison's disease so that appropriate therapy can be initiated in case of an emergency. Provide verbal instruction and handouts about other medications that can cause a need to increase (e.g., phenytoin, barbiturates, rifampin, antacids) or decrease (e.g., estrogen) glucocorticoid dosage. Instruct patients using mineralocorticoid therapy (fludrocortisone) how to take their BP, increase salt intake, and report any significant changes to their health care provider.

The patient should carry an emergency kit at all times with 100 mg of IM hydrocortisone, syringes, and instructions for use. Instruct the patient and significant others in how to give an IM injection in case the hormone therapy cannot be taken orally. Have the patient verbalize instructions and practice IM injections with saline. Provide written instructions on when the dose should be changed.[27]

CORTICOSTEROID THERAPY

Corticosteroids are used to relieve the signs and symptoms associated with many diseases (Table 50-18). Corticosteroids are effective in treating many diseases and disorders. However, the long-term administration of corticosteroids in therapeutic doses often leads to serious complications and side effects (Table 50-19). For this reason, corticosteroid therapy is not recommended for minor chronic conditions. Therapy should be reserved for diseases that have a risk of death or permanent loss of function, and for conditions in which short-term therapy is likely to produce remission or recovery. The potential benefits of treatment must always be weighed against the risks.

A beneficial effect of corticosteroids in one situation may be a harmful one in another. For example, decreasing inflammation in arthritis is an important therapeutic effect, but increasing the risk for infection is a harmful effect. Suppression of inflammation and the immune response may help save lives in persons with anaphylaxis and in those receiving an organ transplant, but it can reactivate latent tuberculosis and greatly reduces resistance to other infections and cancers. The vasopressive

TABLE 50-18 DRUG THERAPY

Diseases and Disorders Treated With Corticosteroids

Hormone Therapy
Adrenal insufficiency
Congenital adrenal hyperplasia

Therapeutic Effect
Allergic Reactions
- Anaphylaxis
- Bee stings
- Contact dermatitis
- Drug reactions
- Serum sickness

- Chronic obstructive pulmonary disease

Other Diseases or Disorders
- Skin diseases
- Malignancies, leukemia, lymphoma
- Immunosuppression
- Inflammation
- Nephrotic syndrome

effect of corticosteroids is critical in enabling a person to function in stressful situations, but can produce hypertension when used for drug therapy. Effects and side effects related to corticosteroid therapy are listed in Table 50-19.

DRUG ALERT: Corticosteroids
- Instruct the patient not to abruptly discontinue these drugs.
- Monitor the patient for signs of infection.
- Instruct patients with diabetes to closely monitor blood glucose.

Patients receive corticosteroid therapy for many reasons (see Table 50-18). Detailed instruction is necessary to ensure patient

TABLE 50-19 DRUG THERAPY

Effects and Side Effects of Corticosteroids

- Hypokalemia may develop.
- Patient is predisposed to peptic ulcer disease.
- Skeletal muscle atrophy and weakness occur.
- Mood and behavior changes may be observed.
- Glucose intolerance predisposes patient to diabetes mellitus.
- Fat from extremities is redistributed to trunk and face.
- Hypocalcemia related to anti–vitamin D effect may occur.
- Healing is delayed, with increased risk for wound dehiscence.
- Susceptibility to infection is increased. Infection develops more rapidly and spreads more widely.
- Manifestations of inflammation, including redness, tenderness, heat, swelling, and local edema, are suppressed.
- Pituitary ACTH synthesis is suppressed. Corticosteroid deficiency is likely if hormones are withdrawn abruptly. Taper corticosteroid doses.
- Blood pressure increases because of excess blood volume and potentiation of vasoconstrictor effects. Hypertension predisposes patient to heart failure.
- Protein depletion decreases bone formation, density, and strength, leading to predisposition to pathologic fractures, especially compression fractures of the vertebrae (osteoporosis).

ACTH, Adrenocorticotropic hormone.

adherence. When corticosteroids are used as nonreplacement therapies, they are taken once daily or once every other day. They should be taken early in the morning with food to decrease gastric irritation. Because exogenous corticosteroid administration may suppress endogenous ACTH and therefore endogenous cortisol (suppression is time and dose dependent), emphasize the danger of abrupt cessation of corticosteroid therapy to patients and caregivers. Corticosteroids taken for longer than 1 week will suppress adrenal production, and oral corticosteroids must be tapered. Ensure that increased doses of corticosteroids are prescribed in acute care or home care settings in situations of physical or emotional stress.

Corticosteroid-induced osteoporosis is an important concern for patients who receive corticosteroid treatment for prolonged periods (longer than 3 months).[28] Therapies to reduce the resorption of bone may include increased calcium intake, vitamin D supplementation, bisphosphonates (e.g., alendronate), and a low-impact exercise program. Further instruction and interventions to minimize the side effects and complications of corticosteroid therapy are presented in Table 50-20.

HYPERALDOSTERONISM

Hyperaldosteronism (Conn's syndrome) is characterized by excessive aldosterone secretion. The main effects of aldosterone are (1) sodium retention and (2) potassium and hydrogen ion excretion. Thus the hallmark of this disease is hypertension with hypokalemic alkalosis. *Primary hyperaldosteronism* (PA) is most commonly caused by a small solitary adrenocortical adenoma. Occasionally multiple lesions are involved and are associated with bilateral adrenal hyperplasia. PA affects women more than men and usually occurs between 30 and 60 years of age. A genetic link has been identified in some patients.[29] Up to 2% of all cases of hypertension are caused by PA. *Secondary hyperaldosteronism* occurs in response to a nonadrenal cause of elevated aldosterone levels such as renal artery stenosis, renin-secreting tumors, and chronic kidney disease.

Elevated levels of aldosterone are associated with sodium retention and excretion of potassium. Sodium retention leads to hypernatremia, hypertension, and headache. Edema does not usually occur because the rate of sodium excretion increases, which prevents more severe sodium retention. The potassium wasting leads to hypokalemia, which causes generalized muscle weakness, fatigue, cardiac dysrhythmias, glucose intolerance, and metabolic alkalosis that may lead to tetany.

Hyperaldosteronism should be suspected in all hypertensive patients with hypokalemia who are not being treated with diuretics. PA is associated with elevated plasma aldosterone levels, elevated sodium levels, decreased serum potassium levels, and decreased plasma renin activity. Adenomas are localized by means of a CT scan or an MRI.[30] If a tumor is not found, plasma 18-hydroxycorticosterone is measured after overnight bed rest. A level greater than 50 ng/dL indicates an adenoma.

TABLE 50-20 PATIENT & CAREGIVER TEACHING GUIDE

Corticosteroid Therapy

Include the following instructions when teaching the patient and caregiver to manage corticosteroid therapy.

1. Plan a diet high in protein, calcium (at least 1500 mg/day) and potassium but low in fat and concentrated simple carbohydrates such as sugar, honey, syrups, and candy.
2. Identify measures to ensure adequate rest and sleep, such as daily naps and avoidance of caffeine late in the day.
3. Develop and maintain an exercise program to help maintain bone integrity.
4. Recognize edema and ways to restrict sodium intake to <2000 mg/day if edema occurs.
5. Monitor glucose levels and recognize symptoms of hyperglycemia (e.g., polydipsia, polyuria, blurred vision). Report hyperglycemic symptoms or capillary glucose levels >120 mg/dL (10 mmol/L).
6. Notify health care provider if experiencing heartburn after meals or epigastric pain that is not relieved by antacids.
7. See an eye specialist yearly to assess for cataracts.
8. Use safety measures such as getting up slowly from bed or a chair and use good lighting to avoid accidental injury.
9. Maintain good hygiene practices and avoid contact with persons with colds or other contagious illnesses to prevent infection.
10. Inform all health care providers about long-term corticosteroid use.
11. Recognize need for increased doses of corticosteroids in times of physical and emotional stress.
12. Never abruptly stop the corticosteroids because this could lead to addisonian crisis and possibly death.

NURSING AND COLLABORATIVE MANAGEMENT PRIMARY HYPERALDOSTERONISM

The preferred treatment for PA is surgical removal of the adenoma (adrenalectomy). A laparoscopic approach is most often used. Before surgery, patients should be treated with potassium-sparing diuretics (spironolactone [Aldactone], eplerenone [Inspra]) and antihypertensive agents to normalize serum potassium levels and BP. Spironolactone and eplerenone block the binding of aldosterone to the mineralocorticoid receptor in the terminal distal tubules and collecting ducts of the kidney, thus increasing the excretion of sodium and water and the retention of potassium. Oral potassium supplements and sodium restrictions may also be necessary. However, potassium supplementation and a potassium-sparing diuretic should not be started simultaneously because of the danger of hyperkalemia. Teach patients taking eplerenone to avoid grapefruit juice.

Patients with bilateral adrenal hyperplasia are treated with a potassium-sparing diuretic (e.g., spironolactone, amiloride [Midamor]) or aminoglutethimide, which blocks aldosterone synthesis. Calcium channel blockers may also be used to control BP. Dexamethasone may be used to decrease adrenal hyperplasia.

Nursing care includes careful assessment for signs of fluid and electrolyte balance (especially potassium) and cardiovascular status. Monitor BP frequently before and after surgery because unilateral adrenalectomy is successful in controlling hypertension in only 80% of patients with an adenoma. Instruct patients receiving maintenance therapy with spironolactone or amiloride about the possible side effects of gynecomastia, impotence, and menstrual disorders, as well as the signs and symptoms of hypokalemia and hyperkalemia. Teach patients how to monitor their own BP and the need for frequent monitoring. Stress the need for continued health supervision.

DISORDERS OF ADRENAL MEDULLA

PHEOCHROMOCYTOMA

Pheochromocytoma, which is a rare condition caused by a tumor in the adrenal medulla affecting the chromaffin cells,

results in an excess production of catecholamines (epinephrine, norepinephrine). The most dangerous immediate effect of the disease is severe hypertension.[31] If left untreated, it may lead to hypertensive encephalopathy, diabetes mellitus, cardiomyopathy, and death. It is most commonly seen in young to middle-aged adults. Pheochromocytoma may be inherited in persons with multiple endocrine neoplasia.

The most striking clinical features of pheochromocytoma are severe, episodic hypertension accompanied by the classic manifestations of severe, pounding headache; tachycardia with palpitations; profuse sweating; and unexplained abdominal or chest pain. Attacks may be provoked by many medications, including antihypertensives, opioids, radiologic contrast media, and tricyclic antidepressants. The attacks may last from a few minutes to several hours.

Although pheochromocytoma is associated with a number of symptoms, the diagnosis is often missed. Pheochromocytoma is an uncommon cause of hypertension, accounting for only 0.1% of all cases. Consider this condition in patients who do not respond to traditional hypertensive treatments.

The simplest and most reliable diagnostic test for pheochromocytoma is measurement of urinary fractionated metanephrines (catecholamine metabolites) and fractionated catecholamines and creatinine, usually done as a 24-hour urine collection. Values are elevated in at least 95% of persons with pheochromocytoma. Serum catecholamines may be elevated during an "attack." CT scans and MRI are used for diagnosing tumors. Avoid palpating the abdomen of a patient with suspected pheochromocytoma, since it may cause the sudden release of catecholamines and severe hypertension.

NURSING AND COLLABORATIVE MANAGEMENT
PHEOCHROMOCYTOMA

The primary treatment of pheochromocytoma is surgical removal of the tumor. Treatment with α- and β-adrenergic receptor blockers is required preoperatively to control BP and prevent an intraoperative hypertensive crisis. The α-adrenergic receptor blocker phenoxybenzamine (Dibenzyline) is given 7 to 10 days preoperatively to reduce BP and alleviate other symptoms of catecholamine excess. After adequate α-adrenergic blockade, β-adrenergic receptor blockers (e.g., propranolol) are used to decrease tachycardia and other dysrhythmias. If β-blockers are started too early, unopposed α-adrenergic stimulation could precipitate a hypertensive crisis. They can also cause orthostatic hypotension. Advise the patient to make postural changes cautiously.

Surgery is most commonly done using a laparoscopic approach. Removal of the adrenal tumor usually cures the hypertension, but hypertension persists in approximately 10% to 30% of patients. If surgery is not an option, metyrosine (Demser) is used to decrease catecholamine production by the tumor.

Case finding is an important nursing role. Any patient with hypertension accompanied by symptoms of sympathoadrenal stimulation should be referred to a health care provider for definitive diagnosis. Assess the patient for the classic triad of symptoms of pheochromocytoma (severe pounding headache, tachycardia, and profuse sweating). Monitor the BP immediately if the patient is experiencing an "attack."

Attempt to make the patient with pheochromocytoma as comfortable as possible. Monitor blood glucose levels to assess for diabetes mellitus. Patients need rest, nourishing food, and emotional support during this period. Preoperative and postoperative care is similar to that for any patient undergoing adrenalectomy except that BP fluctuations from catecholamine excesses tend to be severe and must be carefully monitored. Emphasize the importance of follow-up and routine BP monitoring because hypertension may persist even when the tumor is removed. If metyrosine is being used, instruct the patient to rise slowly and hold onto a secure object, since this drug can cause orthostatic hypotension.

CASE STUDY

Graves' Disease

Jupiterimages/Photos.com/Thinkstock

Patient Profile

R.D., a 47-yr-old white woman, was admitted to the hospital with a high fever. Unable to find a source of infection, the health care provider does an endocrine workup. R.D. is diagnosed with Graves' disease.

Subjective Data

- Reports recent job loss because she is no longer able to tolerate work-related stress
- Reports symptoms including fatigue, unintentional weight loss, insomnia, palpitations, and heat intolerance

Objective Data

Physical Examination

- Fever of 104°F (40°C)
- BP of 150/80 mm Hg, pulse of 116 beats/min, and respiratory rate of 26 breaths/min
- Hot, moist skin
- Fine tremors of the hands
- 4+ deep tendon reflexes and muscle strength of 1 to 2 out of 5

Collaborative Care

- Subtotal thyroidectomy planned for 2 mo later
- Started on propylthiouracil (PTU) and propranolol (Inderal)

Discussion Questions

1. What is the etiology of R.D.'s symptoms?
2. What diagnostic studies would be important in evaluating R.D.'s condition? What results would establish the diagnosis of Graves' disease?
3. Why was surgery delayed?
4. What is the purpose of drug therapy for R.D.?
5. ***Priority Decision:*** What are the patient's priority teaching needs? What teaching strategies would you use if R.D. could not read?
6. What are the nursing interventions for successful long-term management of R.D. after the subtotal thyroidectomy?
7. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses pertinent to this patient while hospitalized? Are there any collaborative problems?
8. ***Evidence-Based Practice:*** Why is R.D. counseled to give up her long-standing cigarette smoking habit?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg.*

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. After a hypophysectomy for acromegaly, postoperative nursing care should focus on
   - **a.** frequent monitoring of serum and urine osmolarity.
   - **b.** parenteral administration of a GH-receptor antagonist.
   - **c.** keeping the patient in a recumbent position at all times.
   - **d.** patient teaching regarding the need for lifelong hormone therapy.
2. A patient with a head injury develops SIADH. Manifestations the nurse would expect to find include
   - **a.** hypernatremia and edema.
   - **b.** muscle spasticity and hypertension.
   - **c.** low urine output and hyponatremia.
   - **d.** weight gain and decreased glomerular filtration rate.
3. The health care provider prescribes levothyroxine (Synthroid) for a patient with hypothyroidism. After teaching regarding this drug, the nurse determines that further instruction is needed when the patient says
   - **a.** "I can expect the medication dose may need to be adjusted."
   - **b.** "I only need to take this drug until my symptoms are improved."
   - **c.** "I can expect to return to normal function with the use of this drug."
   - **d.** "I will report any chest pain or difficulty breathing to the doctor right away."
4. After thyroid surgery, the nurse suspects damage or removal of the parathyroid glands when the patient develops
   - **a.** muscle weakness and weight loss.
   - **b.** hyperthermia and severe tachycardia.
   - **c.** hypertension and difficulty swallowing.
   - **d.** laryngospasms and tingling in the hands and feet.
5. Important nursing intervention(s) when caring for a patient with Cushing syndrome include *(select all that apply)*
   - **a.** restricting protein intake.
   - **b.** monitoring blood glucose levels.
   - **c.** observing for signs of hypotension.
   - **d.** administering medication in equal doses.
   - **e.** protecting patient from exposure to infection.
6. An important preoperative nursing intervention before an adrenalectomy for hyperaldosteronism is to
   - **a.** monitor blood glucose levels.
   - **b.** restrict fluid and sodium intake.
   - **c.** administer potassium-sparing diuretics.
   - **d.** advise the patient to make postural changes slowly.
7. To control the side effects of corticosteroid therapy, the nurse teaches the patient who is taking corticosteroids to
   - **a.** increase calcium intake to 1500 mg/day.
   - **b.** perform glucose monitoring for hypoglycemia.
   - **c.** obtain immunizations due to high risk of infections.
   - **d.** avoid abrupt position changes because of orthostatic hypotension.
8. The nurse teaches the patient that the best time to take corticosteroids for replacement purposes is
   - **a.** once a day at bedtime.
   - **b.** every other day on awakening.
   - **c.** on arising and in the late afternoon.
   - **d.** at consistent intervals every 6 to 8 hours.

1. a, 2. c, 3. b, 4. d, 5. b, e, 6. c, 7. a, 8. c

LEARNING OUTCOMES

1. Describe the structures and functions of the male and female reproductive systems.
2. Summarize the functions of the major hormones essential for the functioning of the male and female reproductive systems.
3. Explain the physiologic changes during the stages of sexual response for both a man and a woman.
4. Link the age-related changes of the male and female reproductive systems to the differences in assessment findings.
5. Select the significant subjective and objective data related to the male and female reproductive systems and information about sexual function that should be obtained from a patient.
6. Select the appropriate techniques to use in the physical assessment of the male and female reproductive systems.
7. Differentiate normal from common abnormal findings of a physical assessment of the male and female reproductive systems.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the male and female reproductive systems.

STRUCTURES AND FUNCTIONS OF MALE AND FEMALE REPRODUCTIVE SYSTEMS

The reproductive system of both males and females consists of primary (or essential) organs and secondary (or accessory) organs. The primary reproductive organs are referred to as **gonads.** The female gonads are the ovaries; the male gonads are the testes. The main responsibility of the gonads is secretion of hormones and production of gametes (ova and sperm). Secondary (or accessory) organs are responsible for (1) transporting and nourishing the ova and sperm and (2) preserving and protecting the fertilized eggs.

Male Reproductive System

The three primary roles of the male reproductive system are (1) production and transportation of sperm, (2) deposition of sperm in the female reproductive tract, and (3) secretion of hormones. The primary reproductive organs in the male are

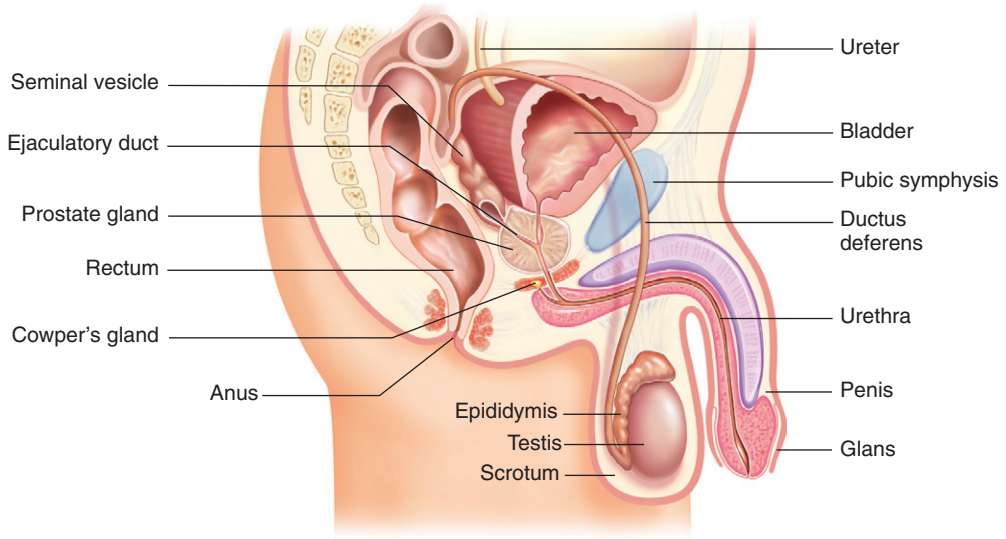

FIG. 51-1 Male reproductive tract.

the testes. Secondary reproductive organs include ducts (epididymis, ductus deferens, ejaculatory duct, and urethra), sex glands (prostate gland, Cowper's glands, and seminal vesicles), and the external genitalia (scrotum and penis)[1] (Fig. 51-1).

Testes. The paired testes are ovoid, smooth, firm organs measuring 1.4 to 2.2 in (3.5 to 5.6 cm) long and 0.8 to 1.2 in (2 to 3 cm) wide. They are within the scrotum, which is a loose protective sac composed of a thin outer layer of skin over a tough connective tissue layer. Within the testes, coiled structures known as seminiferous tubules form *spermatozoa* (immature sperm). The process of sperm production is called **spermatogenesis.** Interstitial cells of the testes lie between the seminiferous tubules and produce the male sex hormone testosterone.

Ducts. Sperm formed in the seminiferous tubules move through a series of ducts. These ducts transport the sperm from the testes to the outside of the body. As sperm exit the testes, they enter and pass through the epididymis, ductus deferens, ejaculatory duct, and urethra.

The **epididymis** is a comma-shaped structure located on the posterosuperior aspect of each testis within the scrotum (see Figs. 51-1 and 51-2). It is a very long, tightly coiled structure that measures about 20 ft in length.[1] The epididymis transports the sperm as they mature. Sperm exit the epididymis through a long, thick tube known as the ductus deferens.

The **ductus deferens** (also known as the *vas deferens*) is continuous with the epididymis within the scrotal sac. It travels upward through the scrotum and continues through the inguinal ring into the abdominal cavity. The spermatic cord is composed of a connective tissue sheath that encloses the ductus deferens, arteries, veins, nerves, and lymph vessels as it ascends up through the inguinal canal (see Fig. 51-2). In the abdominal cavity, the ductus deferens travels up, over, and behind the bladder. Posterior to the bladder the ductus deferens joins the seminal vesicle to form the ejaculatory duct (see Fig. 51-1).

The ejaculatory duct passes downward through the prostate gland, connecting with the urethra. The urethra extends from the bladder, through the prostate, and ends in a slitlike opening (the meatus) on the ventral side of the *glans,* the tip of the penis.

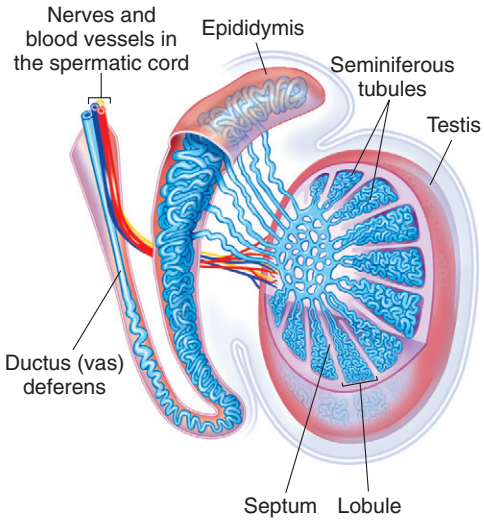

FIG. 51-2 Seminiferous tubules, testis, epididymis, and ductus (vas) deferens in the male.

During the process of ejaculation, sperm travels through the urethra and out of the penis.

Glands. The seminal vesicles, the prostate gland, and Cowper's (bulbourethral) glands are the accessory glands of the male reproductive system. These glands produce and secrete seminal fluid (semen), which surrounds the sperm and forms the *ejaculate.*

The seminal vesicles lie posterior to the bladder and between the rectum and bladder. The ducts of the seminal vesicles fuse with the ductus deferens to form the ejaculatory ducts that enter the prostate gland. The prostate gland lies beneath the bladder. Its posterior surface is in contact with the rectal wall. The prostate normally measures 0.8 in (2 cm) wide and 1.2 in (3 cm) long and is divided into the right and left lateral lobes and an anteroposterior median lobe. Cowper's glands lie on each side of the urethra and slightly posterior to it, just below the prostate. The ducts of these glands enter directly into the urethra.

Secretions from the seminal vesicles, prostate, and Cowper's glands make up most of the fluid in the ejaculate. These various secretions serve as a medium for the transport of sperm and create an alkaline, nutritious environment that promotes sperm motility and survival.

External Genitalia. The external genitalia consist of the penis and the scrotum. The penis consists of a shaft, and the tip is known as the glans. The glans is covered by a fold of skin, the prepuce (or foreskin), that forms at the junction of the glans and the shaft of the penis. In circumcised males the prepuce has been removed. The shaft of the penis consists of erectile tissue composed of the corpus cavernosum, the corpus spongiosum (the fibrous sheath that encases the erectile tissue), and the urethra. The skin covering the penis is thin, loose, and hairless.

Female Reproductive System

The three primary roles of the female reproductive system are (1) production of ova (eggs), (2) secretion of hormones, and (3) protection and facilitation of the development of the fetus in a pregnant female. Like the male, the female has primary and secondary reproductive organs. The primary reproductive organs in the female are the paired ovaries. Secondary reproductive organs include the ducts (fallopian tubes), uterus, vagina, sex glands (Bartholin's glands and breasts), and external genitalia (vulva).

Pelvic Organs

Ovaries. The ovaries are located on either side of the uterus, just behind and below the fallopian (uterine) tubes (Fig. 51-3). The almond-shaped ovaries are firm and solid, approximately 0.6 in (1.5 cm) wide and 1.2 in (3 cm) long. Their functions include ovulation and secretion of the two major reproductive hormones, estrogen and progesterone.

The outer zone of the ovary contains follicles with germ cells, or *oocytes.* Each follicle contains a primordial (immature) oocyte surrounded by granulosa and theca cells. These two layers protect and nourish the oocyte until the follicle reaches maturity and ovulation occurs. However, not all follicles reach maturity. In a process termed *atresia,* most of the primordial follicles become smaller and are reabsorbed by the body. Thus the number of follicles declines from 2 million to 4 million at birth to approximately 300,000 to 400,000 at menarche. Fewer than 500 oocytes are actually released by ovulation during the reproductive years of the normal healthy woman.

Fallopian Tubes. Normally, each month during a woman's reproductive years, one ovarian follicle reaches maturity, and the ovum is ovulated, or expelled, from the ovary through the stimulus of the gonadotropic hormones, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The ovum then travels up a fallopian tube where fertilization by sperm may occur, if sperm are present. An ovum can be fertilized up to 72 hours after its release.

The distal ends of the fallopian tubes consist of fingerlike projections called *fimbriae* that "massage" the ovaries at ovulation to help extract the mature ovum. The tubes, which average 4.8 in (12 cm) in length, extend from the fimbriae to the superior lateral borders of the uterus. Fertilization usually takes place within the outer one third of the fallopian tubes.

Uterus. The uterus is a pear-shaped, hollow, muscular organ (see Fig. 51-3). It is located between the bladder and the rectum. In the mature **nulliparous** (never pregnant) woman, the uterus is approximately 2.4 to 3.2 in (6 to 8 cm) long and 1.6 in (4 cm) wide. The uterine walls consist of an outer serosal layer, the *perimetrium;* a middle muscular layer, the *myometrium;* and an inner mucosal layer, the *endometrium*.

The uterus consists of the fundus, body (or corpus), and cervix (see Fig. 51-3). The body makes up about 80% of the uterus and connects with the cervix at the isthmus, or neck. The cervix is the lower portion of the uterus that projects into the anterior wall of the vaginal canal. It makes up about 15% to 20% of the uterus in the nulliparous female. The cervix consists of the *ectocervix,* the outer portion that protrudes into the vagina, and the *endocervix,* the canal in the opening of the cervix. The ectocervix is covered with squamous epithelial cells, which give it a smooth, pinkish appearance. The endocervix contains a lining of columnar epithelial cells, which give it a rough, reddened appearance. The junction at which the two types of epithelial cells meet is termed the *squamocolumnar junction* and contains the optimal types of cells needed for an accurate Papanicolaou (Pap) test to screen for malignancies.

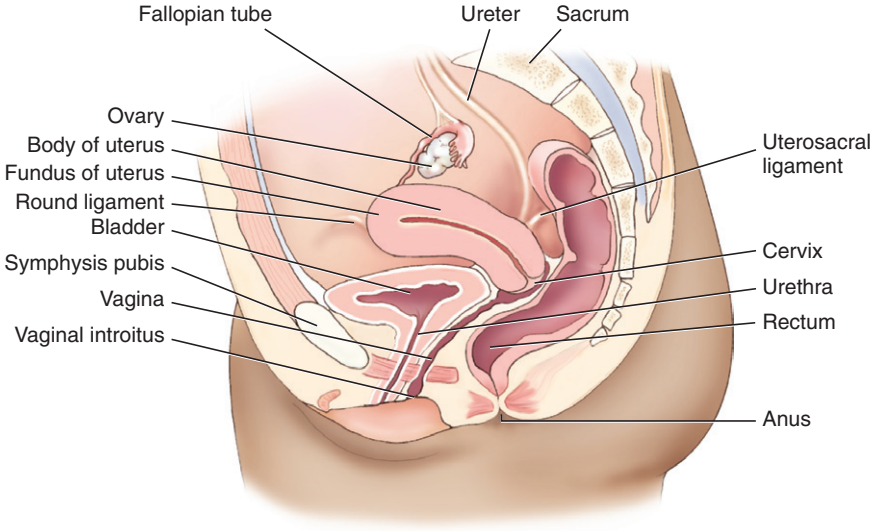

FIG. 51-3 Female reproductive tract.

The cervical canal is 0.8 to 1.6 in (2 to 4 cm) long and is relatively tightly closed. However, the cervix allows sperm to enter the uterus and also allows menses to be expelled. The columnar epithelium, under hormonal influence, provides elasticity during labor for the cervix to stretch to allow passage of a fetus during the birth process. The entrance of sperm into the uterus is facilitated by mucus produced by the cervix under the influence of estrogen. Under normal conditions, the cervical mucus becomes watery, stretchy, and more abundant at ovulation. The postovulatory cervical mucus, under the influence of progesterone, is thick and inhibits sperm passage.

Vagina. The vagina is a tubular structure 3 to 4 in (7.6 to 10 cm) long that is lined with squamous epithelium. The secretions of the vagina consist of cervical mucus, desquamated epithelium, and, during sexual stimulation, a watery secretion. These fluids help protect against vaginal infection. The muscular and erectile tissue of the vaginal walls allows enough dilation and contraction to accommodate the passage of the fetus during labor, as well as penetration of the penis during intercourse. The anterior vaginal wall lies along the urethra and bladder. The posterior vaginal wall is adjacent to the rectum.

Pelvis. The female pelvis consists of four bones (two pelvic bones, sacrum, coccyx) held together by several strong ligaments. The sections of these bones that lie below the iliopectineal line are important during birth and are often a factor determining the ability of a woman to deliver a child vaginally.

External Genitalia. The external portion of the female reproductive system (Fig. 51-4), commonly called the *vulva,* consists of the mons pubis, labia majora, labia minora, clitoris, urethral meatus, Skene's glands, vaginal introitus (opening), and Bartholin's glands.

The **mons pubis** is a fatty layer lying over the pubic bone. It is covered with coarse hair that lies in a triangular pattern. (The male hair pattern is diamond shaped.) The labia majora are folds of adipose tissue that form the outer borders of the vulva. The hairless labia minora form the borders of the vaginal orifice and extend anteriorly to enclose the clitoris.

The *vestibule* is a boat-shaped fossa between the labia minora, extending from the clitoris at the anterior end to the vaginal opening at the posterior end. The perineum is the area between the vagina and the anus. The vaginal introitus is surrounded by thin membranous tissue called the *hymen.* In the adult woman the hymen usually appears as folds or hymenal tags and separates the external genitalia from the vagina. At the posterior aspect of the vagina, a tense band of mucous membrane connecting the posterior ends of the labia minora is referred to as the *posterior fourchette.*

The **clitoris** is erectile tissue that becomes engorged during sexual excitation. It lies anterior to the urethral meatus and the vaginal orifice and is usually covered by the prepuce. Clitoral stimulation is an important part of sexual activity for many women.

Ducts of the Skene's glands lie alongside the urinary meatus and are thought to help lubricate the urinary meatus.[2] The Bartholin's glands, located at the posterior and lateral aspects of the vaginal orifice, secrete a thin, mucoid material believed to contribute slightly to lubrication during sexual intercourse. These glands are not usually palpable unless sebaceous-like cysts form or they are swollen in the presence of an infection, such as a sexually transmitted infection (STI).

Breasts. The breasts are a secondary sex characteristic that develops during puberty in response to estrogen and progesterone. Cyclic hormonal changes lead to regular changes in breast tissue to prepare it for lactation when fertilization and pregnancy occur.

The breasts extend from the second to the sixth ribs, with the tail reaching the axilla (Fig. 51-5). The fully mature breast is dome shaped and contains a pigmented center termed the *areola.* The areolar region contains Montgomery's tubercles, which are similar to sebaceous glands and assist in lubricating the nipple. During lactation, the alveoli secrete milk. The milk then flows into a ductal system and is transported to the lactiferous sinuses. The nipple contains 15 to 20 tiny openings through which the milk flows during breastfeeding. The fibrous and fatty tissue that supports and separates the channels of the mammary duct system is primarily responsible for the varying sizes and shapes of the breasts in different individuals.

The breast has a rich lymphatic network that drains into axillary and clavicular channels (see Fig. 52-5). Superficial

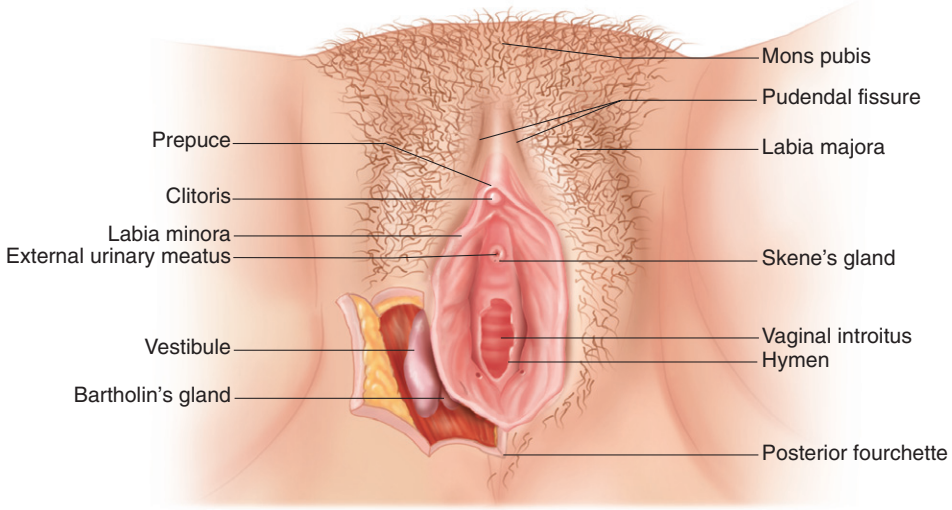

FIG. 51-4 External female genitalia.

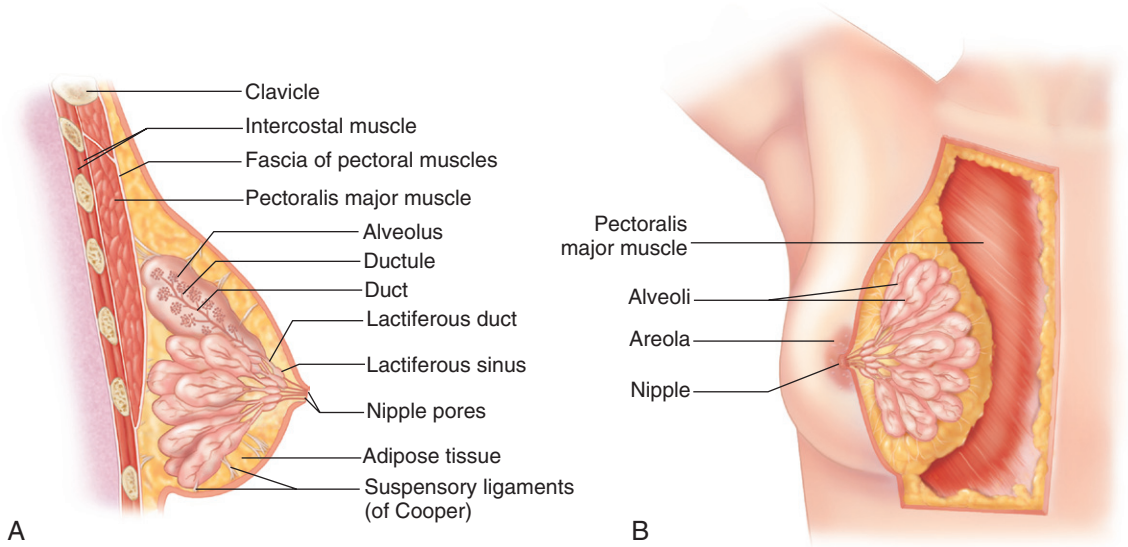

FIG. 51-5 The lactating female breast. **A,** Glandular structures are anchored to the overlying skin and the pectoralis muscle by suspensory ligaments of Cooper. Each lobule of glandular tissue is drained by a lactiferous duct that eventually opens through the nipple. **B,** Anterior view of a lactating breast. In nonlactating breasts, glandular tissue is less evident with adipose tissue comprising most of the breast.

lymph nodes are located in the axilla and are accessible to examination. This system is often responsible for the metastasis of a malignant tumor from the breast to other parts of the body.

Neuroendocrine Regulation of Reproductive System

The hypothalamus, pituitary gland, and gonads secrete numerous hormones (Fig. 51-6). (Endocrine hormones are discussed in Chapter 48.) These hormones regulate the processes of ovulation, spermatogenesis (formation of sperm), and fertilization and the formation and function of the secondary sex characteristics. The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary gland to secrete its hormones, including FSH and LH. LH in males is sometimes called interstitial cell–stimulating hormone (ICSH). The gonadal hormones are estrogen, progesterone, and testosterone.

In women, FSH production by the anterior pituitary stimulates the growth and maturity of the ovarian follicles necessary for ovulation.[3] The mature follicle produces estrogen, which in turn suppresses the release of FSH. Another hormone, inhibin, is also secreted by the ovarian follicle and inhibits both GnRH and FSH secretion. In men, FSH stimulates the seminiferous tubules to produce sperm.

LH contributes to the ovulatory process because it causes follicles to complete maturation and undergo ovulation. It also affects the development of a ruptured follicle (area where ovum exited during ovulation), which turns into a corpus luteum from which progesterone is secreted. Progesterone maintains the rich vascular state of the uterus (secretory phase) in preparation for fertilization and implantation. In men, LH (or ICSH) triggers testosterone production by the interstitial cells of the testes and thus is essential for the full maturation of sperm.

Prolactin has no known function in men. In women, prolactin stimulates the development and growth of the mammary glands. During lactation, it initiates and maintains milk production.

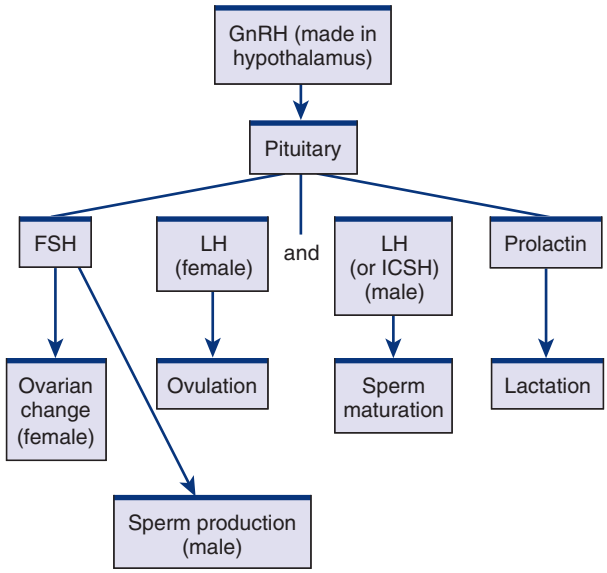

FIG. 51-6 Hypothalamic-pituitary-gonadal axis. Only the major pituitary hormone actions are depicted. *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *ICSH,* interstitial cell–stimulating hormone; *LH,* luteinizing hormone.

The gonadal hormones, estrogen and progesterone, are produced by the ovaries in women. Small amounts of an estrogen precursor are also produced in the adrenal cortices. Estrogen is essential to the development and maintenance of the secondary sex characteristics, the proliferative phase of the menstrual cycle immediately after menstruation, and the uterine changes essential to pregnancy. The role and importance of estrogen in men are not well understood. In men, estrogen is produced predominantly in the adrenal cortex.

Progesterone plays a major role in the menstrual cycle but most specifically in the secretory phase. Like estrogen, progesterone is involved in the bodily changes associated with preg-

TABLE 51-1 GONADAL FEEDBACK MECHANISMS

Negative Feedback

Female

↓ Estrogen ⟶ ↑ GnRH (hypothalamus) ⟶ ↑ FSH (pituitary) ⟶ ↑ Estrogen (ovaries)

Male

↓ Testosterone ⟶ ↑ GnRH (hypothalamus) ⟶ ↑ FSH and LH (or ICSH) (pituitary) ⟶ ↑ Testosterone (testes)

Positive Feedback

↑ Estrogen ⟶ ↑ GnRH (hypothalamus) ⟶ ↑ LH (pituitary)

FSH, Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *ICSH,* interstitial cell–stimulating hormone; *LH,* luteinizing hormone.

nancy. Adequate progesterone is necessary to maintain an implanted egg.

In men, the major gonadal hormone is testosterone, which is produced by the testes. Testosterone is responsible for the development and maintenance of secondary sex characteristics, as well as for adequate spermatogenesis. In women, androgens are produced in small amounts by the adrenal glands and ovaries.

The circulating levels of gonadal hormones are controlled primarily by a *negative feedback process*. Receptors within the hypothalamus and pituitary are sensitive to the circulating blood levels of the hormones (Table 51-1). Increased levels of hormones stimulate a hypothalamic response to decrease the high circulating levels. Likewise, low circulating levels provoke a hypothalamic response that increases the low circulating levels. For example, if the circulating level of testosterone in men is low, the hypothalamus is stimulated to secrete GnRH. This triggers the anterior pituitary to secrete greater amounts of FSH and LH, which in turn causes an increase in the production of testosterone. The high level of testosterone signals a decrease in the production of GnRH and thus of FSH and LH.

In women, however, there is a slight variation. The circulating levels are controlled through a combination of both a negative and a positive feedback system. A *negative feedback control* mechanism exists similar to that described above. When circulating estrogen levels are low, the hypothalamus is stimulated to increase its production of GnRH. GnRH stimulates the pituitary to secrete greater amounts of FSH and LH, resulting in higher levels of estrogen production by the ovaries. Reciprocally higher levels of circulating estrogen result in a decreasing secretion of GnRH and thus a decrease in the secretion of FSH by the pituitary.

Women also have a *positive feedback control* mechanism. Thus with increasing levels of circulating estrogen, a greater level of GnRH is produced, resulting in an increased level of LH from the pituitary. Likewise, lowered levels of estrogen result in a lowered level of LH.

Menarche

Menarche is the first episode of menstrual bleeding, indicating that a girl has reached puberty. Menarche usually occurs at approximately 12 to 13 years of age but can occur as early as 10 years of age in some individuals. Menstrual cycles are often irregular for the first 1 to 2 years after menarche because of *anovulatory cycles* (cycles without ovulation).

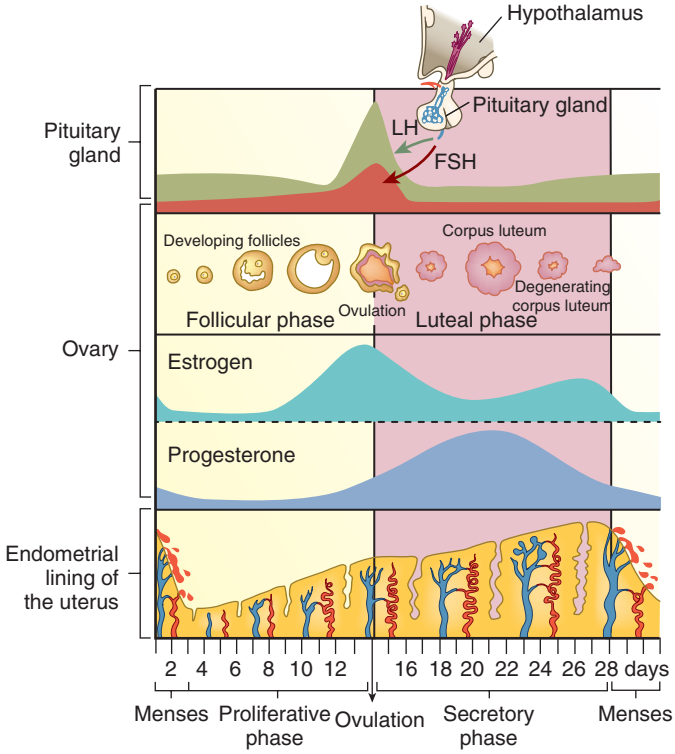

FIG. 51-7 Events of the menstrual cycle. The lines depict the changes in blood hormone levels, the development of the follicles, and the changes in the endometrium during the cycle. *FSH,* Follicle-stimulating hormone; *LH,* luteinizing hormone.

Menstrual Cycle

The major functions of the ovaries are ovulation and the secretion of hormones. These functions are accomplished during the normal **menstrual cycle,** a monthly process mediated by the hormonal activity of the hypothalamus, pituitary gland, and ovaries. Menstruation occurs during each month in which an egg is not fertilized (Fig. 51-7). The endometrial cycle is divided into three phases labeled in relation to uterine and ovarian changes: (1) the *proliferative,* or *follicular, phase;* (2) the *secretory,* or *luteal, phase;* and (3) the *menstrual,* or *ischemic, phase.* The length of the menstrual cycle ranges from 21 to 35 days, with an average of 28 days.[4]

The menstrual cycle begins on the first day of menstruation, which usually lasts 4 to 6 days. Table 51-2 includes characteristics of the menstrual cycle and related teaching. During menstruation, estrogen and progesterone levels are low, but FSH levels begin to increase. During the follicular phase, a single follicle matures fully under the stimulation of FSH. (The mechanism that ensures that usually only one follicle reaches maturity is not known.) The mature follicle stimulates estrogen production, causing a negative feedback with resulting decreased FSH secretion.

Although the initial stage of follicular maturation is stimulated by FSH, complete maturation and ovulation occur only in the presence of LH. When estrogen levels peak on about the twelfth day of the cycle, there is a surge of LH, which triggers ovulation a day or two later. After ovulation (maturation and

TABLE 51-2 PATIENT TEACHING GUIDE

Characteristics of Menstruation

Include the following information when teaching the patient about menstruation.

Characteristic	Teaching
Menarche	
Occurs between ages 10 and 16 yr. Average age at onset is 12-13 yr.	See health care provider regarding possible endocrine or developmental abnormality when delayed.
Interval	
Usually is 21-35 days, but regular cycles as short as 17 days or as long as 45 days are considered normal if pattern is consistent for individual.	Keep written record to identify own pattern of menstrual cycle. Expect some irregularity in perimenopausal period. Be aware that drugs (phenothiazines, opioids, contraceptives) and stressful life events can result in missed periods.
Duration	
Menstrual flow generally lasts 2-8 days.	Realize that pattern is fairly constant but that wide variations do exist.
Amount	
Menstrual flow varies from 20-80 mL per menses; average is 30 mL. Amount varies among women and in the same woman at different times. It is usually heaviest first 2 days.	Count pads or tampons used per day. The average tampon or pad, when completely saturated, absorbs 20-30 mL. Very heavy flow is indicated by complete soaking of two pads in 1-2 hr. Flow increases and then gradually decreases in perimenopausal period. IUD or drugs such as anticoagulants and thiazides can produce heavy menses.
Composition	
Menstrual discharge is mixture of endometrium, blood, mucus, and vaginal cells. It is dark red and less viscous than blood and usually does not clot.	Clots indicate heavy flow or vaginal pooling.

IUD, Intrauterine device.

release of an ovum), LH promotes the development of the corpus luteum.

The fully developed corpus luteum continues to secrete estrogen and initiates progesterone secretion. If fertilization occurs, high levels of estrogen and progesterone continue to be secreted because of the continued activity of the corpus luteum from stimulation by human chorionic gonadotropin (hCG). If fertilization does not take place, menstruation occurs because of a decrease in estrogen production and progesterone withdrawal.

During the *follicular phase,* the endometrial lining of the uterus also undergoes change. As more estrogen is produced, the endometrial lining undergoes proliferative changes, including an increase in the length of blood vessels and glandular tissue.

With ovulation and the resulting increased levels of progesterone, the *luteal* (or *secretory*) *phase* begins. If the corpus luteum regresses (when fertilization does not occur) and estrogen and progesterone levels fall, the endometrial lining can no longer be supported. As a result, the blood vessels contract, and tissue begins to slough (fall away). This sloughing results in the menses and the start of the menstrual phase.[4]

Menopause

Menopause is the physiologic cessation of menses associated with declining ovarian function. It is usually considered complete after 1 year of **amenorrhea** (absence of menstruation). (Menopause is discussed in Chapter 54.)

Phases of Sexual Response

The sexual response is a complex interplay of psychologic and physiologic phenomena and is influenced by a number of variables (e.g., stress, illness). The changes that occur during sexual excitement are similar for men and women. Masters and Johnson described the sexual response in terms of the excitement, plateau, orgasmic, and resolution phases.[5]

Male Sexual Response. The penis and the urethra are essential to the transport of sperm into the vagina and the cervix during intercourse. This transport is facilitated by penile erection in response to sexual stimulation during the *excitement phase*. Erection results from the filling of the large venous sinuses within the erectile tissue of the penis. In the flaccid state the sinuses hold only a small amount of blood, but during the erection stage they are congested with blood. Because the penis is richly endowed with sympathetic, parasympathetic, and pudendal nerve endings, it is readily stimulated to erection. The loose skin of the penis becomes taut as a result of the venous congestion. This erectile tautness allows for easy insertion into the vagina.

As the man reaches the *plateau phase,* the erection is maintained, and the penis increases in diameter as a result of a slight increase in vasocongestion. Testicle size also increases. Sometimes the glans penis becomes more reddish purple.

The subsequent contraction of the penile and urethral musculature during the *orgasmic phase* propels the sperm outward through the meatus. In this process, termed *ejaculation,* sperm are released into the ductus deferens during contractions. Sperm advance through the urethra, where fluids from the prostate and seminal vesicles are added to the ejaculate. The sperm continue their path through the urethra, receiving a small amount of fluid from the Cowper's glands, and are finally ejaculated through the urinary meatus. *Orgasm* is characterized by the rapid release of the vasocongestion and muscular tension (myotonia) that have developed. The rapid release of muscular tension (through rhythmic contractions) occurs primarily in the penis, prostate gland, and seminal vesicles. After ejaculation, a man enters the *resolution phase*. The penis undergoes involution, gradually returning to its unstimulated, flaccid state.

Female Sexual Response. The changes that occur in a woman during sexual excitation are similar to those in a man. In response to stimulation, the clitoris becomes congested and vaginal lubrication increases from secretions from the cervix, Bartholin's glands, and vaginal walls. This initial response is the excitation phase.

As excitation is maintained in the plateau phase, the vagina expands and the uterus is elevated. In the orgasmic phase, contractions occur in the uterus from the fundus to the lower uterine segment. There is a slight relaxation of the cervical os, which helps the entrance of the sperm, and rhythmic contractions of the vagina. Muscular tension is rapidly released through

rhythmic contractions in the clitoris, vagina, and uterus. This phase is followed by a resolution phase in which these organs return to their preexcitation state. However, women do not have to go through the resolution (refractory) recovery state before they can be orgasmic again. They can be multiorgasmic without resolution between orgasms.

GERONTOLOGIC CONSIDERATIONS

EFFECTS OF AGING ON REPRODUCTIVE SYSTEMS

With advancing age, changes occur in the male and female reproductive systems (Table 51-3). In women many of these changes are related to the altered estrogen production that is associated with menopause.[6] A reduction in circulating estrogen along with an increase in androgens in postmenopausal women is associated with breast and genital atrophy, reduction in bone mass, and increased rate of atherosclerosis. Vaginal dryness may occur, which can lead to urogenital atrophy and changes in the composition of vaginal secretions.

A gradual testosterone decline in older men occurs. Manifestations of hormonal decline in men can be physical, psychologic, or sexual. Some of the changes include an increase in prostate size and a decrease in testosterone level, sperm production, muscle tone of the scrotum, and size and firmness of the testicles. Erectile dysfunction and sexual dysfunction occur in some men as a result of these changes.[7]

Gradual changes resulting from advancing age occur in the sexual responses of men and women. The cumulative effects of these changes, as well as the negative social attitude toward sexuality in older adults, can affect the sexual practices of older adults. You have an important role in providing accurate and unbiased information about sexuality and age. Emphasize the normalcy of sexual activity in older adults.

TABLE 51-3 GERONTOLOGIC ASSESSMENT DIFFERENCES

Reproductive Systems

Changes	Differences in Assessment Findings
Male	
Penis	
Decreased subcutaneous fat, decreased skin turgor	Easily retractable foreskin (if uncircumcised). Decrease in size. Fewer sustained erections.
Testes	
Decreased testosterone production	Decrease in size. Change in position (lower).
Prostate	
Benign hyperplasia	Enlargement.
Breasts	
Enlargement	Gynecomastia (abnormal enlargement).
Female	
Breasts	
Decreased subcutaneous fat, increased fibrous tissue, decreased skin turgor	Less resilient, looser, more pendulous tissue. Decreased size. Duct around nipple may feel like stringy strand.
Vulva	
Decreased skin turgor	Atrophy. Decreased amount of pubic hair; decreased size of clitoris and labia.
Vagina	
Atrophy of tissue, decreased muscle tone, alkaline pH	Pale and dry mucosa. Relaxation of outlet, mucosa thins, vagina narrower and shorter, increased potential for infection.
Urethra	
Decreased muscle tone	Cystocele (protrusion of bladder through vaginal wall).
Uterus	
Decreased thickness of myometrium	Decrease in size, uterine prolapse.
Ovaries	
Decreased ovarian function	Nonpalpable ovaries, decreased size.

ASSESSMENT OF MALE AND FEMALE REPRODUCTIVE SYSTEMS

Subjective Data

Important Health Information. In addition to general health information, elicit information specifically relating to the reproductive system. Reproduction and sexual issues are often considered extremely personal and private. Develop trust with the patient to elicit such information. A professional demeanor is important when taking a reproductive or sexual history. Be sensitive, use gender-neutral terms when asking about partners, and maintain an awareness of a patient's culture and beliefs. Begin with the least sensitive information (e.g., menstrual history) before asking questions about more sensitive issues such as sexual practices or STIs.

Past Health History. The past health history should include information about major illnesses, hospitalizations, immunizations, and surgeries. Inquire about any infections involving the reproductive system, including STIs. Also take a complete obstetric and gynecologic history from the female patient.

Common pediatric illnesses that affect reproductive function are mumps and rubella. The occurrence of mumps in young men has been associated with an increase in sterility. Bilateral testicular atrophy may occur secondary to mumps-related orchitis. In the health history ask male patients if they have had mumps, been immunized with the mumps vaccine, or have any indications of sterility.

GENDER DIFFERENCES

Effects of Aging on Sexual Function

Men	Women
• Increased stimulation necessary for erection • Decreased force of ejaculation • Decreased ability to attain or sustain erection • Decreased size and rigidity of the penis at full erection • Decreased libido and interest in sex	• Decreased vaginal lubrication • Decreased sensitivity with labia shrinking and more clitoris exposed • Difficulty in maintaining arousal • Difficulty in achieving orgasm after stimulation • Decreased libido and interest in sex

Rubella is of primary concern to women of childbearing age. If rubella occurs during the first 3 months of pregnancy, the possibility of congenital anomalies is increased. For this reason, you should encourage immunization for all women of childbearing age who have not been immunized for rubella or have not already had the disease. (Rubella immunity can be determined by antibody titers.) However, women should not be immunized if they are already pregnant.[8] Advise women not to conceive for at least 3 months after immunization.

Question the patient regarding current health status and any acute or chronic health problems. Problems in other body systems are often related to problems with the reproductive system. Ask questions relating to possible endocrine disorders, particularly diabetes mellitus (DM), hypothyroidism, and hyperthyroidism, because these disorders directly interfere with women's menstrual cycles and with sexual performance. Men who have DM may experience erectile dysfunction and retrograde ejaculation. In women with uncontrolled DM, pregnancy may have significant health risks. Many other chronic illnesses such as cardiovascular disease, respiratory disorders, anemia, cancer, and kidney and urinary tract disorders may affect the reproductive system and sexual functioning.

Determine if the patient has a history of a stroke. In men, strokes may cause physiologic or psychologic erectile dysfunction. Men who have suffered a myocardial infarction (MI) may experience erectile dysfunction because of fear that sexual activity could precipitate another MI. Women share this concern, both as partners of someone who has had an MI and as patients recovering from an MI. Although most patients have concerns about sexual activity after an MI, many are not comfortable expressing these fears to the nurse. Be sensitive to this concern. In women, a history of cardiovascular disease (e.g., hypertension, thrombophlebitis, angina) is associated with a higher incidence of morbidity and mortality with pregnancy or the use of oral contraceptives.

Medications. Document all prescription and over-the-counter medications that the patient is taking, including the reason for the medication, the dosage, and the length of time that the medication has been taken. Ask the patient about the use of herbal products and dietary supplements.

Particularly relevant in the assessment of the reproductive system is the use of diuretics (sometimes prescribed for premenstrual edema), psychotropic agents (which may interfere with sexual performance), and antihypertensives (some of which may cause erectile dysfunction). Patients who use drugs such as amlodipine (Norvasc), lisinopril (Prinivil), propranolol (Inderal), and clonidine (Catapres) must be closely assessed for these problems.[9] Also note the use of drugs such as alcohol, marijuana, barbiturates, amphetamines, or phencyclidine hydrochloride (PCP [also called "angel dust"]), which can have serious behavioral or physiologic effects on the reproductive system.

In women, document the use of oral contraceptives or other hormone therapy (HT). The long-term use of both estrogen and progesterone in HT appears to increase the risk of blood clots, cardiovascular disease, stroke, and breast cancer in postmenopausal women.[10] The short-term use of HT appears to be appropriate for women experiencing moderate to severe menopausal symptoms. Women who use tobacco have a much higher risk of clotting disorders. (HT is discussed in Chapter 54.)

A history of cholecystitis and hepatitis is important because these conditions may be contraindications for the use of oral contraceptives. Cholecystitis is often aggravated by oral contraceptives, and chronic active inflammation of the liver generally precludes the use of estrogen products because they are metabolized by the liver. Chronic obstructive pulmonary disease may be a contraindication to oral contraceptive use because progesterone thickens respiratory secretions.

Surgery or Other Treatments. Note any surgical procedures in the health history. Surgical procedures involving the reproductive system are listed in Table 51-4. Also document any therapeutic or spontaneous abortions.

CASE STUDY

Patient Introduction

iStockphoto/Thinkstock

A.K. is a 68-yr-old Asian American woman who comes to the breast center because she found a large lump in her right breast while showering. She is somewhat anxious, stating "My breasts are typically lumpy, but this feels different!"

Critical Thinking

As you read through this chapter, think about A.K.'s concerns with the following questions in mind:

1. What are the possible causes for a lump in A.K.'s breast?
2. What would be your priority assessment of A.K.?
3. What questions would you ask A.K.?
4. What should be included in the physical assessment? What would you be looking for?
5. What diagnostic studies might you expect to be ordered?

evolve Answers available at http://evolve.elsevier.com/Lewis/medsurg.

TABLE 51-4 SURGERIES OF THE REPRODUCTIVE SYSTEMS

Surgery	Description
Male	
Herniorrhaphy	Repair of hernia
Orchiectomy	Removal of one or both testes
Prostatectomy	Removal of prostate gland
Repair of testicular torsion	Correction of axial rotation of spermatic cord, which cuts off blood supply to the testicle, the epididymis, and other structures
Varicocelectomy	Repair of varicose vein of scrotum
Vasectomy	Removal of part of ductus (vas) deference. Can be an elective procedure for sterilization or contraception
Female	
Cryosurgery	Use of subfreezing temperature to destroy tissue, especially in treatment of abnormal cells
Dilation and curettage	Dilation of cervix and scraping of endometrium, performed to diagnose disease of uterus, correct heavy or prolonged vaginal bleeding, or empty uterus of products of conception. Also used in the treatment of infertility to correlate state of endometrium and time of cycle
Hysterectomy	Removal of uterus
Mastectomy	Removal of one or both breasts
Oophorectomy	Removal of one or both ovaries
Repair of cystocele	Correction of protrusion of urinary bladder through vaginal wall
Repair of rectocele	Correction of protrusion of rectum into vagina
Salpingectomy	Removal of one or both fallopian tubes
Tubal sterilization	Ligation of fallopian tubes

Functional Health Patterns. The key questions to ask a patient with a reproductive problem are presented in Table 51-5.

Health Perception–Health Management Pattern. Two of the primary focuses of this health pattern are the patient's perception of his or her own health and measures that the patient takes to maintain health. Specifically, ask about self-examination practices and screenings. Mammography (based on current guidelines [see Chapter 52]), Pap tests, and breast self-examinations (BSEs) are integral to a woman's health. Testicular self-examination (TSE) should be practiced by all men, starting in adolescence (see Table 55-9). Starting at age 50, men should discuss with their health care provider the risks and benefits of annual prostate cancer screening with specific antigen (PSA) blood testing and a digital rectal examination (DRE)[11] (see Chapter 55). Men at high risk for prostate cancer (i.e., African Americans, men with prostate cancer in first-degree relatives) should begin these discussions earlier with their provider.

GENETIC RISK ALERT

- Breast, ovarian, uterine, and prostate cancer have known genetic risk factors.
- Having a first-degree relative with any of these cancers significantly increases the risk of cancer for the patient.
- The risk increases if several family members have been affected with these cancers over succeeding generations.
- Individuals with a known hereditary predisposition to breast or ovarian cancer can use this information to make informed decisions about how to minimize their risks.

Family history is also an important component of this health pattern. Inquire about a history of cancer, particularly cancer of the reproductive organs. Determine if the patient has a familial tendency for diabetes mellitus, hypothyroidism, hyperthyroidism, hypertension, stroke, angina, MI, endocrine disorders, or anemia.

Assessment of the reproductive system is incomplete without knowledge of the patient's lifestyle choices. Determine whether a woman uses cigarettes, alcohol, caffeine, or other drugs

TABLE 51-5 HEALTH HISTORY

Reproductive System

Health Perception–Health Management
- How would you describe your overall health?
- *Women:* Explain how you examine your breasts. Have you had a Pap test or mammogram recently? If so, what were the results and dates of these tests?
- *Men:* Explain how you examine your testes. Have you had a prostate examination recently? If so, what were the results and date of this examination?
- Describe the health of your family members. Any history of breast, uterine, ovarian, or prostate cancer?
- Do you use tobacco products, alcohol, or drugs?*

Nutritional-Metabolic
- Describe what you usually eat and drink.
- Have you experienced any changes in weight?*
- How do you feel about your current weight?
- Do you take any nutritional supplements such as calcium or vitamins?*
- Do you have any dietary restrictions?*

Elimination
- Do you experience problems with urination (e.g., pain, burning, dribbling, incontinence, frequency)?*
- Have you had bladder infections? If so, when? How often?
- Do you experience problems with bowel movements?* Do you use laxatives?*

Activity-Exercise
- What activities do you typically do each day?
- Do you have enough energy for your desired activities?
- Can you dress yourself? Feed yourself? Walk without help?

Sleep-Rest
- How many hours do you typically sleep each night?
- Do you feel rested after sleep?
- Do you experience any problems associated with sleeping?*

Cognitive-Perceptual
- Are you able to read and write?
- Do you experience problems with dizziness?*
- Do you experience pain? If yes, where?
- Do you experience pain during sexual activity or intercourse?*

Self-Perception–Self-Concept
- How would you describe yourself?
- Have there been any recent changes that have made you feel differently about yourself?*
- Are you experiencing any problems that are affecting your sexuality?*

Role-Relationship
- Describe your living arrangements. Who do you live with?
- Do you have a significant other? If yes, is this relationship satisfying?
- Are you experiencing any role-related problems in your family?* At work?*
- What are the relationships among your family members?

Sexuality-Reproductive
- Are you sexually active? If so, how many partners do you have?
- What kind of sex do you engage in (e.g., oral, vaginal, rectal)?
- How do you protect yourself against sexually transmitted infections and unwanted pregnancy?
- Are you satisfied with your present means of sexual expression? If no, explain.
- Have you experienced any recent changes in your sexual practices?*
- *Women:* Date of last menstruation, description of menstrual flow, problems with menstruation, age of menarche, age of menopause.
- *Women:* Pregnancy history—number of times pregnant, number of living children, number of miscarriages or abortions.

Coping–Stress Tolerance
- Have there been any major changes in your life within the past couple of years?*
- What is stressful in your life right now?
- How do you handle health problems when they occur?

Value-Belief
- What beliefs do you have about your health and illnesses?
- Do you use home remedies?*
- Is religion an important part of your life?*
- Do you think that any of your personal beliefs or values may be compromised because of your treatment?*

*If yes, describe.

because these substances can be detrimental to both mother and fetus. Cigarette smoking may delay conception and can also increase the risk of morbidity in women using oral contraceptives. Smoking in women is also associated with early menopause. These substances may also adversely affect the sperm count in men and cause erectile dysfunction or decreased libido.

Also document if the patient is allergic to sulfonamides, penicillin, rubber, or latex. Sulfonamides and penicillin are used frequently in the treatment of reproductive and genitourinary problems such as vaginitis and gonorrhea. Rubber and latex are commonly used in diaphragms and condoms. An allergy to these substances precludes their use as contraceptive methods.

Nutritional-Metabolic Pattern. Anemia is a common problem in women in their reproductive years, particularly during pregnancy and the postpartum period. Evaluate the adequacy of the diet with this condition in mind.

Take a thorough nutritional and psychologic history to assess for the presence of an eating disorder. Anorexia nervosa can cause amenorrhea and subsequent problems, such as osteoporosis, that are related to menopause. Obesity can be related to polycystic ovarian syndrome and may be a precursor to type 2 diabetes.

From early adolescence, counsel women regarding adequate calcium and vitamin D intake to prevent osteoporosis. Estimate the patient's daily calcium intake to determine whether supplementation is needed. Evaluate folic acid intake for women in their reproductive years because a deficiency can result in spina bifida and other neural tube defects in the fetus.[12]

Elimination Pattern. Many gynecologic problems can result in genitourinary problems. Stress and urge incontinence is common in older women because of relaxation of the pelvic musculature caused by multiple births or advancing age. Vaginal infections predispose patients to chronic or recurrent urinary tract infections. Metastasis of malignant tumors of the reproductive system to the genitourinary system is possible because of their proximity. Benign prostatic hyperplasia is a common problem of older men. It can alter normal urination, causing retention and difficulty in initiating the urinary stream.

Activity-Exercise Pattern. Record the amount, type, and intensity of activity and exercise. Lack of stress on bones secondary to lack of exercise is an important factor in the development of osteoporosis. Weight-bearing exercise decreases the risk of osteoporosis in women. Women who engage in excessive exercise may experience amenorrhea, which may result from decreased estrogen related to a low percentage of body fat (estrogen is stored in fat cells).[13] Anemia can result in fatigue and activity intolerance and can interfere with satisfactory performance of the activities of daily living.

Sleep-Rest Pattern. Sleep patterns may be affected during the postpartum period and also while raising young children. Hot flashes and sweating that are often present during perimenopause can cause serious sleep interruption when the woman awakens in a drenching sweat. The need to change her nightgown and bedding further disrupts her sleep. Insomnia is also a common complaint of perimenopausal women. Daytime fatigue often results from such sleep disruptions. In men, sleep disturbances may be caused by frequent urination at night associated with prostate enlargement or HT for prostate cancer.

Cognitive-Perceptual Pattern. Pelvic pain is associated with various gynecologic disorders such as pelvic inflammatory disease, ovarian cysts, and endometriosis. **Dyspareunia** (painful intercourse) can be particularly problematic for women. The pain associated with intercourse can create a reluctance to participate in sexual activity and strain relationships with sexual partners. Refer women with dyspareunia to their health care providers.

Self-Perception–Self-Concept Pattern. Changes that occur with aging, such as pendulous breasts and vaginal dryness in women and decreased size of the penis in men, may lead to emotional distress. The subtle changes associated with sexuality and advancing age may alter the self-concept of many persons.

Role-Relationship Pattern. Obtain information regarding the family structure and occupation. Question the patient regarding recent changes in work-related relationships or family conflict. Determine the patient's role in the family as a starting point in determining family dynamics.

Roles and relationships are affected by changes within the family. The addition of a new baby may change family dynamics. Role-relationship patterns change as children begin their careers and move away from home. Another change occurs when people retire.

Sexuality-Reproductive Pattern. The extent and depth of the interview about a patient's sexuality depend primarily on the interviewer's expertise and on the patient's needs and willingness. Before taking a sexual history, assess your comfort with your own sexuality, because any discomfort in questioning becomes obvious to the patient. Carry out interviews in an environment that provides reassurance, confidentiality, and a nonjudgmental attitude. Begin with the least sensitive areas of questioning and then move to more sensitive areas.

For women, obtain a menstrual and an obstetric history. The menstrual history includes the first day of the last menstrual period, description of menstrual flow, age of menarche, and, if applicable, age at menopause. Menstrual history data are used in the detection of pregnancy, infertility, and numerous other gynecologic problems. Have the patient explicitly describe changes in the usual menstrual pattern to determine whether the change is transient and unimportant or connected with a more serious gynecologic problem. *Metrorrhagia* (spotting or bleeding between menstruations), *menorrhagia* (excessive menstrual bleeding), *amenorrhea* (lack of menstruation), and *postcoital bleeding* are examples of such problems.

Identify changes in menstrual patterns associated with the use of contraceptive pills, intrauterine devices (IUDs), birth control patches, vaginal rings, subdermal estrogen-only implants (Jadelle), or medroxyprogesterone (Depo-Provera) injections. Contraceptive pills usually decrease the amount and duration of flow, whereas some IUDs may cause an increase in the amount and duration. Some IUDs also increase the severity of dysmenorrhea. However, newer IUDs contain progestin and may be therapeutic.

The obstetric history includes the number of pregnancies, full-term births, preterm births, and live births. Also include information about any ectopic pregnancies or abortions, either spontaneous or therapeutic. Document any problems that occurred with pregnancy.

A sexual history should include information regarding sexual activity, beliefs, and practices. Explore sexual preference (heterosexual, homosexual, bisexual), the frequency and type of sexual activity (penile-vaginal, penile-rectal, recipient rectal, oral), and the number of partners and protective measures against STIs and pregnancy. Determine the patient's knowledge

TABLE 51-6 SEXUAL HISTORY FORMAT

1. Are you currently in a relationship that involves sexual intercourse? If yes, do you have one or multiple partners?
2. How frequently do you engage in sexual activities? Are you and your partner(s) satisfied with the sexual relationship?
3. How many sexual partners have you had in the past 6 mo?
4. Do you prefer relationships with men, women, or both? (Inquire whether the patient is in a significant relationship.)
5. Has your sex life changed during the past year? If yes, how?
6. Have you ever had a sexually transmitted infection? If yes, what?
7. What are you doing to protect yourself from sexually transmitted infections? If protection is used, what type? Do you use protection every time you have intercourse?
8. Are you currently using any birth control measures? If yes, what type? How long have you been using this product? How effective do you think this has been?
9. Have you ever been in a relationship with anyone who hurt you? Have you ever been forced into sexual acts as a child or an adult?
10. How often have you experienced erectile dysfunction (male) or difficulty with vaginal lubrication (female) or pain with intercourse?

of safe sexual practices. A history of multiple sex partners and unprotected sex increases the risk of contracting an STI. For a woman, this can increase the risk of pelvic inflammatory disease, which can compromise her ability to become pregnant.

Table 51-6 outlines specific questions for a sexual history. Only a skilled interviewer should approach some of these questions, and then only with discretion and sensitivity to cultural differences.

Ask both men and women about their general satisfaction with sexuality. The patient's satisfaction with the opportunities for sexual gratification is important information. Question the patient about sexual beliefs and practices and whether orgasm is achieved. Explore any unexplained change in sexual practices or performance. Problems of the reproductive system can cause physiologic or psychologic problems that can lead to painful intercourse, erectile dysfunction, sexual dysfunction, or infertility. Try to determine both the cause and the effect of such problems.

Coping–Stress Tolerance Pattern. The stress related to situations such as pregnancy or menopause increases dependence on support systems. Determine who the support people are in the patient's life. The diagnosis of an STI can cause stress for the patient and the partner. Explore ways to manage this stress.

Value-Belief Pattern. Sexual and reproductive functioning is closely related to cultural, religious, moral, and ethical values. Be aware of your own beliefs in these areas, and recognize and sensitively react to the patient's personal beliefs associated with reproductive and sexuality issues.

Objective Data

Physical Examination: Male. The examination of the male external genitalia includes inspection and palpation. An examination may be performed with the patient lying or standing. The standing position is generally preferred. Sit in front of the standing patient. Use gloves during examination of the male genitalia.

Pubis. Observe the distribution and general characteristics of the pubic hair and the skin. Normally, the hair is in a diamond-shaped pattern and coarser than scalp hair. The absence of hair is not a normal finding unless the man is shaving or waxing the pubic hair. Carefully assess the skin for irritation and inflammation.

Penis. Note the size and skin texture of the penis and any lesions, scars, or swelling. Also note the location of the urethral meatus and the presence or absence of a foreskin. If present, the foreskin should be retracted to note any redness, discharge, irritation, or swelling. Replace the foreskin over the glans after observation. Then compress the glans to note any discharge and its amount, color, and odor if present. Palpate the penile shaft for tenderness or masses and observe the ventral and dorsal aspects.

Scrotum and Testes. This part of the examination is usually not performed by the nurse generalist. The nurse with advanced skills starts by performing a complete skin examination by lifting each testis to inspect all sides of the scrotal sac. Palpate the scrotum to note changes in consistency or any masses. Note if the testes are descended. The left testis usually hangs lower than the right. An undescended testis is a major risk factor for testicular cancer and a potential cause of male infertility.[14]

Inguinal Region and Spermatic Cord. This part of the examination is usually not performed by the nurse generalist. The examiner with advanced skills first inspects the skin overlying the inguinal regions for rashes or lesions. Then ask the patient to bear down or cough. While he is straining, inspect the inguinal area for a bulge. No bulging should be seen.

Examination of the inguinal area continues with palpation. Palpate the right and left inguinal rings using the index or middle finger. Insert the finger into the lower aspect of the scrotum and follow the spermatic cord upward through the triangular, slitlike opening of the inguinal ring. At this point,

CASE STUDY—cont'd

Subjective Data

iStockphoto/Thinkstock

A focused assessment of A.K. revealed the following information:

PMH: Type 2 diabetes for 5 yr, hypertension, stress incontinence, osteoarthritis. No surgical history.

Medications: metformin (Glucophage) 500 mg PO bid for the past 4 yr, estrogen/medroxyprogesterone (Prempro) 0.3 mg/1.5 mg/day PO for the past 14 yr, lisinopril (Prinivil) 10 mg/day PO for past 3 yr.

Health Perception–Health Management: A.K. has no personal history of breast cancer, but she does have a family history of breast cancer. Her mother was diagnosed at age 60 and her sister at age 40. She is afraid that she may now have cancer. Her last mammogram and clinical breast examination were 2 yr ago. She does not smoke but does enjoy one to two glasses of wine with her dinner every evening.

Nutritional-Metabolic: A.K. is 5 ft, 2 in tall and weighs 166 lb. She reports gaining most of her weight after menopause. She tries to eat a well-balanced meal and watch her carbohydrate intake because of her diabetes.

Elimination: Denies any changes or difficulty with urination or bowel movements except for stress incontinence when she coughs or laughs. States she always wears a panty liner "just in case."

Activity-Exercise: Does not routinely exercise. Occasionally takes a walk around the block with her husband. Otherwise her life is fairly sedentary.

Cognitive-Perceptual: Denies breast pain.

Sexuality-Reproductive: Had onset of menarche at age 11, menopause at age 53. Has two daughters (34 and 32) and a son (30).

ask the patient to bear down and cough. Determine whether the strain produces a bulging of the intestines through the ring, indicating a hernia, a condition that requires follow-up. Also palpate the inguinal lymph nodes. Enlargement of the lymph nodes *(lymphadenopathy)* could suggest a pelvic organ infection or malignancy.

Anus and Prostate. Inspect the anal sphincter and perineal regions for lesions, masses, and hemorrhoids. A DRE is required for all men who have symptoms of prostate trouble, such as difficulty initiating urination and the urge to void frequently. This examination should be performed by the health care provider annually for all men 50 years of age and older.

Physical Examination: Female. Physical examination of women often begins with inspection and palpation of the breasts and axillae and then proceeds to the abdomen and genitalia. Examination of the abdomen provides an opportunity to detect pain or any masses that may involve the genitourinary system. Abdominal examination is discussed in Chapter 39.

Breasts. First examine the breasts by visual inspection. With the patient seated, observe the breasts for symmetry, size, shape, skin color, vascular patterns, dimpling, and unusual lesions. Ask the patient to put her arms at her sides, arms overhead, lean forward, and press hands on hips. Observe for any abnormalities during these maneuvers. Palpate the axillae and the clavicular areas for enlarged lymph nodes.

After the patient assumes a supine position, place a pillow under her back on the side to be examined. Ask the patient to put her arm above and behind her head. These maneuvers flatten breast tissue and make palpation easier. Then palpate the breast in a systematic fashion, preferably using a vertical line (see Fig. 52-1). Use the distal finger pads for palpation. Include the axillary tail of Spence in the examination. This area of the breast lies adjacent to the upper outer quadrant, which is where most breast malignancies develop (see Fig. 52-1). Finally, palpate the area around the areolae for masses. Compress the nipple to detect any discharge or masses. Document the color, consistency, and odor of any discharge.

External Genitalia. Use gloves for examination of the external genitalia. Inspect the mons pubis, labia majora, labia minora, posterior fourchette, perineum, and anal region for characteristics of skin, hair distribution, and contour. Note any lesions, inflammation, swelling, and discharge. Separate the labia to fully inspect the clitoris, urethral meatus, and vaginal orifice.

Internal Pelvic Examination. This part of the examination is usually not performed by the nurse generalist. During the speculum examination, the examiner observes the walls of the vagina and the cervix for inflammation, discharge, polyps, and suspicious growths. During this examination, it is possible to obtain a Pap test and collect cells for culture and microscopic examination. After the speculum examination, a bimanual examination is performed to assess the size, shape, and consistency of the uterus and ovaries. The tubes are not normally palpable.

Parts of the pelvic and bimanual examinations are not included in this text, since they are considered advanced skills and are not usually within the scope of the nurse generalist.

Table 51-7 provides an example of a recording format for the physical assessment findings for the male and female reproductive systems. Tables 51-8 through 51-10 summarize assessment abnormalities of the breasts, female reproductive system, and male reproductive system, respectively.

FOCUSED ASSESSMENT

Reproductive System

Use this checklist to ensure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Vaginal discharge/itching, unusual bleeding	Y	N
Penile pain, lesions, discharge	Y	N
Medications: oral contraceptives, antihypertensives, psychotropics, hormones	Y	N
Self-examinations (breast or testicular examination) and results	Y	N
Clinical examinations of reproductive systems (breast, pelvis, testicular, prostate) and results	Y	N
Pain in the abdomen, pelvis, or genitalia	Y	N

Objective: Diagnostic

Check the following for results and critical values.

Serum hCG	✓
Serum PSA	✓
Culture and sensitivity test results	✓
Hormone levels (testosterone, progesterone, estrogen) if done	✓
Screen for STIs (e.g., *Chlamydia*, gonorrhea)	✓
Laboratory reports: wet mounts, dark-field microscopy	✓
X-ray of pelvis or breasts	✓
Ultrasound of prostate	✓

Objective: Physical Examination

Inspect

External genitalia for redness, swelling, drainage	✓
Breasts for swelling, dimpling, retraction, drainage	✓

Palpate

Breast tissue for masses or inflammation	✓

hCG, Human chorionic gonadotropin; *PSA,* prostate-specific antigen; *STIs,* sexually transmitted infections.

CASE STUDY—cont'd

Objective Data: Physical Examination

iStockphoto/Thinkstock

Focused assessment of A.K. reveals the following: A palpable, firm, fixed, 1.5-cm mass in upper, outer quadrant of right breast. No dimpling, redness, or swelling noted. No masses palpated in left breast. No lymphadenopathy noted.

As you continue to read this chapter, consider diagnostic studies you would anticipate being performed for A.K.

A *focused assessment* is used to evaluate the status of previously identified reproductive problems and to monitor for signs of new problems (see Table 3-6). A focused assessment of the reproductive system is presented in the box above.

DIAGNOSTIC STUDIES OF REPRODUCTIVE SYSTEMS

The most commonly used diagnostic studies in the assessment of the reproductive systems are summarized in Table 51-11 on p. 1233, and select studies are described in more detail below.

Urine Studies

Pregnancy Testing. Pregnancy is generally validated by measuring human chorionic gonadotropin (hCG) in the urine.[15] A solution containing monoclonal antibodies specific for hCG is mixed with a small amount of urine. The presence of hCG causes a change in color of the tested urine.

TABLE 51-7 NORMAL PHYSICAL ASSESSMENT OF REPRODUCTIVE SYSTEM

Male	Female
Breasts	
Nipples soft. No lumps, nodules, swelling, or enlarged tissue noted.	Symmetric without dimpling. Nipples soft. No drainage, retraction, or lesions noted. No masses or tenderness. No lymphadenopathy.
External Genitalia	
Diamond-shaped hair distribution. No penile lesions or discharge noted. Scrotum symmetric, no masses, descended testes. No inguinal hernia.	Triangular hair distribution. Genitalia dark pink, no lesions, redness, swelling, or inflammation in perineal region. No vaginal discharge noted. No tenderness with palpation of Skene's ducts and Bartholin's glands.
Anus	
No hemorrhoids, fissures, or lesions noted.	No hemorrhoids, fissures, or lesions noted.

Home pregnancy test kits use the same assay principle. Positive results are based on the presence of hCG in urine. Some tests can detect pregnancy as early as the first day after a missed menstrual period. These tests are 98% accurate if the test is performed exactly per instructions. A second test is recommended within a week if the first test is negative (assuming menses has not yet occurred).

Hormone Studies. Although estrogen studies are performed on urine, the results are often inaccurate because of variable estrogen levels during the normal cycle and the difficulty in estimating the day of the cycle in women with irregular menses. Adrenal androgens are precursors of estrogens and can be measured in the urine of both men and women. For more information on hormone studies, see Chapter 48.

Blood Studies

Hormone Studies. Serum assays for hCG can detect pregnancy before a woman misses her menstrual period. The prolactin assay is used primarily in the workup of a patient with amenorrhea. High levels of prolactin are normally associated with low levels of estrogen, such as those that occur during lactation. However, the same finding can occur with pituitary adenomas, especially with otherwise unexplained galactorrhea (excessive secretion of breast milk). Serum progesterone and estradiol are sometimes measured to assess ovarian function, particularly for amenorrhea. In addition, hormonal blood studies are essential components of a fertility workup.

Tumor Markers. Biologic tumor markers are used to assess for malignant disease and to monitor therapy (marker levels

TABLE 51-8 ASSESSMENT ABNORMALITIES

Breast

Finding	Description	Possible Etiology and Significance
Nipple inversion or retraction	Recent onset, erythematous, pain, unilateral.	Abscess, inflammation, cancer.
	Recent onset (usually within past year), unilateral presentation, lack of tenderness.	Neoplasm.
Nipple secretions		
• Galactorrhea (female)	Milky, no relationship to lactation, unilateral or bilateral, intermittent or consistent presentation.	Drug therapy, particularly phenothiazines, tricyclic antidepressants, methyldopa. Hypofunction or hyperfunction of thyroid or adrenal glands. Tumors of hypothalamus or pituitary gland. Excessive estrogen. Prolonged suckling or breast foreplay.
• Galactorrhea (male)	Milky, bilateral presentation.	Chorioepithelioma of testes, manifestation of pituitary tumor.
• Purulent	Gray-green or yellow color. Frequent unilateral presentation. Association with pain, erythema, induration, nipple inversion.	Puerperal (after birth) mastitis (inflammatory condition of breast) or abscess.
	Same as above but usually without nipple inversion.	Infected sebaceous cyst.
• Serous discharge	Clear appearance, unilateral or bilateral, intermittent or consistent presentation.	Intraductal papilloma.
• Dark green or multicolored discharge	Thick, sticky, and frequently bilateral.	Ductal ectasia (dilation of mammary ducts).
• Serosanguineous or bloody drainage	Unilateral presentation.	Papillomatosis (widespread development of nipple-like growths), intraductal papilloma, carcinoma (male and female).
Scaling or irritation of nipple	Unilateral or bilateral presentation, crusting, possible ulceration.	Paget's disease, eczema, infection.
Nodules, lumps, or masses	Multiple, bilateral, well-delineated, soft or firm, mobile cysts. Pain. Premenstrual occurrence.	Fibrocystic changes.
	Rubbery consistency, fluid-filled interior, pain.	Ductal ectasia.
	Soft, mobile, well-delineated cyst, absence of pain.	Lipoma, fibroadenoma.
	Erythema, tenderness, induration.	Infected sebaceous cysts, abscesses.
	Usually singular, hard, irregularly shaped, poorly delineated, nonmobile.	Neoplasm.
Dimpling of breast	Unilateral, recent onset, no pain.	Neoplasm.

TABLE 51-9 ASSESSMENT ABNORMALITIES

Female Reproductive System

Finding and Description	Possible Etiology and Significance
Vulvar Discharge	
White, thick, curdy, frequent itching and inflammation, lack of odor or yeast-like smell	Candidiasis (*Candida* or yeast infection), vaginitis
Thin gray or white, copious flow, malodorous or fishy, vulvar irritation	Bacterial vaginosis infection
Frothy green or yellow color; malodorous	*Trichomonas vaginalis*
Bloody discharge	*Chlamydia trachomatis* or *Neisseria gonorrhoeae* infection, menstruation, trauma, cancer
Vulvar Erythema	
Bright or beefy red color, itching	*Candida albicans*, allergy, chemical vaginitis
Reddened base, painful vesicles or ulcerations	Genital herpes
Macules or papules, itching	Chancroid (STI), contact dermatitis, scabies, pediculosis
Vulvar Growths	
Soft, fleshy growth, nontender	Condyloma acuminatum
Flat and warty appearance, nontender	Condyloma latum
Same as either of above, possible pain	Neoplasm
Reddened base, vesicles, and small erosions; pain	Lymphogranuloma venereum, genital herpes, chancroid
Indurated, firm ulcers, no pain	Chancre (syphilis), granuloma inguinale
Abdominal Pain or Tenderness	
Intermittent or consistent tenderness in right or left lower quadrant	Salpingitis (infection of fallopian tube), ectopic pregnancy, ruptured ovarian cyst, PID, tubal or ovarian abscess
Periumbilical location, consistent occurrence	Cystitis, endometritis (inflammation of endometrium), ectopic pregnancy
Abnormal Vaginal Bleeding	
Unusual and inappropriate uterine bleeding	Dysfunctional uterine bleeding, usually anovulatory bleeding, menorrhagia (heavy menstrual bleeding), metrorrhagia (irregular, frequent bleeding), postmenopausal bleeding

PID, Pelvic inflammatory disease.

TABLE 51-10 ASSESSMENT ABNORMALITIES

Male Reproductive System

Finding and Description	Possible Etiology and Significance
Penile Growths or Masses	
Indurated, smooth, disklike appearance; absence of pain; singular presentation	Chancre
Papular to irregularly shaped ulceration with pus, lack of induration	Chancroid
Ulceration with induration and nodularity	Cancer
Flat, wartlike nodule	Condyloma latum
Elevated, fleshy, moist, elongated projections with single or multiple projections	Condyloma acuminatum
Localized swelling with retracted, tight foreskin	Paraphimosis (inability to replace foreskin to its normal position after retraction), trauma
Vesicles, Erosions, or Ulcers	
Painful, erythematous base. Vesicular or small erosions	Genital herpes, balanitis (inflammation of glans penis), chancroid
Painless, singular, small erosion with eventual lymphadenopathy	Lymphogranuloma venereum, cancer
Scrotal Masses	
Localized swelling with tenderness, unilateral or bilateral presentation	Epididymitis (inflammation of epididymis), testicular torsion, orchitis (mumps)
Swelling, tenderness	Incarcerated hernia
Swelling without pain. Unilateral or bilateral presentation. Translucent, cordlike or wormlike appearance	Hydrocele (accumulation of fluid in outer covering of testes), spermatocele (firm, sperm-containing cyst of epididymis), varicocele (dilation of veins that drain testes), hematocele (accumulation of blood within scrotum)
Firm, nodular testes or epididymis. Frequent unilateral presentation	Tuberculosis, cancer
Penile Discharge	
Clear to purulent color, minimal to copious flow	Urethritis or gonorrhea, *Chlamydia trachomatis* infection, trauma
Penile or Scrotal Erythema	
Macules and papules	Scabies, pediculosis
Inguinal Masses	
Bulging unilateral presentation during straining	Inguinal hernia
1- to 3-cm nodules	Lymphadenopathy

rise as disease progresses and fall with disease regression). α-Fetoprotein (AFP), hCG, and CA-125 are sometimes used as tumor markers for reproductive system malignancies. A specific tumor antigen such as PSA is another type of tumor marker, frequently used for prostate cancer.

Serology Tests for Syphilis. The Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin (RPR) test detect the presence of antibodies in the serum of patients infected with syphilis. These tests are inexpensive and reliable but have high levels of false-positive results. The fluorescent treponemal antibody absorption (FTA-Abs) test is highly reliable and should be used after a positive VDRL or RPR.

Cultures and Smears

Cultures and smears are most frequently used in the diagnosis of STIs. Specimens for cultures and smears are commonly taken from the vagina, endocervix, and rectum for females and the urethra and rectum for males. For a culture, the specimen is placed on a special culture medium. A smear involves rubbing the specimen on a slide for direct examination. Gram stain smears have been shown to be effective in the diagnosis of *Chlamydia* infection. A nucleic acid amplification test (NAAT)

Text continued on p. 1236

TABLE 51-11 DIAGNOSTIC STUDIES

Male and Female Reproductive Systems

Study	Description and Purpose	Nursing Responsibility
Urine Studies		
Human chorionic gonadotropin (hCG)	Detects pregnancy. Also detects hydatidiform mole and chorioepithelioma (in men and women). *Males and nonpregnant females:* Negative	Obtain menstrual history from patient, including birth control methods. Determine presence or absence of presumptive signs of pregnancy (e.g., breast changes, increased whitish vaginal discharge).
Testosterone	Detects tumors and developmental anomalies of the testes. *Female:* 2-12 mcg/24 hr (6.9-41.6 nmol/24 hr) *Male:* 40-135 mcg/24 hr (139-469 nmol/24 hr)	Instruct patient to collect 24-hr urine specimen and to keep refrigerated.
Follicle-stimulating hormone (FSH)	Indicates gonadal failure because of pituitary dysfunction. *Female:* Follicular phase: 2-15 U/24 hr Midcycle: 8-60 U/24 hr Luteal phase: 2-10 U/24 hr Postmenopause: 35-100 U/24 hr *Male:* 3-11 U/24 hr	Instruct patient to collect 24-hr urine specimen. Indicate phase of menstrual cycle, if menopausal, and if on oral contraceptives or hormones.
Blood Studies		
Prolactin	Detects pituitary dysfunction that can cause amenorrhea. *Female:* 3.8-23.2 ng/mL (3.8-23.2 mg/L) *Male:* 3.0-14.7 ng/mL (3.0-14.7 mg/L)	Observe venipuncture site for bleeding or hematoma formation.
Prostate-specific antigen (PSA)	Detects prostate cancer. Also a sensitive test for monitoring response to therapy. *Reference interval:* <4 ng/mL (<4 mcg/L)	No food or fluid restrictions. Collect 5 mL blood. Observe venipuncture site for bleeding.
hCG	Detects pregnancy. Can also be used as a tumor marker for testicular malignancy. Also used to detect hydatidiform mole. *Males and nonpregnant females:* <5 mIU/mL (<5 IU/L)	Find out where patient is in her menstrual cycle, whether she has missed menses, and if so, how late she is.
Testosterone	Determines whether elevated androgens are due to testicular, adrenal, or ovarian dysfunction or pituitary tumors. Serum testosterone also drawn to assess male infertility and tumors of testicle or ovary. *Male:* 280-1100 ng/dL (10.4-38.17 nmol/L) *Female:* 15-70 ng/dL (0.52-2.43 nmol/L)	Collect health history to eliminate potential sources of interference with accuracy of results (e.g., use of corticosteroids or barbiturates, hypothyroidism or hyperthyroidism).
Progesterone	Determines cause of infertility, monitors success of drugs for infertility or the effect of treatment with progesterone, determines whether ovulation is occurring, and diagnoses problems with the adrenal glands and some types of cancer. *Female:* Follicular phase: 15-70 ng/dL (0.5-2.2 nmol/L) Luteal phase: 200-2500 ng/dL (6.4-79.5 nmol/L) Postmenopause: <40 ng/dL (1.28 nmol/L) *Male:* 13-97 ng/dL (0.4-3.1 nmol/L)	Observe venipuncture site for bleeding or hematoma formation. Include information about last menstrual period and trimester of pregnancy because progesterone levels vary with gestation.
Estradiol	Measures ovarian function. Useful in assessing estrogen-secreting tumors and states of precocious female puberty. May be used to confirm perimenopausal status. Increased serum estradiol levels in men may be indicative of testicular tumors. *Female:* Follicular phase: 20-150 pg/mL (73-1285 pmol/L) Luteal phase: 30-450 pg/mL (110-1652 pmol/L) Postmenopause: ≤20 pg/mL (≤73 pmol/L) *Male:* 10-50 pg/mL (37-184 pmol/L)	Observe venipuncture site for bleeding or hematoma formation.
FSH	Indicates gonadal failure due to pituitary dysfunction. Used to validate menopausal status. *Female:* Follicular phase: 1.37-9.9 mU/mL Ovulatory phase: 6.17-17.2 mU/mL Luteal phase: 1.09-9.2 mU/mL Postmenopause: 19.3-100.6 mU/mL *Male:* 1.42-15.4 mU/mL	No food or fluid restrictions required. State phase of menstrual cycle, if menopausal, or if on oral contraceptive or hormones.
Venereal Disease Research Laboratory (VDRL) (flocculation)	Nonspecific antibody tests used to screen for syphilis. Positive readings can be made within 1-2 wk after appearance of primary lesion (chancre) or 4-15 wk after initial infection. *Reference interval:* Negative or nonreactive	Observe venipuncture site for bleeding or hematoma formation.
Rapid plasma reagin (RPR) (agglutination)	Nonspecific antibody test used to screen for syphilis. *Reference interval:* Negative or nonreactive	Obtain data to identify conditions such as hepatitis, pregnancy, and autoimmune diseases that may interfere with accuracy of results.

Continued

TABLE 51-11 DIAGNOSTIC STUDIES—cont'd

Male and Female Reproductive Systems

Study	Description and Purpose	Nursing Responsibility
Blood Studies—cont'd		
Fluorescent treponemal antibody absorption (FTA-Abs)	Detects syphilis antibodies. Also detects early syphilis with great accuracy. Usually performed if results of VDRL and RPR are questionable. *Reference interval:* Negative or nonreactive	Inform patient that blood sample will be drawn. Observe venipuncture site for bleeding or hematoma formation.
Cultures and Smears		
Dark-field microscopy	Direct examination of specimen obtained from potential syphilitic lesion (chancre) is performed to detect *Treponema pallidum.*	Avoid direct skin contact with open lesion.
Wet mounts	Direct microscopic examination of specimen of vaginal discharge is performed immediately after collection. Determines presence or absence and number of *Trichomonas* organisms, bacteria, white and red blood cells, and candidal buds or hyphae. Other clues or causes of inflammation or infection may be determined.	Explain procedure and purpose to patient. Instruct patient not to douche before examination. Prepare for collection of specimens (glass slide, 10%-20% potassium hydroxide [KOH] solution, sodium chloride [NaCl] solution, and cotton-tipped applicators).
Cultures	Specimens of vaginal, urethral, or cervical discharge are cultured to assess for gonorrhea or *Chlamydia* organisms. Rectal and throat cultures may also be taken, depending on data obtained from sexual history.	Obtain specific contact and sexual history, including oral and rectal intercourse. Instruct against douching before examination. Obtain urethral specimen from men before they void. Instruct sexually active women with multiple partners to have at least a yearly culture for gonorrhea and *Chlamydia*. Instruct sexually active men to have any discharge evaluated immediately to rule out gonorrhea strains that do not cause classic symptoms of dysuria.
Gram stain	Used for rapid detection of gonorrhea. Presence of gram-negative intracellular diplococci generally warrants treatment. Not highly accurate for women. Also a valid alternative for *Chlamydia* testing.	Same as above.
Cytologic Studies		
Papanicolaou (Pap) test	Microscopic study of exfoliated cells via special staining and fixation technique to detect abnormal cells. Most commonly studies cells obtained directly from the endocervix and ectocervix.	Instruct sexually active women to have Pap test according to American Cancer Society guidelines *(www.cancer.org)*. Instruct patient not to douche for at least 24 hr before examination. Collect careful menstrual and gynecologic history.
Nipple discharge test	Cytologic study of nipple discharge.	Indicate if patient is taking hormonal preparations or other drugs, is breastfeeding, or has a history of amenorrhea. Instruct patient that nipple discharge should always be evaluated.
Radiologic Studies		
Mammography		
• Screening	X-ray image of breast tissue on radiographic film is used to assess breast tissue. Detects benign and malignant masses.	Instruct patient about the examination and American Cancer Society recommendations for screening (see Chapter 52).
• Diagnostic	Performed when patient has suspicious clinical symptoms or abnormality found on screening mammogram. Additional views of affected breast are taken.	
Ultrasound (abdominal and transvaginal)	Measures and records high-frequency sound waves as they pass through tissues of variable density. In women, useful in detecting masses >3 cm, such as ectopic pregnancy, IUD, ovarian cyst, and hydatidiform mole. In men, used to detect testicular torsion or masses.	Instruct patient that a full bladder may be required depending on reason for the study.
Ultrasound-guided biopsy	Use of ultrasound guidance while performing a biopsy. Ultrasound is used to direct the biopsy needle into the region of interest and obtain a sample of tissue. Removal of small tissue sample to diagnose infection, inflammation, or mass.	Inform patient of purpose for this procedure. It is usually done as an outpatient procedure.
Computed tomography (CT) of pelvis	Detects tumors within the pelvis.	Inform patient of procedure. Patient must lie still during the procedure. If IV contrast medium is used, check for iodine allergy.
Magnetic resonance imaging (MRI)	Radio waves and magnetic field are used to view soft tissue. Useful after an abnormal mammogram or for breast dysplasia. Also used to diagnose abnormalities in the female and male reproductive systems.	Screen patient for metal parts and pacemaker. Inform patient the procedure is painless. Patient must lie still during the procedure.

TABLE 51-11 DIAGNOSTIC STUDIES—cont'd

Male and Female Reproductive Systems

Study	Description and Purpose	Nursing Responsibility
Invasive Procedures		
Breast biopsy	Histologic examination of excised breast tissue, obtained either by needle aspiration or excisional biopsy.	*Before biopsy:* Instruct patient about operative procedures and sedation. *After biopsy:* Perform wound care and instruct patient about breast self-examination.
Hysteroscopy	Allows visualization of uterine lining through insertion of scope through cervix. Used mainly to diagnose and treat abnormal bleeding such as polyps and fibroids. Biopsy may be taken during procedure.	Explain purpose and method of procedure and that it may be done in the physician's office. Inform patient that mild cramping and slight bloody discharge after procedure is normal.
Hysterosalpingogram	Involves instillation of contrast media through cervix into uterine cavity and subsequently through the fallopian tubes. X-ray images taken to detect abnormalities of uterus and its adnexa (ovaries and tubes) as contrast progresses through them. Test may be most useful in diagnostic assessment of fertility (e.g., to detect adhesions near ovary, an abnormal uterine shape, blockage of tubal pathways).	Inform patient about procedure and that it may be fairly uncomfortable. Ask about iodine allergy.
Colposcopy	Direct visualization of cervix with binocular microscope that allows magnification and study of cellular dysplasia and cervix abnormalities. Used as follow-up for abnormal Pap test and for examination of women exposed to DES in utero. Biopsy of cervix may be taken during examination. Valuable in decreasing number of false-negative cervical biopsies.	Instruct patient about this outpatient procedure. Inform patient that this examination is similar to speculum examination.
Conization	Cone-shaped sample of squamocolumnar tissue of cervix is removed for direct study.	Explain purpose and method of procedure and that it requires use of surgical facilities and anesthesia. Instruct patient to avoid sexual intercourse and tampons for about 3-4 wk. Also discuss necessity for 3-wk follow-up.
Loop electrosurgical excision procedure (LEEP)	Excision of cervical tissue via an electrosurgical instrument. Diagnoses and treats cervical dysplasia. Minimizes amount of tissue removed, preserves childbearing ability.	Explain purpose and method of procedure and that it may be done in the physician's office. Patient may feel slight tingling or abdominal cramping during procedure. Discharge, bleeding, and cramping may occur for 1-3 days after procedure.
Culdotomy, culdoscopy, and culdocentesis	*Culdotomy* is an incision made through posterior fornix of cul-de-sac and allows visualization of peritoneal cavity (i.e., uterus, tubes, and ovaries). *Culdoscopy* can then be used to closely study these structures. This technique is valuable in fertility evaluations. Withdrawal of fluid *(culdocentesis)* allows examination of fluid.	Explain purpose and method of procedure. Prepare patient for vaginal operation with preoperative instruction and sedation. Perform assessment of bleeding and discomfort after surgery.
Laparoscopy (peritoneoscopy)	Allows visualization of pelvic structures via fiberoptic scopes inserted through small abdominal incisions. Instillation of CO_2 into cavity improves visualization. Used in diagnostic assessment of uterus, tubes, and ovaries (Fig. 51-8). Can be used in conjunction with tubal sterilization.	Before surgery, instruct patient about procedure, prepare abdomen, and reassure patient about sedation. Inform patient of probability of shoulder pain because of air in the abdomen.
Dilation and curettage (D&C)	Operative procedure dilates cervix and allows curetting of endometrial lining. Used in assessment of abnormal bleeding and cytologic evaluation of lining.	Before surgery, instruct patient about procedure and sedation. Perform postoperative assessment of degree of bleeding (frequent pad check during first 24 hr).
Fertility Studies		
Semen analysis	Semen is assessed for volume (2-5 mL), viscosity, sperm count (>20 million/mL), sperm motility (60% motile), and percent of abnormal sperm (60% with normal structure).	Instruct patient to bring in fresh specimen within 2 hr after ejaculation.
Basal body temperature assessment	Measurement indirectly indicates whether ovulation has occurred. (Temperature rises at ovulation and remains elevated during secretory phase of normal menstrual cycle.)	Instruct woman to take temperature using special basal temperature thermometer (calibrated in tenths of degrees) every morning before getting out of bed. Instruct to record temperature on graph.
Huhner, Sims-Huhner, test	Mucus sample of cervix is examined within 2-8 hr after intercourse. Total number of sperm is assessed in relation to number of live sperm. Used to determine whether cervical mucus is "hostile" to passage of sperm from vagina into uterus.	Instruct couples to have intercourse at estimated time of ovulation and be present for test within 2-8 hr after intercourse.
Endometrial biopsy	Small curette is used to obtain piece of endometrial lining to assess endometrial changes common to progesterone secretion after ovulation. Also used to assess abnormal menstrual or postmenopausal uterine bleeding.	Tell patient test must be performed postovulation. Explain that procedure should cause only short period of uterine cramping and light, bloody vaginal discharge for about 24 hr.
Hysterosalpingogram	Same as operative procedures.	Same as operative procedures.
Serum progesterone	Same as blood studies.	Same as blood studies.

DES, Diethylstilbestrol; *IUD,* intrauterine device.

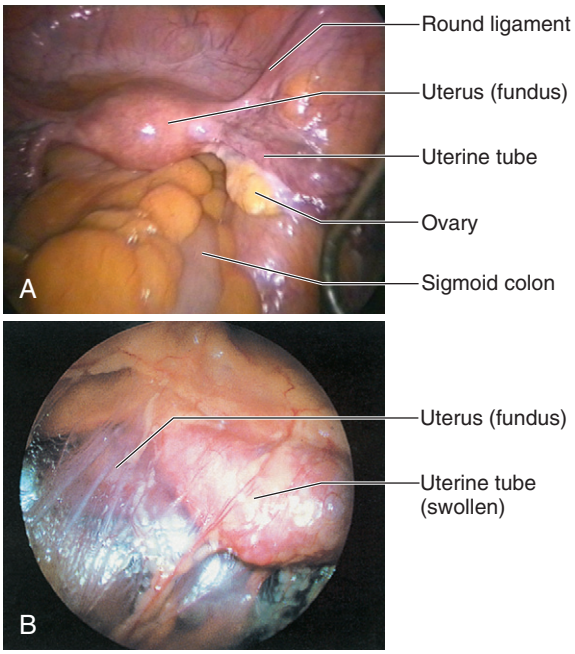

FIG. 51-8 Laparoscopic views of the female pelvis. **A,** Normal image. **B,** Pelvic inflammatory disease. Note reddish inflammatory membrane covering and fixing the ovary and uterus to the surrounding structures.

can screen for both gonorrhea and *Chlamydia* from a wide variety of samples, including vaginal, endocervical, urinary, and urethral specimens. Dark-field microscopy involves the direct examination of a specimen obtained from a chancre for the diagnosis of syphilis.

CASE STUDY—cont'd

Objective Data: Diagnostic Studies

iStockphoto/Thinkstock

The breast specialist orders the following for A.K.:

- Digital mammography
- Ultrasound of breasts
- MRI of breasts

The mammography reveals an increased density on the right breast. The ultrasound identifies the mass as solid and not fluid filled. The MRI confirms the presence of a suspicious mass in the right breast.

The health care provider schedules A.K. for a fine-needle aspiration (FNA) biopsy. The results of the ultrasound-guided FNA biopsy reveal an adenocarcinoma.

Radiologic Studies

Mammography. Mammography, one of the most frequently used diagnostic tools to assess the reproductive system, is used to detect breast masses. Mammography and screening guidelines for mammography are discussed in Chapter 52.

Ultrasound. Ultrasound has many applications for diagnostic studies. Pelvic ultrasound is used to obtain images of the pelvic organs. Transvaginal ultrasound is used to visualize the female genital tract. These types of ultrasound are also used to detect pregnancy in the uterus, ectopic pregnancy, ovarian cysts, and other pelvic masses.

Breast ultrasound is useful in the detection of fluid-filled masses. In men, ultrasound is used to detect testicular masses and testicular torsion. Transrectal ultrasound (TRUS) is useful for diagnosing prostate tumors.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A normal male reproductive function that may be altered in a patient who undergoes a prostatectomy is
   a. sperm production.
   b. production of testosterone.
   c. production of seminal fluid.
   d. release of sperm from the epididymis.
2. Estrogen production by a mature ovarian follicle causes
   a. decreased secretion of FSH and LH.
   b. increased production of GnRH and FSH.
   c. release of GnRH and increased secretion of LH.
   d. decreased release of FSH and decreased progesterone production.
3. Female orgasm is the result of *(select all that apply)*
   a. constriction of the cervical os.
   b. uterine and vaginal contractions.
   c. vaginal enlargement and uterine elevation.
   d. clitoral swelling and increased vaginal lubrication.
   e. rapid release of muscular tension in the reproductive structures.
4. An age-related finding noted by the nurse during the assessment of the older woman's reproductive system is
   a. dyspareunia.
   b. vaginal dryness.
   c. nipple retraction.
   d. increased sensitivity of labia.
5. Significant information about a patient's past health history related to the reproductive system should include
   a. extent of sexual activity.
   b. general satisfaction with sexuality.
   c. previous sexually transmitted infections.
   d. self-image and relationships with others.
6. To evaluate the female patient's breasts, the nurse would use the examination technique of *(select all that apply)*
   a. palpation.
   b. inspection.
   c. percussion.
   d. auscultation.
7. An abnormal finding noted during physical assessment of the male reproductive system is
   a. descended testes.
   b. symmetric scrotum.
   c. slight clear urethral discharge.
   d. the glans covered with prepuce.

8. The nurse is caring for a patient scheduled for an endometrial biopsy who is having difficulty becoming pregnant. The nurse explains to the woman that
   a. the outpatient procedure is usually done preovulation.
   b. bleeding and discharge are common 2 to 4 days after the procedure.
   c. a small sample of tissue is obtained to diagnose and treat cervical dysplasia.
   d. common changes in endometrial cells in relation to progesterone levels will be assessed.

1. c, 2. c, 3. b, c, d, e, 4. b, 5. c, 6. a, b, 7. c, 8. d

LEARNING OUTCOMES

1. Summarize screening guidelines for the early detection of breast cancer.
2. Describe accurate clinical breast examination techniques, including inspection and palpation.
3. Explain the types, causes, clinical manifestations, and nursing and collaborative management of common benign breast disorders.
4. Assess the risk factors for breast cancer.
5. Describe the pathophysiology and clinical manifestations of breast cancer.
6. Describe the collaborative care and nursing management of breast cancer.
7. Specify the physical and psychologic preoperative and postoperative aspects of nursing management for the patient undergoing a mastectomy.
8. Explain the indications for reconstructive breast surgery, types and complications of reconstructive breast surgery, and nursing management after reconstructive breast surgery.

Paget's disease, p. 1245

Breast disorders are a significant health concern for women. Whether the actual diagnosis is a benign condition or a malignancy, the initial discovery of a lump or change in the breast often triggers intense feelings of anxiety, fear, and denial.

The most frequently encountered breast disorders in women are fibrocystic changes, fibroadenoma, intraductal papilloma, ductal ectasia, and breast cancer. In a woman's lifetime there is a 1 in 8 chance she will be diagnosed with breast cancer.[1] In men, gynecomastia is the most common breast disorder.

ASSESSMENT OF BREAST DISORDERS

Breast Cancer Screening Guidelines

Screening guidelines for the early detection of breast cancer include the following:[2-5]

- Yearly mammograms starting at age 40 and continuing for as long as a woman is in good health. A controversial recommended change is that women at normal risk for breast cancer should begin annual screening at age 50 and stop screening at age 75.[6]

Reviewed by Carole Martz, RN, MS, AOCN, CBCN, Clinical Coordinator, Living in the Future Cancer Survivorship Program, Northshore University Health System, Highland Park Hospital, Highland Park, Illinois; Shannon T. Harrington, RN, PhD, Nursing Lecturer, School of Nursing, Old Dominion University, Norfolk, Virginia; Mary Scheid, RN, MSN, OCN, CBCN, Breast Health Nurse, NCMC Breast Center, North Colorado Medical Center, Greeley, Colorado; and Mary Blessing, RN, MSN, Director, Academic RN Residency Program, University of New Mexico Hospitals, Albuquerque, New Mexico.

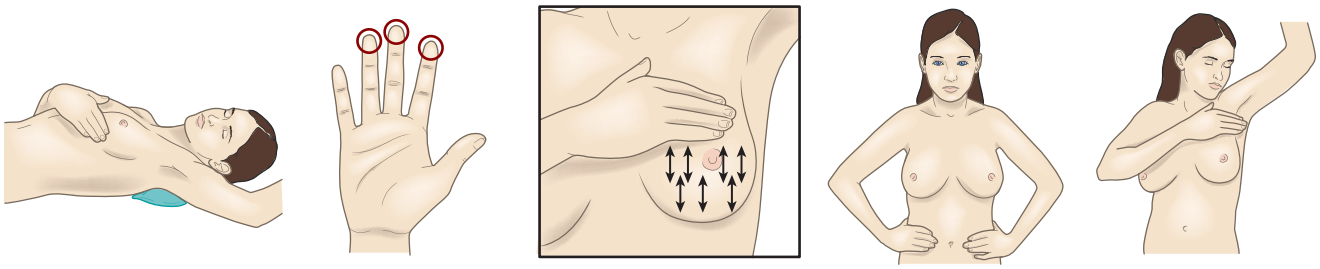

FIG. 52-1 Breast self-examination and patient instruction. *1,* Lie down and place your left arm behind your head. Lying down spreads breast tissue evenly and thinly over the chest wall, making it easier to feel the tissue. *2,* Use finger pads of three middle fingers on your right hand to feel for lumps in left breast. Use overlapping dime-sized circular motions to feel the breast tissue. Use three different levels of pressure to feel the breast tissue. Light pressure to feel tissue closest to the skin; medium pressure to feel a little deeper; and firm pressure to feel tissue closest to the chest and ribs. A firm ridge in the lower curve of each breast is normal. *3,* The up-and-down (vertical) pattern is recommended for examining the entire breast. Move around the breast in an up-and-down pattern starting at an imaginary line straight down your side from the underarm (including the tail of Spence, which is the triangular breast tissue projecting into the axilla), and moving across the breast to the middle of the sternum. Examine the entire breast going down until you feel only ribs and up to the neck or clavicle. Repeat procedure while examining your right breast. *4,* Stand in front of a mirror. Place your hands firmly on your hips, which will tighten the pectoralis muscles. Look at your breasts for size, shape, redness, scaliness, or dimpling of the breast skin or nipple. *5,* Examine each underarm while standing or sitting with arm slightly raised. Check for any lump, hard knot, or thickening of tissue.

- Clinical breast examination (CBE) preferably at least every 3 years for women in their 20s and 30s, and every year for women beginning at age 40.[7]
- Women should report any breast changes promptly to their health care provider. Breast self-examination (BSE) is an option for women starting at age 20.
- Women at increased risk (family history, genetic link, past breast cancer) should talk with their health care provider about the benefits and limitations of starting mammography screening earlier, having additional tests (e.g., breast ultrasound or magnetic resonance imaging [MRI]), or having more frequent examinations.

In recent years there has been some controversy regarding the value of BSE and its role in reducing mortality rates from breast cancer in women. While the benefit of BSE in reducing breast cancer deaths continues to be reviewed, BSE remains a useful technique in helping women develop awareness of how their breasts normally look and feel. Teach women beginning at age 20 the benefits and limitations of BSE and the importance of reporting breast changes (e.g., nipple discharge, a lump) to their health care provider.[8]

When teaching the woman about BSE, include information related to potential benefits, limitations, and harm (chance of a false-positive test result). Allow time for questions about the procedure and a return demonstration. At every periodic health examination, ask the woman who is performing BSE to demonstrate her technique. For women who choose to do BSE, the technique has recently been revised (Fig. 52-1).

BSE is recommended on a monthly schedule. For women who are having regular menstrual periods, this would be right after menstruation when breasts are less lumpy and tender. If menses are irregular or a woman is postmenopausal, advise choosing the same day each month. For women taking oral contraceptives, the first day of a new package may be a helpful reminder.

Diagnostic Studies

Radiologic Studies. Several techniques can be used to screen for breast disease or to help diagnose a suspicious physical finding. *Mammography* is a method used to visualize the breast's internal structure using x-rays (Fig. 52-2). This generally well-tolerated procedure can detect suspicious lumps that cannot be felt. Mammography has significantly improved the early and accurate detection of breast malignancies. Improved imaging technology has also reduced the radiation dose from mammography.

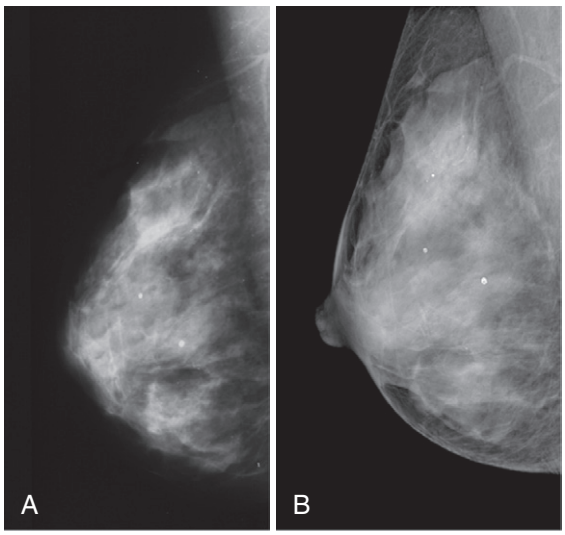

FIG. 52-2 Screening mammogram showing dense breast tissue and benign, scattered microcalcifications of a 57-year-old. **A,** Using conventional x-rays. **B,** Using digital x-rays.

Digital mammography is a technique in which x-ray images are digitally coded into a computer (see Fig. 52-2). It is not clear whether mammogram interpretation has improved with the aid of a computer. The associated costs of using computer-aided detection may also outweigh the benefits.[9]

Three-dimensional (3D) mammography, a new type of mammogram that produces a 3D image of the breast, provides a clearer view of overlapping breast tissue structures. 3-D images help to accurately detect and diagnose breast cancer.

Calcifications are the most easily recognized mammogram abnormality (see Fig. 52-2). These deposits of calcium crystals form in the breast for many reasons, such as inflammation, trauma, and aging. Although most calcifications are benign, they may also be associated with preinvasive cancer.

A comparison of current and prior mammograms may show early tissue changes. Because some tumors metastasize late, early detection by mammography allows for earlier treatment and the prevention of metastasis. In younger women, mammography is less sensitive because of the greater density of breast tissue, resulting in more false-negative results.

About 10% to 15% of all breast cancers cannot be seen on mammography and are detected by palpation or additional diagnostic studies, including ultrasound and MRI. If the clinical findings are suspicious and the mammogram is normal, an ultrasound or MRI may be used. Based on these additional findings, a biopsy may be done.

Ultrasound is used in conjunction with mammography. It may be used to differentiate a solid mass from a cystic mass, to evaluate a mass in a pregnant or lactating woman, or to locate and biopsy a suspicious lesion.

The somo-v ABUS is an ultrasound device for breast cancer screening for use in women with dense breasts. The somo-v ABUS scans a woman's breast, capturing multiple ultrasound images that can be reviewed in 3D. This device is used along with standard mammography in women with a negative mammogram and no breast cancer symptoms.

MRI is recommended as a sensitive screening tool for women who are at high risk for breast cancer, whose mammography or ultrasound is suspicious for malignancy, or who have previously had an occult breast cancer detected by mammogram.

Biopsies. A definitive diagnosis of a suspicious area is made by analyzing biopsied tissue. Biopsy techniques include *fine-needle aspiration* (FNA), core (core needle), vacuum-assisted, and surgical biopsies.

FNA biopsy is performed by inserting a needle into a lesion to sample fluid from a breast cyst, remove cells from intercellular spaces, or sample cells from a solid mass. Before the procedure, the breast area is first locally anesthetized. Then the needle is placed into the breast, and fluid and cells are aspirated into a syringe. Three or four passes are usually made. If the results are negative with a suspicious lesion, an additional biopsy may be necessary. Inform patients that biopsy results are usually available in 1 to 3 days.

A *core* (*core needle) biopsy* involves removing small samples of breast tissue using a hollow "core" needle. For palpable lesions, this is accomplished by fixing the lesion with one hand and performing a needle biopsy with the other. In the case of nonpalpable lesions, *stereotactic mammography, ultrasound,* or MRI image guidance is used. Stereotactic mammography uses computers to pinpoint the exact location of a breast mass based on mammograms. With ultrasound, the radiologist or surgeon watches the needle on the ultrasound monitor to help guide it to the area of concern. Because a core biopsy removes more tissue than an FNA, it is more accurate.

Vacuum-assisted biopsy is a version of core biopsy that uses a vacuum technique to help collect the tissue sample. In core biopsy, several separate needle insertions are used to acquire multiple samples. During vacuum-assisted biopsy, the needle is inserted only once into the breast, and the needle can be rotated, which allows for multiple samples through a single needle insertion.

A surgical biopsy is used to remove a breast mass or lump or to obtain a sample of breast tissue for analysis. A surgical biopsy is usually performed in an operating room. Ten years ago, most breast biopsies were surgical procedures. Today less invasive biopsy procedures, such as core biopsies, are used.

BENIGN BREAST DISORDERS

MASTALGIA

Mastalgia (breast pain) is the most common breast-related complaint in women.[10] The most common form is *cyclic mastalgia,* which coincides with the menstrual cycle. It is described as diffuse breast tenderness or heaviness. Breast pain may last 2 or 3 days or most of the month. The pain is related to hormonal sensitivity. The symptoms often decrease with menopause.

Noncyclic mastalgia has no relationship to the menstrual cycle and can continue into menopause. It may be constant or intermittent throughout the month and last for several years. Symptoms include a burning, aching, or soreness in the breast. The pain may be from trauma, fat necrosis, ductal ectasia, costochronditis, or arthritic pain in the chest or neck radiating to the breast.

Mammography and targeted ultrasound are frequently done to exclude cancer and provide information on the etiology of mastalgia. Some relief for cyclic pain may occur by reducing intake of caffeine and dietary fat; taking vitamins E, A, and B complex and gamma-linolenic acid (evening primrose oil); and continually wearing a support bra. Compresses, ice, analgesics, and antiinflammatory drugs may also help. Helpful drugs include oral contraceptives and danazol (Danocrine). The androgenic side effects of danazol (acne, edema, hirsutism) may make this therapy unacceptable for many women.

BREAST INFECTIONS

Mastitis

Mastitis is an inflammatory condition of the breast that occurs most frequently in lactating women (Table 52-1). *Lactational mastitis* manifests as a localized area that is erythematous, painful, and tender to palpation. Fever is often present. The infection develops when organisms (usually staphylococci) gain access to the breast through a cracked nipple. In its early stages, mastitis can be cured with antibiotics. Breastfeeding should continue unless an abscess is forming or purulent drainage is noted. The mother may wish to use a nipple shield or to hand-express milk from the involved breast until the pain subsides. The woman should see her health care provider promptly to begin a course of antibiotic therapy. Any breast that remains red, tender, and not responsive to antibiotics requires follow-up care and evaluation for inflammatory breast cancer.[11]

Lactational Breast Abscess

If lactational mastitis persists after several days of antibiotic therapy, a lactational breast abscess may have developed. In this condition, the skin may become red and edematous over the involved breast, often with a corresponding palpable mass, and the patient may have a fever. Antibiotics alone are insufficient treatment for a breast abscess. Ultrasound-guided drainage of the abscess or surgical incision and drainage are necessary. The drainage is cultured, sensitivities are obtained, and therapy with

TABLE 52-1 BENIGN BREAST DISORDERS*

Disorder	Risk Factors	Clinical Manifestations
Lactational mastitis	Occurs in up to 10% of postpartum lactating mothers (both primipara and multipara), usually 2-4 wk after birth.	Warm to touch, indurated, painful, often unilateral, most commonly caused by *Staphylococcus aureus*.
Fibrocystic changes	Most common between ages 35 and 50.	Not usually discrete masses—nodularity instead. Usually accompanied by cyclic pain and tenderness. Mass(es) often cyclic in occurrence (movable, soft).
Cysts	Most common over age 35. Incidence decreases after menopause. Develop in one out of every 14 women.	Palpable fluid-filled mass (movable, soft). Multiple cysts can occur and recur. Rarely associated with breast cancer.
Fibroadenoma	Commonly occurs in 10% of all women ages 15-40.	Palpable mass (firm, movable), usually 2-3 cm in size, rarely associated with breast cancer.
Fat necrosis	Many women report previous history of trauma to breast.	Usually a hard, tender, mobile, indurated mass with irregular borders.
Ductal ectasia	Perimenopausal woman—most common in women in their 50s, previous lactation, inverted nipples.	Fixation of nipple, usually accompanied by nipple discharge of thick gray material. Often associated with breast pain.

*This list is not inclusive; other benign breast disorders are discussed in the text.

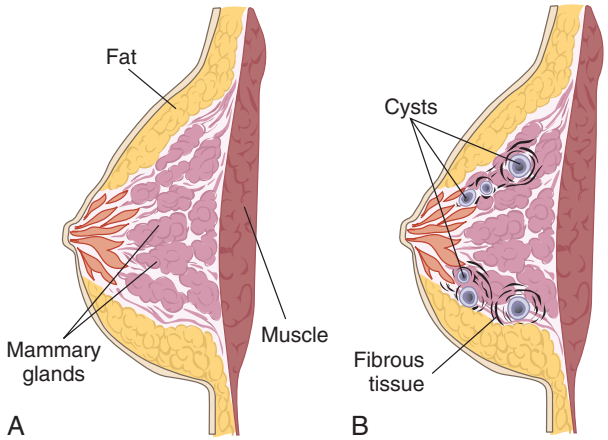

FIG. 52-3 **A,** Normal breast tissue. **B,** Fibrocystic breast tissue.

an appropriate antibiotic is begun. Breastfeeding can continue in most cases with ongoing treatment of the abscess.

FIBROCYSTIC CHANGES

Fibrocystic changes in the breast are a benign condition characterized by changes in breast tissue[12] (Fig. 52-3). The changes include the development of excess fibrous tissue, hyperplasia of the epithelial lining of the mammary ducts, proliferation of mammary ducts, and cyst formation. Fibrocystic changes are thought to be due to a heightened responsiveness of breast tissue to circulating estrogen and progesterone. These changes produce pain related to nerve irritation from edema in the connective tissue and to fibrosis that pinches the nerve. Fibrocystic changes are the most common breast disorder.

The use of the term *fibrocystic disease* is incorrect because the cluster of problems is actually an exaggerated response to hormonal influence. The terms *fibrocystic condition* or *fibrocystic complex* are more accurate.

Fibrocystic changes alone are not associated with increased breast cancer risk. Masses or nodularities can appear in both breasts. They are often found in the upper, outer quadrants and usually occur bilaterally.

Fibrocystic changes occur most frequently in women between 35 and 50 years of age but often begin as early as 20 years of age. Pain and nodularity often increase over time but tend to subside after menopause unless high doses of estrogen replacement are used. Fibrocystic changes most commonly occur in women with premenstrual abnormalities, nulliparous women, women with a history of spontaneous abortion, nonusers of oral contraceptives, and women with early menarche and late menopause. Symptoms related to fibrocystic changes often worsen in the premenstrual phase and subside after menstruation.

Manifestations of fibrocystic breast changes include one or more palpable lumps that are often round, well delineated, and freely movable within the breast (see Table 52-1). Discomfort ranging from tenderness to pain may also occur. The lump is usually observed to increase in size and perhaps in tenderness before menstruation. Cysts may enlarge or shrink rapidly. Nipple discharge associated with fibrocystic breasts is often milky, watery-milky, yellow, or green.

Mammography may be helpful in distinguishing fibrocystic changes from breast cancer. However, in some women the breast tissue is so dense that it is difficult to obtain a mammogram. In these situations, ultrasound may be more useful in differentiating a cystic mass from a solid mass.

NURSING AND COLLABORATIVE MANAGEMENT
FIBROCYSTIC CHANGES

With the initial discovery of a discrete mass in the breast by a woman or her health care provider, aspiration or surgical biopsy may be indicated. If the nodularity is recurrent, a wait of 7 to 10 days may be planned in order to note any changes that may be related to the menstrual cycle. With large or frequent cysts, surgical removal may be favored over repeated aspiration. An excisional biopsy may be done if (1) no fluid is found on aspiration, (2) the fluid that is found is hemorrhagic, or (3) a residual mass remains after fluid aspiration. The biopsy is usually performed in an outpatient surgery unit.

Biopsies in women with fibrocystic disease may be indicated if these women have an increased risk for breast cancer. Atypical hyperplasia discovered by breast biopsy increases a woman's risk of developing breast cancer later in life.

Encourage the woman with cystic changes to maintain regular follow-up care. Also teach her BSE to self-monitor changes. Severe fibrocystic changes may make palpation of the breast more difficult. Teach her to report any changes in symptoms or changes found during the BSE so they can be evaluated.

Treatment for a fibrocystic condition is similar to that described earlier for mastalgia. Teach the woman with fibrocystic breasts that she may expect a recurrence of the cysts in one

or both breasts until menopause and that the cysts may enlarge or become painful just before menstruation. Additionally, reassure her that the cysts do not "turn into" cancer. Advise her that any new lump that does not respond in a cyclic manner over 1 to 2 weeks should be examined by her health care provider.

FIBROADENOMA

Fibroadenoma is a common cause of discrete benign breast lumps in young women. It generally occurs in women between 15 and 40 years of age. It is the most frequent cause of breast masses in women under 25 years of age.

The possible cause of fibroadenoma may be increased estrogen sensitivity in a localized area of the breast. Fibroadenomas are usually small (but can be large [2 to 3 cm]), painless, round, well delineated, and very mobile. They may be soft but are usually solid, firm, and rubbery in consistency. There is no accompanying retraction or nipple discharge. The lump is often painless. The fibroadenoma may appear as a single unilateral mass, although multiple bilateral fibroadenomas have been reported. Growth is slow and often ceases when the size reaches 2 to 3 cm. Size is not affected by menstruation. However, pregnancy can stimulate dramatic growth.

Fibroadenomas are easily detected by physical examination and may be visible on mammography and ultrasound. However, definitive diagnosis requires FNA, core, or surgical biopsy and tissue examination by a pathologist to exclude other tumors. Treatment of fibroadenomas can include observation with regular monitoring after a malignancy has been ruled out, or surgical excision. In women over 35 years of age, all new lesions should be evaluated by breast ultrasound and possible biopsy.

As an alternative to surgery, tumor removal can be done using *cryoablation*. In this procedure, a cryoprobe is inserted into the tumor using ultrasound guidance. Extremely cold gas is piped into the tumor. The frozen tumor dies and gradually shrinks.

NIPPLE DISCHARGE

Nipple discharge may occur spontaneously or as a result of nipple manipulation. A milky secretion is due to inappropriate lactation (termed **galactorrhea**) and may be a result of problems such as drug therapy, endocrine problems, and neurologic disorders. Nipple discharge may also be idiopathic (no known cause).

Secretions can also be serous, grossly bloody, or brown to green.[13] These secretions may be caused by either benign or malignant disease. A cytology slide may be made of the secretion to determine the specific disease. Diseases associated with nipple discharge include malignancies, cystic disease, intraductal papilloma, and ductal ectasia. Treatment depends on identification of the cause. In most cases, nipple discharge is not related to malignancy.

Intraductal Papilloma

An **intraductal papilloma** is a benign, soft, wartlike growth found in the mammary ducts. It is usually unilateral. Typically, the nipple has a bloody discharge that can be intermittent or spontaneous. Most intraductal papillomas are beneath the areola, and they may be difficult to palpate. They are usually found in women 40 to 60 years of age. A single duct or several ducts may be involved. Treatment includes excision of the papilloma and the involved duct or duct system. Papillomas may be associated with an increased risk of cancer.

Ductal Ectasia

Ductal ectasia (duct dilation) is a benign breast disease of perimenopausal and postmenopausal women involving the ducts in the subareolar area. It usually involves several bilateral ducts. Multicolored, sticky nipple discharge is the primary symptom. Ductal ectasia is initially painless but may progress to burning, itching, and pain around the nipple, as well as swelling in the areolar area. Inflammatory signs are often present, the nipple may retract, and the discharge may become bloody in more advanced disease. Ductal ectasia is not associated with malignancy. If an abscess develops, warm compresses and antibiotics are usually effective treatments. Therapy consists of close follow-up examinations or surgical excision of the involved ducts.

GYNECOMASTIA IN MEN

Gynecomastia, a transient, noninflammatory enlargement of one or both breasts, is the most common breast problem in men. The condition is usually temporary and benign. Gynecomastia in itself is not a risk factor for breast cancer. The most common cause of gynecomastia is a disturbance of the normal ratio of active androgen to estrogen in plasma or within the breast itself.

Gynecomastia may also be a manifestation of other problems. It is seen in developmental abnormalities of the male reproductive organs. It may also accompany diseases such as testicular tumors, adrenal cancer, pituitary adenomas, hyperthyroidism, and liver disease.[14] Gynecomastia may occur as a side effect of drug therapy, particularly with estrogens and androgens, digitalis, isoniazid (INH), ranitidine (Zantac), and spironolactone (Aldactone). The use of heroin and marijuana can also cause gynecomastia.

Senescent Gynecomastia

Senescent gynecomastia occurs in many older men. A probable cause is the elevation in plasma estrogen in older adult men as the result of increased conversion of androgens to estrogens in peripheral circulation. Although initially unilateral, the tender, firm, centrally located enlargement may become bilateral. When gynecomastia is characterized by a discrete, circumscribed mass, it must be biopsied to differentiate it from the rarer breast cancer in males. Senescent hyperplasia requires no treatment and generally regresses within 6 to 12 months.

GERONTOLOGIC CONSIDERATIONS

AGE-RELATED BREAST CHANGES

The loss of subcutaneous fat and structural support and the atrophy of mammary glands often result in pendulous breasts in the postmenopausal woman. Encourage older women to wear a well-fitting bra. Adequate support can improve physical appearance and reduce pain in the back, shoulders, and neck. It can also prevent *intertrigo* (dermatitis caused by friction between opposing surfaces of skin). Sagging breasts can be surgically lifted (mastopexy). This procedure can be done in conjunction with breast reconstruction after a mastectomy is performed.

The decrease in glandular tissue in older women makes a breast mass easier to palpate. This decreased density is likely a

result of age-related decreases in estrogen. Rib margins may be palpable in a thin woman and can be confused with a mass. That is why it is so important that women become familiar with their own breasts and what is normal for them. Because the incidence of breast cancer increases with age, encourage older women to continue BSE, to have annual mammograms and CBEs, and to have any breast mass evaluated by their health care provider.

BREAST CANCER

Breast cancer is the most common malignancy in American women except for skin cancer. It is second only to lung cancer as the leading cause of death from cancer in women. In the United States more than 230,480 new cases of invasive breast cancer and more than 57,650 cases of in situ breast cancer are diagnosed annually.[1] About 2140 of those new cases are diagnosed in men. Approximately 39,920 deaths (39,510 women and 410 men) occur each year related to breast cancer.

The incidence of breast cancer is slowly decreasing, with a slight drop in the number of deaths related to breast cancer. This decline may be the result of the decreased use of hormone therapy after menopause.[2] Approximately 2.6 million women are alive in the United States today who are breast cancer survivors.

Patients diagnosed with localized breast cancer with no axillary node involvement have a 5-year survival rate of 98%. Conversely, only 23% of patients diagnosed with advanced-stage breast cancer with metastases to distant sites will survive 5 years or more.[1,2]

Etiology and Risk Factors

Although the etiology is not completely understood, a number of risk factors are related to breast cancer (Table 52-2). Risk factors appear to be cumulative and interacting. Therefore the presence of multiple risk factors may greatly increase the overall risk, especially for people with a positive family history.

Risk Factors for Women. The risk factors most associated with breast cancer include female gender and advancing age. Women are at far greater risk than men, with 99% of breast cancers occurring in women. Increasing age also increases the risk of developing breast cancer. The incidence of breast cancer in women under 25 years of age is very low and increases gradually until age 60. After age 60, the incidence increases dramatically.

Hormonal regulation of the breast is related to the development of breast cancer, but the mechanisms are poorly understood. The hormones estrogen and progesterone may act as tumor promoters to stimulate breast cancer growth if malignant changes in the cells have already occurred. The Women's Health Initiative study showed that the use of combined hormone therapy (estrogen plus progesterone) increases the risk of breast cancer and also the risk of having a larger, more advanced breast cancer at diagnosis.[15] The use of estrogen therapy alone for longer than 10 years (for women with a prior hysterectomy) increases a woman's long-term risk for breast cancer. A link may exist between recent oral contraceptive use and increased risk of breast cancer for younger women.[16]

Modifiable risk factors include excess weight gain during adulthood, sedentary lifestyle, smoking, dietary fat intake, obesity, and alcohol intake.[10] Environmental factors such as radiation exposure may also play a role.

TABLE 52-2 RISK FACTORS FOR BREAST CANCER

Risk Factor	Comments
Female	Women account for 99% of breast cancer cases.
Age ≥50 yr	Majority of breast cancers are found in postmenopausal women. After age 60, increase in incidence.
Hormone use	Use of estrogen and/or progesterone as hormone therapy, especially in postmenopausal women.
Family history	Breast cancer in a first-degree relative, particularly when premenopausal or bilateral, increases risk.
Genetic factors	Gene mutations *(BRCA1* or *BRCA2)* play a role in 5%-10% of breast cancer cases.
Personal history of breast cancer, colon cancer, endometrial cancer, ovarian cancer	Personal history significantly increases risk of breast cancer, risk of cancer in other breast, and recurrence.
Early menarche (before age 12), late menopause (after age 55)	A long menstrual history increases the risk of breast cancer.
First full-term pregnancy after age 30, nulliparity	Prolonged exposure to unopposed estrogen increases risk for breast cancer.
Benign breast disease with atypical epithelial hyperplasia, lobular carcinoma in situ	Atypical changes in breast biopsy increase the risk of breast cancer.
Dense breast tissue	Mammograms harder to read and interpret. Dense tissue may be associated with more aggressive tumors.
Weight gain and obesity after menopause	Fat cells store estrogen, which increases the likelihood of developing breast cancer.
Exposure to ionizing radiation	Radiation damages DNA (e.g., prior treatment for Hodgkin's lymphoma).
Alcohol consumption	Women who drink ≥1 alcoholic beverage per day have an increased risk of breast cancer.
Physical inactivity	Breast cancer risk is decreased in physically active women.

Genetic Link

Family history of breast cancer is an important risk factor, especially if the involved family member also had ovarian cancer, was premenopausal, had bilateral breast cancer, or is a first-degree relative (i.e., mother, sister, daughter). Having any first-degree relative with breast cancer increases a woman's risk of breast cancer 1.5 to 3 times, depending on age. A breast cancer risk assessment tool for health care providers is available through the National Cancer Institute (see Resources at the end of this chapter). About 5% to 10% of all breast cancers are hereditary. This means that specific genetic abnormalities that contribute to the development of breast cancer have been inherited (passed from parent to child). Most inherited cases of breast cancer are associated with mutations in two genes: *BRCA1* and *BRCA2* (*BRCA* stands for *BR*east *CA*ncer). Everyone has *BRCA* genes. The *BRCA1* gene, located on chromosome 17, is a tumor suppressor gene that inhibits tumor development when func-

GENETICS IN CLINICAL PRACTICE

Breast Cancer

Genetic Basis
- Mutations occur in *BRCA1* and/or *BRCA2* genes.
- Normally these genes are tumor suppressor genes involved in DNA repair.
- Transmission is autosomal dominant.

Incidence
- Approximately 5% to 10% of breast cancers are related to *BRCA1* and *BRCA2* gene mutations.
- Women with *BRCA1* and *BRCA2* gene mutations have a 40% to 80% lifetime risk of developing breast cancer.
- *BRCA1* and *BRCA2* gene mutations are associated with early-onset breast cancer that is more likely to involve both breasts.
- Men with mutations in *BRCA1* and *BRCA2* have an increased risk of breast cancer and prostate cancer.
- Family history of both breast and ovarian cancer increases the risk of having a *BRCA* mutation.

Genetic Testing
- DNA testing is available for *BRCA1* and *BRCA2* gene mutations.

Clinical Implications
- Most breast cancers (about 90%-95%) are not inherited. They are associated with genetic changes that occur after a person is born (somatic mutations). There is no risk of passing on the mutated gene to children.
- Bilateral oophorectomy and/or bilateral mastectomy reduces the risk of breast cancer in women with *BRCA1* and *BRCA2* mutations.
- Mutations in the *BRCA1* and *BRCA2* genes increase the risk of ovarian cancer.
- Genetic counseling and testing for *BRCA* mutations should be considered for women whose personal or family history puts them at high risk for a genetic predisposition to breast cancer.

*BRCA, BR*east *CA*ncer.

tioning normally. Women who have *BRCA1* mutations have a 40% to 80% lifetime chance of developing breast cancer. The *BRCA2* gene, located on chromosome 11, is another tumor suppressor gene. Women with a mutation of this gene have a similar risk of breast cancer.

Mutations in *BRCA* genes may cause as many as 10% to 40% of all inherited breast cancers. As many as 1 in 200 to 400 women in the United States may be carriers for these genetic abnormalities. Women with *BRCA* mutations are also at higher risk for developing ovarian, colon, pancreatic, and uterine cancers.[17]

In addition to *BRCA* gene mutations, many other abnormal genes have been identified that increase a person's risk of developing breast cancer. These include the tumor suppressor gene *p53* (which inhibits tumor development when functioning normally), *ATM* (which helps to repair damaged deoxyribonucleic acid [DNA]), and *CHEK2* (which stops tumor growth).

Most people who develop breast cancer do not inherit an abnormal breast cancer gene, and they do not have a family history of breast cancer. Ongoing research continues to investigate the role of genes in the development of breast cancer.

Risk Factors for Men. Predisposing risk factors for breast cancer in men include hyperestrogenism, a family history of breast cancer, and radiation exposure. A thorough examination of the male breast should be a routine part of a physical examination. Men in *BRCA*-positive families may consider genetic testing. Men with an abnormal *BRCA* gene also have an increased risk of developing prostate cancer.

TABLE 52-3 TYPES OF BREAST CANCER

Type	Frequency of Occurrence
Noninvasive	20%
• Ductal carcinoma in situ	
Invasive/Infiltrating Ductal Carcinoma	70%-75%
• Medullary	
• Tubular	
• Colloid (mucinous)	
• Inflammatory	
• Paget's disease	
Invasive/Infiltrating Lobular Carcinoma	5%-10%

Prophylactic Oophorectomy and Mastectomy. In women with *BRCA1* or *BRCA2* mutations, prophylactic bilateral oophorectomy can decrease the risk of breast cancer and ovarian cancer. Removing the ovaries lowers the risk of breast cancer because the ovaries are the main source of estrogen in a premenopausal woman. Removing the ovaries does not reduce the risk of breast cancer in postmenopausal women because the ovaries are not the main producers of estrogen in these women. A woman who has a high risk of developing breast cancer (i.e., related to factors such as family history and prior tissue biopsies) may choose (in consultation with her physician and genetic counselor) to undergo prophylactic bilateral mastectomy.

Younger women with hereditary (non-*BRCA*) early-stage, estrogen receptor–negative breast cancer may have a higher risk of developing a secondary primary breast cancer in the unaffected (contralateral) breast.[18] These women may also choose to have the unaffected breast removed prophylactically at the time of initial surgery for breast cancer or at a later time.

Pathophysiology

The main components of the breast are lobules (milk-producing glands) and ducts (milk passages that connect the lobules and the nipple). In general, breast cancer arises from the epithelial lining of the ducts *(ductal carcinoma)* or from the epithelium of the lobules *(lobular carcinoma)*. Breast cancers may be *in situ* (within the duct) or invasive (arising from the duct and invading through the wall of the duct).

Metastatic breast cancer is breast cancer that has spread to other organs, with the most common sites being bone, liver, lung, and brain. Cancer growth rates can range from slow to rapid. Factors that affect cancer prognosis are tumor size, axillary node involvement (the more nodes involved, the worse the prognosis), tumor differentiation, estrogen and progesterone receptor status, and *human epidermal growth factor receptor 2* (HER-2) status. HER-2 is a protein that helps regulate cell growth. It is overexpressed in about 25% of patients with breast cancer.[19,20]

Types of Breast Cancer

Breast cancer can be classified as noninvasive or invasive, and ductal or lobular (Table 52-3).

Noninvasive Breast Cancer. An estimated 20% of all diagnosed breast cancers are noninvasive. These intraductal cancers include *ductal carcinoma in situ* (DCIS) and *lobular carcinoma in situ* (LCIS). DCIS tends to be unilateral and may progress to invasive breast cancer if left untreated.

Although the management of DCIS can be controversial, patients should discuss treatment options with their health care

provider, including breast-conserving treatment (lumpectomy), mastectomy with breast reconstruction, radiation therapy, and/or hormone therapy (tamoxifen [Nolvadex], anastrozole [Arimidex]).

The term *lobular carcinoma in situ* is somewhat misleading. Although LCIS is a risk factor for developing breast cancer, it is not known to be a premalignant lesion. No surgical or radiation treatment is indicated for LCIS. Hormone therapy may be used as a preventive measure to reduce breast cancer risk for some patients.

Invasive (Infiltrating) Ductal Carcinoma. *Invasive (infiltrating) ductal carcinoma* is the most common type of breast cancer. It starts in the milk duct and then breaks through the wall of the duct, invading the surrounding tissue. From there it may metastasize to other parts of the body.

Types of invasive (infiltrating) ductal carcinoma include *medullary carcinoma,* which accounts for 15% of all breast cancers. It most frequently occurs in women in their late 40s and 50s, manifesting with cells that resemble the medulla of the brain. *Tubular carcinoma* accounts for about 2% of all breast cancers. This type of breast cancer is usually found in women over 50. It has an excellent prognosis. *Colloid (mucinous) carcinoma* accounts for about 1% to 2% of all breast cancer. These tumors, which produce mucus, usually have a favorable prognosis.

Inflammatory Breast Cancer. *Inflammatory breast cancer* is an aggressive and fast-growing breast cancer with a high risk for metastasis. The lymph channels in the skin of the breast become blocked by cancer cells. Because of skin involvement, the breast looks red, feels warm, and has a thickened appearance that is often described as resembling an orange peel *(peau d'orange).*[21] Sometimes the breast develops ridges and small bumps that look like hives. A breast mass may or may not be present.

Paget's Disease. **Paget's disease** is a rare breast malignancy characterized by a persistent lesion of the nipple and areola with or without a mass. (This is different from Paget's disease of the bone, which is discussed in Chapter 64.) Most women with Paget's disease have underlying ductal carcinoma. Only in rare cases is the cancer confined to the nipple itself.

Itching, burning, bloody nipple discharge with superficial skin erosion and ulceration may be present. Diagnosis of Paget's disease is confirmed by pathologic examination of the lesion. Nipple changes are often diagnosed as an infection or dermatitis, which can lead to treatment delays.

The treatment of Paget's disease is surgical removal of the involved tissue (central lumpectomy or mastectomy). Radiation therapy may also be used after surgery. The prognosis is good when the cancer is confined to the nipple. The nursing care for the patient with Paget's disease is the same as the care for a patient with breast cancer.

Invasive (Infiltrating) Lobular Carcinoma. *Invasive (infiltrating) lobular carcinoma* begins in the lobules (milk-producing glands) of the breast. The cancer cells can break out of the lobule and have the potential to metastasize to other areas of the body. Invasive lobular carcinoma is a type of breast cancer that usually appears as a subtle thickening in the upper outer quadrant of the breast. Often positive for estrogen and progesterone receptors, these tumors respond well to hormone therapy.

Clinical Manifestations

Breast cancer is usually detected as a lump or thickening in the breast or mammographic abnormality. It occurs most often in the upper, outer quadrant of the breast, which is the location of most of the glandular tissue (Fig. 52-4). Breast cancers vary in their growth rate. If palpable, breast cancer is characteristically hard and may be irregularly shaped, poorly delineated, nonmobile, and nontender.

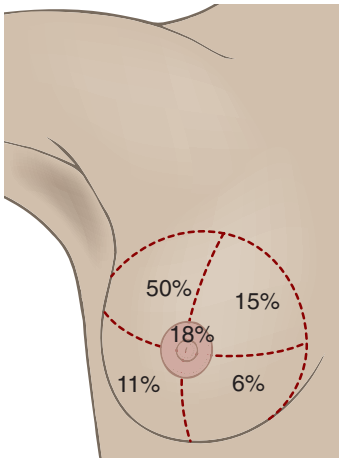

FIG. 52-4 Distribution of where breast cancer occurs.

A small percentage of breast cancers cause nipple discharge. The discharge is usually unilateral and may be clear or bloody. Nipple retraction may occur. Peau d'orange may occur due to plugging of the dermal lymphatics. In large cancers, infiltration, induration, and dimpling (pulling in) of the overlying skin may also occur.

Complications

The main complication of breast cancer is recurrence (Table 52-4). Recurrence may be *local* or *regional* (skin or soft tissue near the mastectomy site, axillary or internal mammary lymph nodes) or distant (most commonly involving bone, lung, brain, and liver). However, metastatic disease can be found in any site in the body.

Widely disseminated or metastatic disease involves the growth of colonies of cancerous breast cells in parts of the body distant from the breast. Metastases primarily occur through the lymphatics, usually those of the axilla (Fig. 52-5). However, the cancer can spread to other parts of the body without invading the axillary nodes even when the primary breast tumor is small. Even in patients who do not have lymph node involvement (node-negative breast cancer), there is a possibility of distant metastasis.

Diagnostic Studies

In addition to radiologic and biopsy studies used to diagnose breast cancer (see earlier discussion in this chapter on pp. 1239-1240), other tests are used to predict the risk of local or systemic recurrence. These tests include axillary lymph node status, tumor size, estrogen and progesterone receptor status, cell-proliferative indices, and genomic assays.

Axillary lymph node involvement is one of the most important prognostic factors in breast cancer. *Axillary lymph nodes* are often examined to determine if cancer has spread to the axilla on the side of the breast cancer. The more nodes involved, the greater the risk of recurrence.

Lymphatic mapping and *sentinel lymph node dissection* (SLND) help the surgeon identify the lymph node(s) that drain first from the tumor site *(sentinel node).* An SLND is less inva-

TABLE 52-4 SITES OF BREAST CANCER RECURRENCE AND METASTASIS

Site	Clinical Manifestations
Local Recurrence	
Skin, chest wall	Firm, discrete nodules. Occasionally pruritic, usually painless, commonly in or near a scar.
Regional Recurrence	
Lymph nodes	Enlarged nodes in axilla or supraclavicular area, usually nontender.
Distant Metastasis	
Skeletal	Localized pain of gradually increasing intensity, percussion tenderness at involved sites, pathologic fracture caused by involvement of bone cortex.
Spinal cord	Progressive back pain, localized and radiating. Change in bladder or bowel function. Loss of sensation in lower extremities.
Brain	Headache described as "different," unilateral sensory loss, focal muscular weakness, hemiparesis, incoordination (ataxia), nausea and vomiting unrelated to medication, cognitive changes.
Pulmonary (including lung nodules and pleural effusions)	Shortness of breath, tachypnea, nonproductive cough (not present in all patients).
Liver	Abdominal distention. Right lower quadrant abdominal pain sometimes with radiation to scapular area. Nausea and vomiting, anorexia, weight loss. Weakness and fatigue. Hepatomegaly, ascites, jaundice. Peripheral edema. Elevated liver enzymes.
Bone marrow	Anemia, infection, increased bleeding, bruising, petechiae. Weakness, fatigue, mild confusion, light-headedness. Dyspnea.

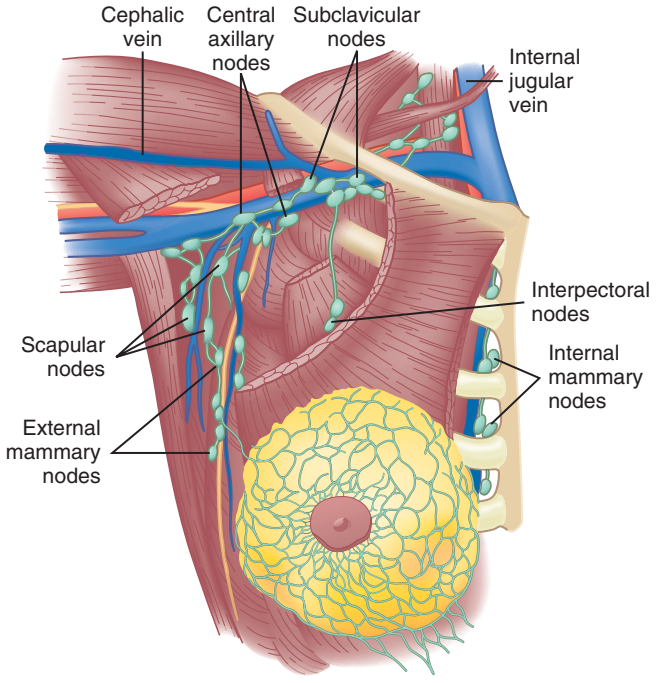

FIG. 52-5 Lymph nodes and drainage in the axilla. The sentinel lymph node is usually found in the external mammary nodes. A complete axillary dissection would remove all nodes.

sive than an axillary lymph node dissection (ALND). In SLND a radioisotope and/or blue dye is injected into the affected breast, and intraoperatively it is determined in which sentinel lymph nodes (SLNs) the radioisotope or dye is located. A local incision is made in the axilla, and the surgeon dissects the blue-stained or radioactive SLNs. Generally, with an SLND, one to four axillary lymph nodes are removed. The nodes may be sent for pathologic analysis. If the SLNs are negative, no further axillary surgery is required. If the SLNs are positive, a complete axillary dissection may be done, depending on the patient's clinical situation. SLND is associated with lower morbidity rates and greater accuracy compared with complete ALND.

Tumor size is a prognostic variable: the larger the tumor, the poorer the prognosis. The wide variety of biologic types of breast cancer explains the variability of disease behavior. In general, the more well differentiated (like the original cell type) the tumor, the less aggressive it is. The cells of poorly differentiated (unlike the original cell type) tumors appear morphologically disorganized, and they are more aggressive.

Estrogen and progesterone receptor status is another diagnostic test useful for decisions about both treatment and prognosis.[12] Receptor-positive tumors (1) commonly show histologic evidence of being well differentiated, (2) frequently have a *diploid* (more normal) DNA content and low proliferative indices, (3) have a lower chance for recurrence, and (4) are frequently hormone dependent and responsive to hormone therapy. Receptor-negative tumors (1) are often poorly differentiated histologically, (2) have a high incidence of *aneuploidy* (abnormally high or low DNA content) and higher proliferative indices, (3) frequently recur, and (4) are usually unresponsive to hormone therapy.

Ploidy status correlates with tumor aggressiveness. Diploid tumors have been shown to have a significantly lower risk of recurrence than aneuploid tumors.

Cell-proliferative indices indirectly measure the rate of tumor cell proliferation. The percentage of tumor cells in the synthesis (S) phase of the cell cycle (see Chapter 16, Fig. 16-1) is another important prognostic indicator. Patients with cells that have high S-phase fractions have a higher risk for recurrence and earlier cancer death.

Another prognostic indicator is the marker HER-2. Overexpression of this receptor has been associated with unusually aggressive tumor growth, a greater risk for recurrence, and a poorer prognosis in breast cancer.[20] About 25% of metastatic breast cancers produce excessive HER-2. The presence of this marker assists in the selection and sequence of drug therapy and predicts the patient's response to treatment.

A patient whose breast cancer tests negative for all three receptors (estrogen, progesterone, and HER-2) has *triple-negative breast cancer.*[22] This subtype of breast cancer accounts for approximately 10% to 20% of cases. The incidence of triple-negative breast cancer is higher in Hispanics, African Americans, younger women, and women with a *BRCA1* mutation. These patients tend to have more aggressive tumors with a poorer prognosis.

A *genomic assay* is a test that uses a sample of the breast cancer tissue to analyze the activity of a group of genes. Knowing whether certain genes are present or absent, or overly active or not active enough, can provide information about the risk of recurrence and the likely benefit of chemotherapy or hormone therapy. Two genomic assays are currently in use for breast cancer: Oncotype DX and MammaPrint. These tests are typi-

cally reserved for patients who (1) have early-stage breast cancer with no to few lymph nodes involved; and (2), in the case of Oncotype DX, have estrogen receptor–positive breast cancer that can be treated with hormone therapy.

Cancer markers for breast cancer include CA 15-3 and CA 27-29. These proteins are produced by the *MUC1* gene. Breast cancer cells shed copies of these proteins into the bloodstream. These markers are not specific or sensitive enough to be used as a screening tool to detect early breast cancer. Although not recommended at this time, these markers may be used to monitor a patient's response to treatment of invasive breast cancer and detect recurrence of the disease.

Collaborative Care

A wide range of treatment options is available to the patient and health care providers making critical decisions about how to treat breast cancer (Table 52-5). Prognostic factors are considered when treatment decisions are made. The therapeutic regimen is often determined by the clinical stage and biology of the cancer.

Staging of Breast Cancer. The most widely accepted staging method for breast cancer is the TNM system.[23] This system uses tumor size (T), nodal involvement (N), and presence of metastasis (M) to determine the stage of disease. The stage of a breast cancer describes its size and the extent to which it has spread (Table 52-6).

The stages range from 0 to IV, with stage 0 being in situ cancer with no lymph node involvement and no metastasis. Further classification within these stages depends on tumor size and the number of lymph nodes involved. Stage IV indicates metastatic spread, regardless of tumor size or lymph node involvement. The presence or absence of malignant cells in lymph nodes remains a powerful prognostic factor related to local recurrence or metastasis after primary therapy.

Surgical Therapy. Surgery is considered the primary treatment for breast cancer. Table 52-7 describes the most common surgical procedures used to treat breast cancer. The most common surgical options for resectable breast cancer are (1) breast conservation surgery (lumpectomy) and (2) modified radical mastectomy. Most women diagnosed with early-stage breast cancer (tumors smaller than 4 to 5 cm) are candidates for either treatment choice. The overall survival rate with lumpectomy and radiation is about the same as that with modified radical mastectomy.

Breast-Conserving Surgery. Breast-conserving surgery (also called **lumpectomy** or partial mastectomy) usually involves removal of the entire tumor along with a margin of normal surrounding tissue (Fig. 52-6, *A*). After surgery, radiation therapy is delivered to the entire breast, ending with a boost to

TABLE 52-5 COLLABORATIVE CARE

Breast Cancer

Diagnostic

Prediagnosis

- Health history, including risk factors
- Physical examination, including breast and lymph nodes
- Mammography
- Ultrasound
- Breast MRI (if indicated)
- Biopsy

Postdiagnosis

- Lymphatic mapping and sentinel lymph node dissection (SLND)
- Estrogen and progesterone receptor status
- Cell-proliferative indices
- HER-2 marker
- Genetic assays (MammaPrint and Oncotype DX)

Staging

- Complete blood count, platelet count
- Calcium and phosphorus levels
- Liver function tests
- Chest x-ray
- Bone scan (if indicated)
- CT scan of chest, abdomen, pelvis (if indicated)
- MRI (if indicated)
- PET/CT scan (if indicated)

Collaborative Therapy

Surgery

- Breast-conserving surgery (lumpectomy) with SLND and biopsy and/or axillary lymph node dissection
- Modified radical mastectomy (may include immediate or delayed reconstruction)

Radiation Therapy

- Primary radiation therapy
- Brachytherapy
- Palliative radiation therapy

Drug Therapy (see Table 52-8)

- Chemotherapy
- Hormone therapy
- Biologic and targeted therapy
- Chemotherapy
- Hormone therapy
- Biologic and targeted therapy

TABLE 52-7 SURGICAL PROCEDURES FOR BREAST CANCER

Procedure	Side Effects	Complications	Patient Issues
Breast-Conserving Surgery (Lumpectomy) With Radiation Therapy			
Wide excision of tumor, sentinel lymph node dissection (SLND) and/or axillary lymph node dissection (ALND). Radiation therapy.	Breast soreness Breast edema Skin reactions Arm swelling Sensory changes in breast and arm	*Short-term:* Moist desquamation,* hematoma, seroma, infection *Long-term:* Fibrosis, lymphedema,† myositis, pneumonitis,* rib fractures*	Prolonged treatment* Impaired arm mobility† Change in texture and sensitivity of breast
Modified Radical Mastectomy			
Removal of breast, preservation of pectoralis muscle. SLND and/or ALND.	Chest wall tightness, scar Phantom breast sensations Lymphedema Sensory changes Impaired range of motion	*Short-term:* Skin flap necrosis, seroma, hematoma, infection *Long-term:* Sensory loss, muscle weakness, lymphedema	Loss of breast Incision Body image Need for prosthesis Impaired arm mobility
Tissue Expansion and Breast Implants			
Expander used to slowly stretch tissue. Saline gradually injected into reservoir over weeks to months. Insertion of implant under musculofascial layer of chest wall.	Discomfort Chest wall tightness	*Short-term:* Skin flap necrosis, wound separation, seroma, hematoma, infection *Long-term:* Capsular contractions, displacement of implant	Altered body image Prolonged physician visits to expand implants Potential additional surgeries for nipple construction, symmetry
Breast Reconstruction Tissue Flap Procedures			
Transverse Rectus Abdominis Musculocutaneous (TRAM) Flap			
Musculocutaneous flap (muscle, skin, fat, blood supply) is transposed from abdomen to the mastectomy site. May be done concurrently with mastectomy.	Pain related to two surgical sites and extensive surgery	*Short-term:* Delayed wound healing, infection, skin flap necrosis, abdominal hernia, hematoma	Prolonged postoperative recovery
Deep Inferior Epigastric Artery Perforator (DIEP) Flap			
Free flap that transfers skin and fat from the abdomen to the chest. Differs from TRAM flap because no muscle is moved.	Requires more time in surgery than TRAM flap Pain related to two surgical sites	If procedure fails, tissue flap may die and have to be completely removed If tissue dies, new reconstruction may not be done for 6-12 mo	Patients may experience less pain and restriction of movement than with a TRAM flap.

*Specific to radiation therapy.
†If ALND (less likely with SLND).

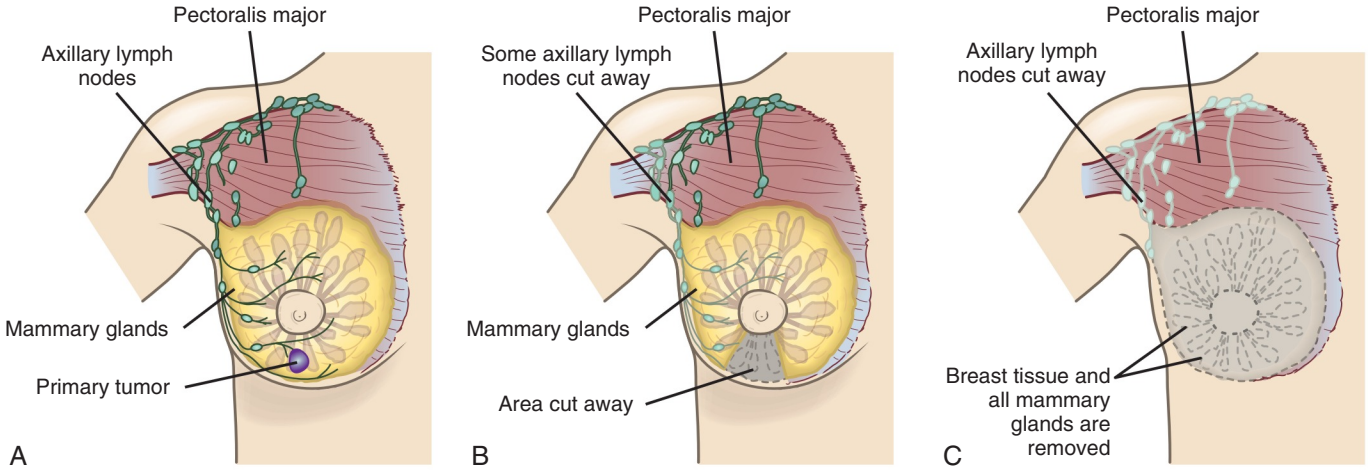

FIG. 52-6 Breast cancer surgery. **A,** Preoperative. **B,** Lumpectomy. **C,** Modified radical mastectomy.

the tumor bed. If evidence exists that the risk for recurrence is high, chemotherapy may be administered before radiation therapy. Contraindications to breast-conserving surgery include the following: breast size is too small in relation to the tumor size to yield an acceptable cosmetic result, masses and calcifications are multifocal (within the same breast quadrant), masses are multicentric (in more than one quadrant), and diffuse calcifications occur in more than one quadrant. Contraindications to radiation therapy (e.g., active lupus or prior radiation therapy in the radiation field) may make mastectomy a better surgical option.

One of the main advantages of breast-conserving surgery and radiation is that it preserves the breast, including the nipple. The goal of the combined surgery and radiation is to maximize

EVIDENCE-BASED PRACTICE

Applying the Evidence

M.S. is a 53-yr-old woman who was diagnosed with breast cancer 2 wk ago. She is recovering from a lumpectomy with negative lymph nodes. Her physician has recommended adjuvant therapy with radiation.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
The addition of radiation therapy to lumpectomy reduces the risk of local cancer recurrence.	Radiation is recommended even with negative lymph nodes after a lumpectomy. Many patients have minimal or no side effects from radiation therapy. The most common ones are fatigue, malaise, skin reactions, and ulcers or irritation of the skin.	She tells you that she is not sure if she wants to have the radiation treatment because she is afraid of the side effects.

Your Decision and Action

Review the possible side effects and how they can be managed. Then explain the risks of not taking the radiation treatment, which can include recurrence. She tells you that she will discuss it with her husband and possibly reconsider. You understand her concerns and inform the physician of her indecisiveness.

Reference for Evidence

National Cancer Institute: Breast cancer treatment: stage I, II, IIIA, and operable IIIC breast cancer. Retrieved from *www.cancer.gov/cancertopics/pdq/treatment/breast/healthprofessional/page6*.

the benefits of both cancer treatment and cosmetic outcome while minimizing risks. Disadvantages of this surgery include the increased cost of the surgery plus radiation over surgery alone and the possible side effects of radiation.

Axillary Lymph Node Dissection. Axillary lymph node dissection (ALND) on the same side as the breast cancer is often performed when breast-conserving surgery is done. A typical ALND generally involves the removal of 12 to 20 nodes. Recently, sentinel lymph node dissection (SLND) has become the standard of care, with ALND reserved for patients when clinically indicated (evidence of disease in the axilla) (see Fig. 52-5). Examination of the lymph nodes provides prognostic information and helps determine further treatment (chemotherapy, hormone therapy, or both).

Lymphedema (accumulation of lymph in soft tissue) can occur as a result of the excision or radiation of lymph nodes[24] (Fig. 52-7). When the axillary nodes cannot return lymph fluid to the central circulation, the fluid accumulates in the arm, hand, or breast, causing obstructive pressure on the veins and venous return. The patient may experience heaviness, pain, impaired motor function in the arm, and numbness and paresthesia of the fingers. Fever and a red, painful rash may also be present with infection of the affected arm. These symptoms may indicate the beginning or worsening of lymphedema. Cellulitis and progressive fibrosis of the skin can result from lymphedema. (See further discussion on lymphedema later in this chapter on p. 1254.)

Modified Radical Mastectomy. A *modified radical mastectomy* includes removal of the breast and axillary lymph nodes, but it preserves the pectoralis major muscle (Fig. 52-6, *B*). This surgery would be selected over breast-conserving surgery if the tumor were too large to excise with good margins and attain a reasonable cosmetic result. Some patients may select this surgical procedure over lumpectomy when presented with a choice.

FIG. 52-7 Lymphedema. Accumulation of fluid in the tissue after excision of lymph nodes.

When a modified radical mastectomy is performed, the patient has the option of breast reconstruction. If the patient chooses to have reconstructive surgery, it can be performed immediately after the mastectomy, or it can be delayed until postoperative recovery is complete.

Postmastectomy Pain Syndrome. *Postmastectomy pain syndrome* can occur in patients after a mastectomy or an axillary node dissection. Common symptoms include chest and upper arm pain, tingling down the arm, numbness, shooting or pricking pain, and unbearable itching that persist beyond the normal 3-month healing time. The most common theory for the onset of this syndrome is injury to intercostobrachial nerves, which are sensory nerves that exit the chest wall muscles and provide sensation to the shoulder and the upper arm.

Treatments include nonsteroidal antiinflammatory drugs, antidepressants, topical lidocaine patches, EMLA (local anesthetics: lidocaine and prilocaine), and antiseizure drugs (e.g., gabapentin [Neurontin]). Other possible treatment modalities include imagery, biofeedback, physical therapy to prevent "frozen shoulder" syndrome as a result of inadequate movement, and psychologic counseling with a therapist trained in the management of chronic pain syndromes.

Radiation Therapy. Radiation therapy is one form of *adjuvant (additional)* therapy that can be used after surgery. Radiation therapy may be used for breast cancer as treatment to (1) prevent local breast cancer recurrences after breast-conserving surgery; (2) prevent local and nodal recurrences after mastectomy; or (3) relieve pain caused by local, regional, or distant recurrence.

Primary Radiation Therapy. When radiation therapy is a primary treatment, it is usually performed after excision of the breast mass. The decision to use radiation therapy after mastectomy is based on the probability that local residual cancer cells are present. The possible presence of residual cells is related to tumor size and biology and number of involved lymph nodes.

In traditional whole breast (and regional lymph nodes in some cases) radiation treatment, the area is radiated 5 days per

week over the course of about 5 to 7 weeks. An external beam of radiation is used to deliver an approximate total dose of 45 to 50 Gy (4500 to 5000 cGy or rads). A "boost" is a dose of radiation delivered to the area in which the original tumor was located. It can be given by external beam and adds five to eight more treatments to the total number given.

Studies are examining whether whole breast radiation over 3 weeks and accelerated partial-breast radiation (radiation to area surrounding the tumor site) over 7 days are safe and effective alternatives to traditional radiation. In both these approaches, larger radiation doses are used for each treatment session.[25]

Fatigue, skin changes, and breast edema may be temporary side effects of external beam radiation therapy. Radiation of the axilla and/or supraclavicular nodes may be indicated when lymph nodes are involved to decrease the risk of axillary recurrence. Radiating a localized area will not prevent distant metastasis. Chemotherapy may be used in select cases (e.g., local recurrence after mastectomy). (Nursing management of the patient receiving radiation therapy is discussed in Chapter 16.)

Brachytherapy. *Brachytherapy* (internal radiation) is used for partial-breast radiation as an alternative to traditional external radiation treatment for early-stage breast cancer. Radiation is delivered directly into the cavity left after a tumor is surgically removed by a lumpectomy. This approach is a minimally invasive way to deliver radiation. Because the radiation is concentrated and focused on the area with the highest risk for tumor recurrence, internal radiation only requires 5 days. Traditional external radiation treatments can take 5 to 7 weeks. Internal radiation therapy is primarily delivered using a multicatheter method or balloon-catheter system.

In the *multicatheter method* (e.g., SAVI) many very small catheters are placed in the breast at the site of the tumor. The SAVI is inserted through a small incision, and the catheter bundle expands uniformly. The ends of the catheters stick out through little holes in the skin. Small radioactive seeds are placed in the catheters. The seeds are left in place just long enough to deliver the radiation dose (e.g., 5 to 10 minutes). The tiny radioactive seeds are inserted only during treatment and then removed. The radiation does not remain in the body between treatments or after the final treatment is over.

In the *balloon-catheter system,* the balloon is placed where the tumor is located. The balloon is filled with fluid to keep it in place. Radioactive seeds are inserted (Fig. 52-8). Radiation is emitted by a tiny radioactive seed attached by a wire on the way to an afterloader, a computer-controlled machine. The seed travels through the MammoSite applicator into the inflated balloon. As with the multicatheter system, the radiation does not remain in the body between treatments or after the final treatment is over. Once the final session is completed, the balloon is deflated and the system is removed.

Internal radiation may also be used as a boost therapy in conjunction with external radiation. The long-term effectiveness and safety of brachytherapy is currently under investigation.[25]

Palliative Radiation Therapy. In addition to reducing the primary tumor mass with a resultant decrease in pain, radiation therapy is also used to treat symptomatic metastatic lesions in such sites as bone, soft tissue organs, brain, and chest. Radiation therapy often relieves pain and is successful in controlling recurrent or metastatic disease.

Drug Therapy. Drug therapy, another type of adjuvant therapy, is used to destroy tumor cells that may have spread to distant sites. Drug therapy can decrease the rate of recurrence and increase the length of survival. Because of the risk for recurrent disease, nearly all women with evidence of node involvement, particularly those who are hormone receptor negative, will have some type of drug therapy. Some women, particularly those with a larger or more aggressive tumor, are known to be at higher risk for recurrent or metastatic disease. These women may be recommended for systemic therapy even when there is no evidence of node involvement. Weighing the risks and benefits of drug therapy is a complex process.

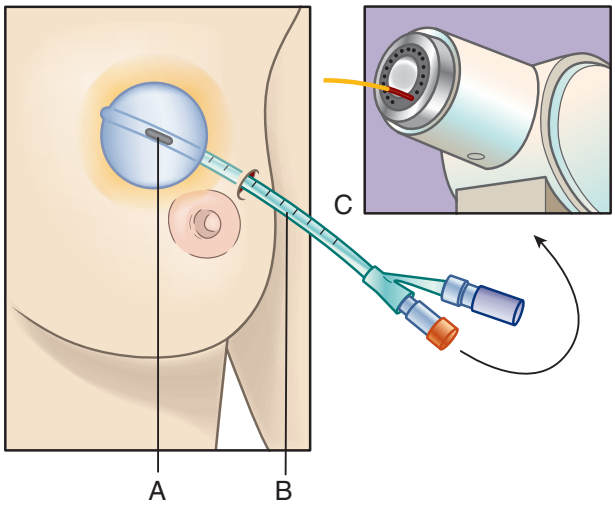

FIG. 52-8 High-dose brachytherapy for breast cancer. The MammoSite system involves the insertion of a single small balloon catheter *(B)* at the time of the lumpectomy or shortly thereafter into the tumor resection cavity (the space that is left after the surgeon removes the tumor). A tiny radioactive seed *(A)* is inserted into the balloon, connected to a machine called an afterloader *(C),* and delivers the radiation therapy.

Chemotherapy. Chemotherapy refers to the use of cytotoxic drugs to destroy cancer cells. Many breast cancers are responsive to chemotherapy. In some patients, chemotherapy is given preoperatively. Preoperative *(neoadjuvant)* chemotherapy may decrease the size of the primary tumor, with the goal of less extensive surgery.

The use of combinations of drugs is usually superior to the use of a single drug. The benefit of combination treatment results from the use of drugs that have different mechanisms of action and work at different parts of the cell cycle. The more common combination-therapy protocols are (1) CMF—cyclophosphamide (Cytoxan), methotrexate, and 5-fluorouracil (5-FU); (2) AC—doxorubicin (Adriamycin) and cyclophosphamide, with or without the addition of a taxane such as paclitaxel (Taxol) or docetaxel (Taxotere); or (3) CEF or CAF—cyclophosphamide, epirubicin (Ellence) or doxorubicin (Adriamycin), and 5-FU.

DRUG ALERT: Doxorubicin (Adriamycin)

- Monitor for signs of cardiotoxicity and heart failure (e.g., new onset of shortness of breath, pedal edema, decreased activity tolerance, dysrhythmias, ECG changes).
- Instruct patient not to have immunizations without physician's approval.
- Instruct patient to avoid contact with those who recently received live virus vaccine.

Docetaxel, capecitabine (Xeloda), ixabepilone (Ixempra), and an albumin-bound form of paclitaxel (Abraxane) are used in women whose metastatic breast cancer has not responded to

standard chemotherapy. Vinorelbine (Navelbine), used to treat metastatic breast cancer, is better tolerated with fewer and milder side effects than other chemotherapy drugs. Eribulin mesylate (Halaven), a microtubule inhibitor, may be used in treating metastatic breast cancer in patients who have received at least two prior chemotherapy regimens.[26]

Because healthy cells are also affected by chemotherapy, a variety of side effects accompany this treatment modality. The incidence and severity of common side effects are influenced by the specific drug combination, drug schedule, and dosage. The most common side effects involve rapidly dividing cells in the gastrointestinal tract (nausea, anorexia, weight loss), bone marrow (anemia), and hair follicles (alopecia [hair loss]).

Cognitive changes during and after treatment, especially with chemotherapy, have been reported in patients with cancer. This phenomenon, called *"chemobrain,"* may affect up to 83% of breast cancer survivors.[27] These changes include difficulties in concentration, memory, focus, and attention. It is not clear if chemobrain is related to specific cancer treatments or is an overall systemic reaction.[28]

Hormone Therapy. Estrogen can promote the growth of breast cancer cells if the cells are estrogen receptor positive. Hormone therapy can block the effect and source of estrogen, thus promoting tumor regression. Hormone therapy may be used as an adjuvant to primary treatment or in patients with recurrent or metastatic cancer.

Both estrogen and progesterone receptor status assays have been developed to identify women whose breast cancers are likely to respond to hormone therapy. These assays reliably predict whether hormone therapy is a treatment option. Chances of tumor regression are significantly greater in women whose tumors contain estrogen and progesterone receptors.

Hormone therapy can (1) block estrogen receptors or (2) suppress estrogen synthesis by inhibiting aromatase, an enzyme needed for estrogen synthesis (Table 52-8). Antiestrogens include tamoxifen, toremifene (Fareston), and fulvestrant (Faslodex).

Estrogen Receptor Blockers. Tamoxifen has been the hormonal agent of choice in estrogen receptor–positive women with all stages of breast cancer over the past 30 years. It is commonly used in early-stage or advanced breast cancer and to treat recurrent disease. Tamoxifen may also be used in high-risk premenopausal and postmenopausal women to prevent breast cancer. Side effects of tamoxifen may include hot flashes, mood swings, vaginal discharge and dryness, and other effects commonly associated with decreased estrogen. It also increases the risk of blood clots, cataracts, stroke, and endometrial cancer in postmenopausal women. Treatment with tamoxifen is generally prescribed for 5 years.

DRUG ALERT: Tamoxifen (Nolvadex)

- Irregular vaginal bleeding or spotting may occur.
- Decreased visual acuity, corneal opacity, and retinopathy can occur in women receiving high doses (240-320 mg/day for >17 mo). These problems may be irreversible.
- Instruct patient to immediately report decreased visual acuity.
- Monitor for signs of deep vein thrombosis, pulmonary embolism, and stroke, including shortness of breath, leg cramps, and weakness.

Toremifene is an antiestrogen agent similar to tamoxifen. It is indicated in the treatment of metastatic breast cancer in postmenopausal women. Fulvestrant may be given to women with advanced breast cancer who no longer respond to tamoxifen. Fulvestrant is given intramuscularly on a monthly basis. Common side effects include injection site pain, fatigue, hot flashes, and nausea.

TABLE 52-8 DRUG THERAPY

Breast Cancer

Drug Class	Mechanism of Action	Indications
Hormone Therapy		
Estrogen Receptor Blockers		
tamoxifen (Nolvadex)	Blocks estrogen receptors (ERs)	ER-positive breast cancer in premenopausal and postmenopausal women Used as a preventive measure in high-risk premenopausal and postmenopausal women
toremifene (Fareston)	Blocks ERs	ER-positive breast cancer in postmenopausal women only
fulvestrant (Faslodex)	Blocks ERs	ER-positive breast cancer in postmenopausal women only
Aromatase Inhibitors		
anastrozole (Arimidex) letrozole (Femara) exemestane (Aromasin)	Prevents production of estrogen by inhibiting aromatase	ER-positive breast cancer in postmenopausal women only
Estrogen Receptor Modulator		
raloxifene (Evista)	In breast blocks the effect of estrogen In bone promotes effect of estrogen and prevents bone loss	Postmenopausal women
Biologic and Targeted Therapy		
trastuzumab (Herceptin) pertuzumab (Perjeta)	Blocks HER-2 receptor	ER-positive breast cancer in postmenopausal women only
lapatinib (Tykerb)	Inhibits HER-2 tyrosine kinase and EGFR tyrosine kinase	ER-positive breast cancer in postmenopausal women only

EGFR, Epidermal growth factor receptor; *HER-2,* human epidermal growth factor receptor 2.

Aromatase Inhibitors. Aromatase inhibitor drugs interfere with the enzyme aromatase, which is needed for the synthesis of estrogen. These drugs, including anastrozole, letrozole (Femara), and exemestane (Aromasin), are used in the treatment of breast cancer in postmenopausal women. Aromatase inhibitors do not block the production of estrogen by the ovaries. Thus they are of little benefit and may be harmful in premenopausal women.

Clinical trials have demonstrated greater disease-free survival when these drugs are given after tamoxifen treatment has ended. They also appear to be more effective than tamoxifen in preventing breast cancer recurrence and possibly more effective in preventing contralateral disease (disease in the other breast).[29]

Aromatase inhibitors have different side effects than tamoxifen. They rarely cause blood clots, and they do not cause endometrial cancer. Because they block the production of estrogen in postmenopausal women, osteoporosis and bone fractures

may occur. These drugs have been associated with night sweats, nausea, arthralgias, and myalgias.

Estrogen Receptor Modulator and Others. Raloxifene (Evista) is a selective estrogen receptor modulator that produces both estrogen-agonistic effects on bone and estrogen-antagonistic effects on breast tissue. (Raloxifene is discussed in the section on osteoporosis in Chapter 64.)

Additional drugs that may be used to suppress hormone-dependent breast tumors include megestrol acetate (Megace), diethylstilbestrol (DES), and fluoxymesterone (Halotestin).

Biologic and Targeted Therapy. Trastuzumab (Herceptin) is a monoclonal antibody to HER-2. After the antibody attaches to the antigen, it is taken into the cells and eventually kills them.[20] It can be used alone or in combination with chemotherapy agents such as docetaxel or paclitaxel to treat patients whose tumors overexpress HER-2. Additional genetic testing (e.g., SPoT-Light test) may offer information on which patients are good candidates for treatment with trastuzumab.

DRUG ALERT: Trastuzumab (Herceptin)
- Use with caution in women with preexisting heart disease.
- Monitor for signs of ventricular dysfunction and heart failure.

Ado-trastuzumab emtansine (Kadcyla) is trastuzumab connected to a chemotherapy drug called DM1. This antibody-drug combination is a new kind of targeted cancer drug that can attach to certain types of cancer cells and deliver the chemotherapy directly to them.

Pertuzumab (Perjeta) is a new anti-HER-2 therapy that is used for patients who have not received prior treatment for metastatic breast cancer with an anti-HER-2 agent or chemotherapy. Pertuzumab is combined with trastuzumab and docetaxel.

Lapatinib (Tykerb) works inside the cell by blocking the function of the HER-2 protein. It may be used in combination with capecitabine for patients with advanced metastatic disease who are HER-2 positive. The combination treatment is indicated for women who have become resistant to other cancer drugs.

Advanced breast cancer in postmenopausal women who are estrogen and progesterone receptor positive and HER-2 positive may be treated with lapatinib in combination with letrozole. Everolimus (Afinitor) is used in combination with exemestane to treat postmenopausal women with advanced hormone-receptor positive, HER-2-negative breast cancer. The drug combination is intended for use in women with recurrence or progression of their cancer after treatment with letrozole or anastrozole.

Denosumab (Prolia, Xgeva), a monoclonal antibody, may be used to increase bone mass in patients at high risk of fracture from aromatase inhibitor therapy. It is also given to prevent fractures in patients with metastasis to the bone. (The use of biologic and targeted therapies is discussed in Chapter 16.)

Follow-up and Survivorship Care. After treatment for breast cancer, the patient will have ongoing survivorship care. Recommended follow-up examinations generally occur every 3 to 6 months for the first 5 years, and then annually thereafter. Survivorship care plans summarize a patient's care and care plan for ongoing surveillance.[30] In addition, advise women to perform monthly BSE and self–chest wall examination, and report any changes to their health care provider. Local recurrence of breast cancer is usually at the surgical site. The woman should have appropriate breast imaging done at regular intervals (usually 6 months to 1 year) as determined by her risk of recurrence and breast cancer history.

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

What Is the Effect of Physical Activity in Cancer Survivors?

Clinical Question

For cancer survivors (P) does physical activity (I) improve physical and psychologic outcomes (O) after primary treatment completion (T)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence
- Thirty-four RCTs of cancer survivors; 22 studies were of breast cancer survivors. Intervention was mostly aerobic exercise. Duration of physical activity ranged from 3 to 60 wk (median of 13 wk). Control groups mainly were sedentary or assigned no exercise.
- Breast cancer survivors who did physical activity had an increased ability to bench and leg press, improved quality of life, and decreased fatigue and depression.
- Overall, cancer survivors who exercised showed improved body mass index (BMI), body weight, peak oxygen consumption, distance walked in 6 min, handgrip strength, and quality of life.

Conclusion
- Physical activity has positive effects on physical and psychologic outcomes and quality of life.

Implications for Nursing Practice
- To help patients get interested in physical activity, discuss their favorite forms of exercise, hobbies, and activities.
- Help patients identify physical activity resources (e.g., walking paths, swimming pool, gym).
- Assess the patient's barriers to active participation in exercise.
- When possible, assist patient in adhering to recommended activities.

CULTURALLY COMPETENT CARE

BREAST CANCER

Differences exist in the incidence, mortality rates, and relevant care issues among diverse ethnic groups related to breast cancer (see Cultural & Ethnic Health Disparities box on the facing page). In addition, cultural differences may involve gender roles, health beliefs, religion, and family structure. Other differences may be due to dietary factors and disparities related to access to and use of CBEs and screening mammograms.

Cultural values strongly influence how women respond to and cope with breast cancer and treatment. Health beliefs and behaviors are influenced by diverse cultural norms.[31] Breast cancer screening, diagnosis, and treatment are affected by the cultural values and meanings (body image, sexuality, modesty, motherhood) attached to the breasts. Women may delay screening or treatment for varying reasons, including an acceptance of disease as inevitable fate or "God's will," a mistrust of Western medicine, lack of health care benefits, fear, modesty, or the stigma of a cancer diagnosis.

CULTURAL & ETHNIC HEALTH DISPARITIES

Breast Cancer

- White women have a higher incidence of breast cancer than other ethnic groups.
- African American women have lower survival rates from breast cancer than white women, even when diagnosed at an early stage.
- Triple-negative breast cancer (negative for estrogen, progesterone, and HER-2 receptors) has a higher incidence in Hispanic and African American women.
- Breast cancer incidence and mortality rates are lower among Hispanic and Asian/Pacific Islander women than among white and African American women.
- Breast cancer is the most commonly diagnosed cancer among Hispanic women.
- Hispanic women, especially Mexican Americans, have the lowest rate of cancer screening of any ethnic group.
- Hispanic and African American women are more likely to be diagnosed at a later stage of breast cancer than white women.

HER-2, Human epidermal growth factor receptor 2.

NURSING MANAGEMENT BREAST CANCER

NURSING ASSESSMENT

Many factors need to be considered when you assess a patient with a breast problem. The history of the breast disorder assists in establishing the diagnosis. Investigate the presence of nipple discharge, pain, rate of growth of the lump, breast asymmetry, and correlation with the menstrual cycle.

Carefully document the size and location of the lump or lumps. Assess the physical characteristics of the lesion, such as consistency, mobility, and shape. If nipple discharge is present, note the color and consistency and whether it occurs from one or both breasts.

Subjective and objective data that should be obtained from an individual suspected of having or diagnosed with breast cancer are presented in Table 52-9.

NURSING DIAGNOSES

Nursing diagnoses related to the care of a patient diagnosed with breast cancer vary. After diagnosis and before a treatment plan has been selected, the following nursing diagnoses would apply:

- Decisional conflict *related to* lack of knowledge about treatment options and their effects
- Fear and/or anxiety *related to* diagnosis of breast cancer
- Disturbed body image *related to* physical and emotional effects of treatment modalities

If a mastectomy or lumpectomy is planned, the nursing diagnoses may include, but are not limited to, those presented in eNursing Care Plan 52-1 (available on the website for this chapter).

PLANNING

The overall goals are that the patient with breast cancer will (1) actively participate in the decision-making process related to treatment, (2) adhere to the therapeutic plan, (3) communicate about and manage the side effects of adjuvant therapy, and (4) access and benefit from the support provided by significant others and health care providers.

TABLE 52-9 NURSING ASSESSMENT

Breast Cancer

Subjective Data

Important Health Information

Past health history: Benign breast disease with atypical changes; previous unilateral breast cancer; menstrual history (early menarche with late menopause); pregnancy history (nulliparity or first full-term pregnancy after age 30); previous endometrial, ovarian, or colon cancer; hyperestrogenism and testicular atrophy (in men)

Medications: Hormones, especially as postmenopausal hormone therapy and in oral contraceptives, infertility treatments

Surgery or other treatments: Exposure to therapeutic radiation (e.g., Hodgkin's lymphoma or thyroid radiation)

Functional Health Patterns

Health perception–health management: Family history of breast cancer (especially mother or sister, young age at diagnosis); history of abnormal mammogram or atypical prior biopsy; palpable change found on BSE; frequent alcohol use

Nutritional-metabolic: Obesity; unexplained severe weight loss (possible indicator of metastasis)

Cognitive-perceptual: Changes in cognition, headache, bone pain (possible indicators of metastasis)

Sexuality-reproductive: Unilateral nipple discharge (clear, milky, or bloody); change in breast contour, size, or symmetry

Coping–stress tolerance: Psychologic stress

Self-perception–self-concept: Anxiety regarding threat to self-esteem

Physical activity: Level of usual activity

Objective Data

General

Axillary and supraclavicular lymphadenopathy

Integumentary

Hard, irregular, nonmobile breast lump most often in upper, outer sector, possibly fixated to fascia or chest wall; thickening of breast; nipple inversion or retraction, erosion; edema ("peau d'orange"), erythema, induration, infiltration, or dimpling (in later stages); firm, discrete nodules at mastectomy site (possible indicator of local recurrence); peripheral edema (possible indicator of metastasis)

Respiratory

Pleural effusions (possible indicator of metastasis)

Gastrointestinal

Hepatomegaly, jaundice; ascites (possible indicators of liver metastasis)

Possible Diagnostic Findings

Finding of mass or change in tissue on breast examination; abnormal mammogram, ultrasound, or breast MRI; positive results of FNA or surgical biopsy or similar results with a needle biopsy

BSE, Breast self-examination; *FNA,* fine-needle aspiration.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Review the risk factors in Table 52-2. A person can reduce her risk factors by maintaining a healthy weight, exercising regularly, limiting alcohol, eating nutritious food, and never smoking (or quitting if she does smoke).

It is important for you to encourage people to adhere to the breast cancer screening guidelines presented on pp. 1238-1239. If a person is at high risk, she needs to develop an individualized plan with the health care provider. Early detection can decrease the morbidity and mortality associated with breast cancer.

Along with these lifestyle choices, there are other risk-reduction options for women at high risk. Genetic testing for *BRCA* gene mutations is available. People with a strong family

history of breast cancer should talk with their health care provider about the possibility of genetic testing. Routine screening for genetic abnormalities in women without evidence of a strong family history of breast cancer is not warranted.

In women with an abnormal *BRCA1* or *BRCA2* gene, prophylactic oophorectomy may reduce their risk of developing breast cancer. In deciding whether and when to undergo this surgical procedure, women should receive counseling about the risks and benefits of prophylactic oophorectomy, including fertility issues.

Prophylactic surgery decisions require a great deal of thought, patience, and discussion with the health care provider, genetic counselor, and family. Patients need to consider these options and make decisions with which they feel comfortable. Removing both breasts and ovaries at a young age does not eliminate the risk of breast cancer. A small risk exists that cancer can develop in the areas where the breasts used to be. Close follow-up is necessary, even after prophylactic surgery.

ACUTE INTERVENTION. The times of waiting for the initial biopsy results and waiting for the care provider to make treatment recommendations are difficult for the woman and her family.[32] Even after the health care provider has discussed treatment options, the woman often relies on you to clarify and expand on these options. During this stressful time, the woman may not be coping effectively. Appropriate nursing interventions are to explore the woman's usual decision-making processes, help her evaluate the advantages and disadvantages of the options, provide information relevant to the decision, clarify unresolved issues with the health care provider, and support the patient and family once the decision is made.

Regardless of the surgery planned, provide the patient with sufficient information to ensure informed consent. Some patients seek extensive, detailed information to maintain a sense of control, whereas others avoid information to decrease anxiety and fear. Be sensitive to the individual's need for and preferred type of information. These include (1) preoperative instructions on pain control and what to expect after surgery (e.g., reporting of complications, dressing and drain care, turning, coughing, deep breathing); (2) a review of mobility restrictions and postoperative exercises; and (3) explanation of the recovery period from the time of surgery until the first postoperative visit.

The woman who has breast-conserving surgery usually has an uncomplicated postoperative course with variable pain intensity. Pain primarily depends on the extent of the lymph node dissection performed. If an ALND has been done or if a woman had a mastectomy, drains are generally left in place and patients are discharged home with them. Teach the patient and the family, with a return demonstration, how to manage the drains at home.

Restoring arm function on the affected side after mastectomy and ALND is a key nursing goal. In the hospital, place the woman in a semi-Fowler's position with the arm on the affected side elevated on a pillow. Flexing and extending the fingers should begin in the recovery room with progressive increases in activity encouraged. Postoperative arm and shoulder exercises are instituted gradually (Fig. 52-9). These exercises are designed to prevent contractures and muscle shortening, maintain muscle tone, and improve lymph and blood circulation. The difficulty and pain encountered in performing what used to be simple tasks included in the exercise program may cause frustration and depression. The goal of all exercise is a gradual return to full range of motion within 4 to 6 weeks.

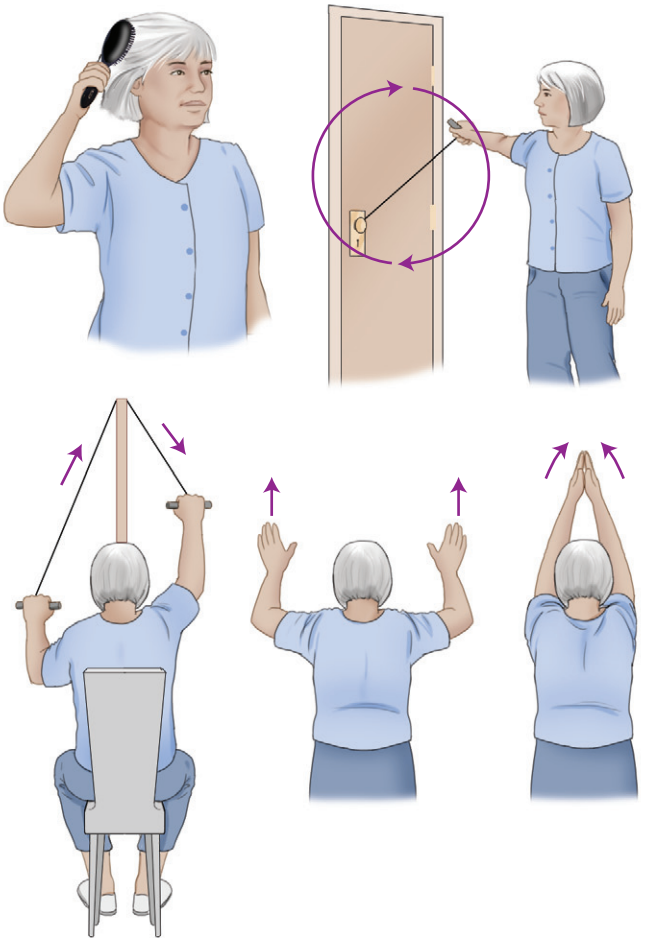

FIG. 52-9 Postoperative exercises for the patient with a mastectomy or lumpectomy with axillary lymph node dissection.

Postoperative discomfort can be minimized by administering analgesics regularly when the patient is in pain and about 30 minutes before initiating exercises. When the patient is able to shower, the warm water on the involved shoulder often relaxes the muscle and reduces joint stiffness. Application of ice, except where contraindicated with plastic surgery procedures, can reduce swelling, inflammation, and pain.

The incidence of arm lymphedema ranges from 2% to 65%, and it can develop 1 to 5 years after surgery.[33] Women who are overweight or obese have a higher risk of developing lymphedema. Teach the woman measures to prevent and reduce lymphedema, including no blood pressure readings, venipunctures, or injections on the affected arm. The affected arm should not be dependent for long periods, and caution should be used to prevent infection, burns, or compromised circulation on the affected side.

If trauma to the arm occurs, the area should be washed thoroughly with soap and water and observed. A topical antibiotic ointment and a bandage or other sterile dressing may be applied.

When the patient's lymphedema is acute (see Fig. 52-7), complete decongestive therapy may be recommended. This therapy consists of a massage-like technique to mobilize the subcutaneous accumulation of fluid. This may then be followed by use of compression bandaging and an intermittent pneumatic compression sleeve. The sleeve applies mechanical massage to the arm and facilitates lymph drainage up toward

the heart. Elevation of the arm so that it is level with the heart, diuretics, and isometric exercises may be used to reduce the fluid volume in the arm. To maintain maximum volume reduction, the patient may need to wear a fitted compression sleeve during waking hours and preventively during air travel.

Emotional and Psychologic Care. Throughout history, the female breast has been regarded as a symbol of beauty, femininity, sexuality, and motherhood. The potential loss of a breast, or part of a breast, may be devastating for many women because of the significant psychologic, social, sexual, and body image implications associated with it.

From the time of diagnosis through treatment, survivorship, or metastatic disease, the woman may exhibit signs of distress or tension (e.g., tachycardia, increased muscle tension, sleep disturbances, restlessness, changes in appetite or mood). Assess the woman's body language and affect during periods of high stress and indecision so that appropriate interventions, including referral to a mental health provider, can be initiated.

Remain sensitive to the complex psychologic impact that a diagnosis of cancer and subsequent breast surgery can have on a woman and her family. A relationship in which the woman can express her feelings is therapeutic. With an accepting attitude and the offer of resources, you can help with the feelings of fear, anger, anxiety, and depression. Help to meet the woman's psychologic needs by

- Providing a safe environment for the expression of the full range of feelings.
- Helping her identify sources of support and strength, such as her partner, family, and spiritual or religious practices.
- Encouraging her to identify and learn individual coping strengths.
- Promoting communication between the patient and her family or friends.
- Providing accurate and complete answers to questions about her disease; treatment options; and reproductive, fertility, or lactation issues (if appropriate).
- Making resources available for mental health counseling.
- Offering information about local and national community resources. Referring her to peer support resources, such as Reach to Recovery or local breast cancer organizations, is invaluable. The Reach to Recovery program of the American Cancer Society is a rehabilitation program to help meet the psychologic, physical, and cosmetic needs of women who have had breast surgery. The American Cancer Society and the National Cancer Institute can provide excellent materials to assist you in meeting the special needs of women with breast cancer.

AMBULATORY AND HOME CARE. Explain the specific follow-up plan to the patient and emphasize the importance of ongoing monitoring and self-care. Immediately after surgery, advise the patient to report to the health care provider symptoms such as fever, inflammation at the surgical site, erythema, postoperative constipation, and unusual swelling. Other changes to report are new back pain, weakness, shortness of breath, and change in mental status, including confusion.

For women who have had a mastectomy without breast reconstruction, a variety of products are available. These include garments such as camisoles with soft breast prosthetic inserts or a fitted prosthesis with bra. Should the woman choose a breast prosthesis, a certified fitter can help her select a comfortable, more permanent weighted prosthesis and bra, generally at 4 to 8 weeks postoperatively. Your role is to present the choices and resources without judgment.

How the loss of part or all of the breast and cancer affect the woman's sexual identity, body image, and relationships can vary. If you are comfortable, initiate a discussion of sexuality by inviting questions about relationships or intimacy concerns. Often the husband, sexual partner, or family members need help dealing with their emotional reactions to the diagnosis and surgery before they can provide effective support for the patient. There are no physical reasons why a mastectomy would prevent sexual satisfaction. The woman taking hormone therapy may have a decreased sexual drive or vaginal dryness. She may need to use lubrication to prevent discomfort during intercourse. Concerns about sexuality are not well addressed by many health care providers.[34] If difficulty in adjustment or other problems develop, counseling may be necessary to deal with the emotional component of a mastectomy and the diagnosis of cancer.

Depression and anxiety may occur with the continued stress and uncertainty of a cancer diagnosis. A woman's self-esteem and identity may also be threatened. The support of family and friends and participation in a cancer support group are important aspects of care that may improve the patient's quality of life.

COMPLEMENTARY & ALTERNATIVE THERAPIES

Imagery

Imagery is the use of one's mind to generate images that have a calming effect on the body

Scientific Evidence*

- Good evidence for decreasing cancer pain and postoperative pain.
- Good evidence for treatment of migraine or tension headache in conjunction with standard medical care.

Nursing Implications

- Used by nurses to help patients promote relaxation, decrease stress, and manage pain.
- Should be used as a supplemental technique, not a replacement for medical care.

*Based on a systematic review of scientific literature. Retrieved from *www.naturalstandard.com*.

EVALUATION

The expected outcomes for the patient after a mastectomy or lumpectomy are presented in eNursing Care Plan 52-1 (available on the website for this chapter).

GERONTOLOGIC CONSIDERATIONS

BREAST CANCER

A major risk for breast cancer is increasing age, and more than half of all breast cancers are diagnosed in women who are age 65 or older. Older women are less likely to have mammograms. Screening and treatment decisions for breast cancer should be based on a woman's general health status rather than biologic age, since health status has a greater influence on tolerance to treatment and long-term prognosis. In addition to medical co-morbidities and life expectancy, treatment decisions for the older woman with breast cancer should be based on an assessment of nutritional and functional status; vision, gait, and balance; and the presence of delirium, dementia, or depression.

Breast cancer treatment is similar for older and younger patients, including the use of surgery, radiation therapy, and

drug therapy. For healthy older women, breast cancer survival rates are similar to those of younger women when matched by cancer stage.

MAMMOPLASTY

Mammoplasty is the surgical change in the size or shape of the breast. It may be done electively for cosmetic purposes to either enlarge or reduce the size of the breasts. It may also be done to reconstruct the breast after a mastectomy.

A professional, nonjudgmental attitude and clear information about surgical breast options is most useful for women engaged in decision making about mammoplasty. The desire to change the appearance of the breasts has special significance for each woman as she attempts to alter or recreate her body image. Be aware of the cultural value the woman places on the breast. Help the patient set realistic expectations about what mammoplasty can accomplish and about possible complications (e.g., hematoma formation, hemorrhage, infection). If an implant is involved, capsular contracture and loss of the implant are possible.

Breast Reconstruction

Breast reconstructive surgery is done to achieve symmetry and to restore or preserve body image. It may be done simultaneously with a mastectomy or some time afterward. The timing of reconstructive surgery is individualized based on the patient's physical and psychologic needs. Breast reconstruction is also safe and effective for older women.[35]

Indications. The main indication for breast reconstruction is to improve a woman's self-image, regain a sense of normalcy, and assist in coping with the loss of the breast. Current reconstruction techniques cannot restore lactation, nipple sensation, or erectility. Although the breast will not fully resemble its premastectomy appearance, the reconstructed appearance usually represents an improvement over the mastectomy scar (Fig. 52-10). The contour of the breast is restored without the use of an external prosthesis.

Types of Reconstruction

Breast Implants and Tissue Expansion. A tissue expander can be used to stretch the skin and the muscle at the mastectomy site before inserting permanent implants (Fig. 52-11). The use of tissue expanders and breast implants is the most common breast reconstruction technique currently used. Placement of the expander may be immediate or delayed. The tissue expander is placed in a pocket under the pectoralis muscle, which protects the implant and provides soft tissue coverage. The tissue expander is minimally inflated and then gradually filled by weekly injections of sterile water or saline solution. This procedure stretches the skin and muscle and can be painful. A small magnet is embedded in most expanders to help locate the port where the fluid is injected. Therefore a woman should not have an MRI with a magnet in place. In a second procedure, the expander is surgically removed and a permanent implant is inserted. Some expanders are designed to remain in place and become the implant, eliminating the need for a second surgical procedure. Tissue expansion does not work well in individuals with extensive scar tissue from surgery or radiation therapy.

The body's natural response to the presence of a foreign substance is the formation of a fibrous capsule around the implant. If excessive capsular formation occurs as a result of infection, hematoma, trauma, or reaction to a foreign body, a

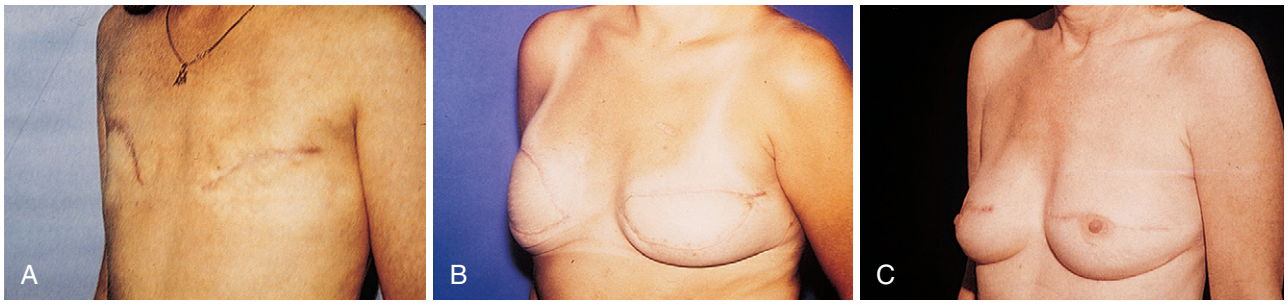

FIG. 52-10 **A,** Appearance of chest after bilateral mastectomy. **B,** Postoperative breast reconstruction before nipple-areolar reconstruction. **C,** Postoperative breast reconstruction after nipple-areolar reconstruction.

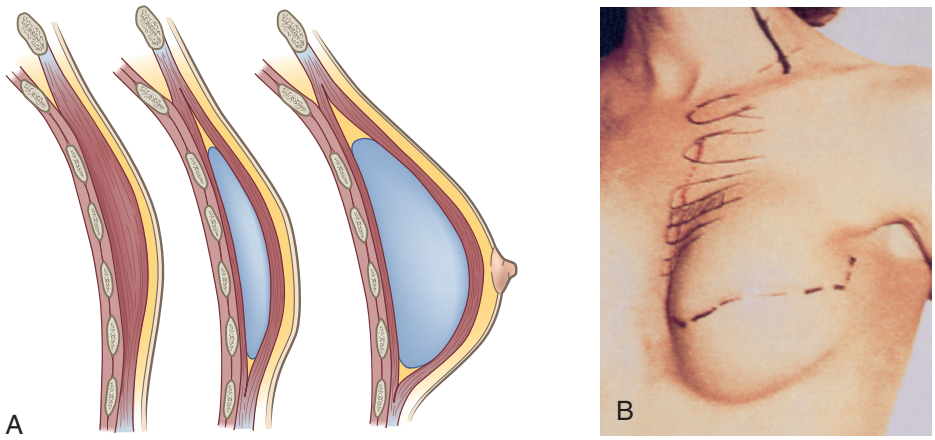

FIG. 52-11 **A,** Tissue expander with gradual expansion. **B,** Tissue expander in place after mastectomy.

contracture can develop, resulting in deformity. Although surgeons differ in their approaches to the prevention of contracture formation, gentle manual massage around the implant is routine. Other adverse outcomes include wrinkling, scarring, asymmetry, pain, and infection at the incision site.[36]

Tissue Flap Procedures. Another choice for breast reconstruction is the use of autologous tissue to recreate a breast mound. If insufficient muscle is left after mastectomy or if the chest wall has been radiated, the person's own tissue may be used to repair the soft tissue defects. Musculocutaneous flaps are most often taken from the back (latissimus dorsi muscle) or the abdomen (transverse rectus abdominis muscle). In the latissimus dorsi musculocutaneous flap, a block of skin and muscle from the patient's back is used to replace tissue removed during mastectomy. A small implant may be needed beneath the flap to gain reasonable breast shape and size. A disadvantage of this technique is an additional scar on the back.

The *transverse rectus abdominis musculocutaneous (TRAM) flap* is a frequently used flap operation. The rectus abdominis muscles are paired flat muscles running from the rib cage down to the pubic bone. Arteries running inside the muscles provide branches at many levels, and these branches supply the fat and skin across a large expanse of the abdomen. With this technique, the surgeon elevates a large block of tissue from the lower abdominal area, but leaves it attached to the rectus muscle (Fig. 52-12). This tissue is then tunneled or placed as "free flaps" under the skin up to the area where the breast will be reconstructed. Then it is molded and fashioned to form a breast. The abdominal incision is closed, giving the patient a result that is similar to having an abdominoplasty ("tummy tuck"). This surgical procedure can last 6 to 8 hours with recovery taking 6 to 8 weeks. Some patients have reported pain and fatigue for up to 3 months. Complications include bleeding, seroma, hernia, infection, and low back pain. An implant may be used in addition to the flap if the flap does not provide the desired cosmetic result alone.

A *deep inferior epigastric artery perforator (DIEP) flap* is a version of the free flap that does not use muscle tissue. With the DIEP flap, only the skin and fat are taken from the same lower abdominal area as the TRAM flap. Patients may experience less pain and restriction of movement with this procedure.

Total skin-sparing mastectomy is the preservation of the skin of the nipple and areola with the removal of underlying breast tissue. It can be done at the same time as immediate breast reconstructive surgery.

Nipple-Areolar Reconstruction. Many patients undergoing breast reconstruction also have nipple-areolar reconstruction. Nipple reconstruction gives the reconstructed breast a much more natural appearance (Fig. 52-10, *C*). Nipple-areolar reconstruction is usually done a few months after breast reconstruction. Tissue to construct a nipple may be taken from the opposite breast or from a small flap of tissue on the reconstructed breast mound. The areola may be grafted from the labia, skin in the area of the groin, or lower abdominal skin, or it may be tattooed with a permanent pigmented dye. In some patients, a small implant may be placed under the completed nipple-areolar reconstruction to add additional projection.

Breast Augmentation

In augmentation mammoplasty (the procedure to enlarge the breasts), an implant is placed in a surgically created pocket between the capsule of the breast and the pectoral fascia, or ideally under the pectoralis muscle. Most implants are silicone envelopes filled with a fluid such as dextran, saline, or silicone. Implants filled with silicone gel most closely resemble the human breast. The U.S. Food and Drug Administration (FDA) has approved the use of silicone gel implants for breast augmentation and reconstruction.[36] Studies continue to collect data on the safety and effectiveness of these implants.

Saline-filled implants are often used in the United States. The silicone shells are filled with normal saline. This implant has an outer shell of silicone that is filled with highly refined soybean oil.

Breast Reduction

For some women, large breasts can be a source of physical and psychologic discomfort. They can interfere with normal daily activities such as walking, using a computer, and driving a car. The weight of large breasts can lead to back, shoulder, and neck problems, including degenerative nerve changes. Overly large breasts can interfere with self-esteem, self-image, and comfort in wearing some clothing. Reduction in the size of the breasts

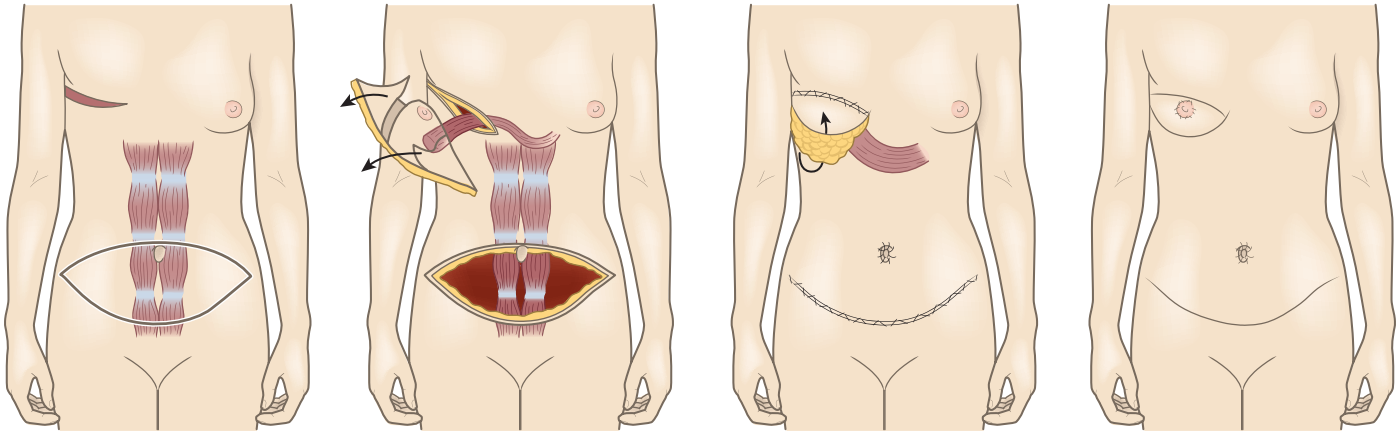

FIG. 52-12 Transverse rectus abdominis musculocutaneous (TRAM) flap. **A,** TRAM flap is planned. **B,** The abdominal tissue, while attached to the rectus muscle, nerve, and blood supply, is tunneled through the abdomen to the chest. **C,** The flap is trimmed to shape the breast. The lower abdominal incision is closed. **D,** Nipple and areola are reconstructed after the breast is healed.

CASE STUDY

Breast Cancer

iStockphoto/Thinkstock

Patient Profile

A.K., a 68-year-old married Asian American woman, has been diagnosed with breast cancer (see Chapter 51 case study on p. 1226). She is scheduled for surgery in the morning for a lumpectomy and sentinel lymph node dissection with possible axillary dissection.

Collaborative Care

Preoperative

- When she is seen in the preoperative clinic 1 week before surgery, she is crying uncontrollably and says, "My husband does not want to look at me anymore. He is afraid of what I am going to look like with a flat chest."
- She says, "I cannot sleep and I just pace the floor at night."
- Expresses concern that her two daughters (34 and 32) and their daughters are going to get "this horrible disease."

Operative Procedure

- A lumpectomy and sentinel lymph node dissection are performed.
- A.K. has cancer cells in her sentinel lymph node.
- Axillary node dissection is then done involving the removal of 12 to 20 nodes.

Postoperative

- Does not want to leave hospital. She wants to stay in bed.
- Fever with swelling and restricted range of motion in right arm.
- Pain not controlled well with pain medication.

Follow-up Findings and Treatment

- Two positive lymph nodes are found.
- Scheduled for outpatient chemotherapy followed by external beam radiation.

Discussion Questions

1. What in A.K.'s breast cancer experience with her family members (see assessment case study in Chapter 51 on p. 1229) might influence her coping response?
2. What information would you provide to A.K. about her surgery?
3. What complication did she develop after her surgery?
4. Which common postoperative exercises will A.K. need to practice after her surgery?
5. ***Delegation Decision:*** Which of the following personnel should provide this instruction to A.K.: registered nurse, licensed practical/vocational nurse, unlicensed assistive personnel?
6. What community resources are available to help A.K. and her family adjust to the change in her body and to cope with the diagnosis of cancer? How can you access these resources?
7. What information is important for you to provide to A.K. about her radiation treatment and chemotherapy?
8. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
9. What information is important for you to provide to A.K. and her daughters? What early detection measures are important for them to know?
10. ***Evidence-Based Practice:*** A.K. wants to know what the psychologic benefit may be for her daughters if they decide on a breast cancer genetic risk assessment.

evolve Answers and a corresponding concept map available at *http://evolve.elsevier.com/Lewis/medsurg*.

can have positive effects on the patient's psychologic and physical health.

Reduction mammoplasty is performed by resecting wedges of tissue from the upper and lower quadrants of the breast. The excess skin is removed, and the areola and nipple are relocated on the breast. Lactation can usually be accomplished if massive amounts of tissue are not removed and the nipples are left connected during surgery.

NURSING MANAGEMENT
BREAST AUGMENTATION AND REDUCTION

Breast augmentation and breast reduction may be done in the outpatient surgical area, or they may involve overnight hospitalization. General anesthesia is used. Drains are generally placed in the surgical site to prevent hematoma formation and then removed 2 or 3 days after surgery or when drainage is under 20 to 30 mL/day. The drainage must be examined for color and odor to detect postoperative infection or hemorrhage. Also monitor the woman's temperature. Dressings should be changed as necessary using sterile technique. After surgery, assure the woman that the breast's appearance will improve when healing is completed. Depending on physician preference, the patient may be instructed to wear a bra that provides good support continuously for 2 or 3 days after breast reduction or augmentation. Depending on the extent of the operation, most women resume normal activities within 2 to 3 weeks. Strenuous exercise may not be appropriate until several weeks later.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. You are a community health nurse planning a program on breast cancer screening guidelines for women in the neighborhood. To best promote the participants' learning and adherence, you would include *(select all that apply)*
   - **a.** a short audiotape on the BSE procedure.
   - **b.** a packet of articles from the medical literature.
   - **c.** written guidelines for mammography and CBE.
   - **d.** a discussion of the value of early breast cancer detection.
   - **e.** community resources where they can obtain an ultrasound and MRI.
2. In teaching a patient who wants to perform BSE, you inform her that the technique involves both the palpation of the breast tissue and
   - **a.** palpation of cervical lymph nodes.
   - **b.** hard squeezing of the breast tissue.
   - **c.** a mammogram to evaluate breast tissue.
   - **d.** inspection of the breasts for any changes.

3. You are caring for a young woman who has painful fibrocystic breast changes. Management of this patient would include
   a. scheduling a biopsy to rule out malignant changes.
   b. teaching that symptoms will probably subside if she stops using oral contraceptives.
   c. preparing her for surgical removal of the lumps, since they will become larger and more painful.
   d. explaining that restrictions of coffee and chocolate and supplements of vitamin E may relieve some discomfort.
4. When discussing risk factors for breast cancer with a group of women, you emphasize that the greatest known risk factor for breast cancer is
   a. being a woman over age 60.
   b. experiencing menstruation for 30 years or more.
   c. using hormone therapy for 5 years for menopausal symptoms.
   d. having a paternal grandmother with postmenopausal breast cancer.
5. A patient with breast cancer has a lumpectomy with sentinel lymph node dissection that is positive for cancer. You explain that, of the other tests done to determine the risk for cancer recurrence or spread, the results that support the more favorable prognosis are *(select all that apply)*
   a. well-differentiated tumor.
   b. estrogen receptor–positive tumor.
   c. overexpression of HER-2 cell marker.
   d. involvement of two to four axillary nodes.
   e. aneuploidy status from cell proliferation studies.
6. A modified radical mastectomy has been scheduled for your patient with breast cancer. Postoperatively, to restore arm function on the affected side, you would
   a. apply heating pads or blankets to increase circulation.
   b. place daily ice packs to minimize the risk of lymphedema.
   c. teach passive exercises with the affected arm in a dependent position.
   d. emphasize regular exercises for the affected shoulder to increase range of motion.
7. Preoperatively, to meet the psychologic needs of a woman scheduled for a modified radical mastectomy, you would
   a. discuss the limitations of breast reconstruction.
   b. include her significant other in all conversations.
   c. promote an environment for expression of feelings.
   d. explain the importance of regular follow-up screening.
8. To prevent capsular formation after breast reconstruction with implants, teach the patient to
   a. gently massage the area around the implant.
   b. bind the breasts tightly with elastic bandages.
   c. exercise the arm on the affected side to promote drainage.
   d. avoid strenuous exercise until the implant has healed.

1. c, d, 2. d, 3. d, 4. a, 5. a, b, 6. d, 7. c, 8. a

LEARNING OUTCOMES

1. Assess the factors contributing to the high incidence of sexually transmitted infections (STIs).
2. Describe the etiology, clinical manifestations, complications, and diagnostic abnormalities of gonorrhea, syphilis, chlamydial infections, genital herpes, and genital warts.
3. Compare and contrast primary genital herpes with recurrent genital herpes.
4. Explain the collaborative care and drug therapy of gonorrhea, syphilis, chlamydial infections, genital herpes, and genital warts.
5. Integrate the nursing assessment and nursing diagnoses for patients who have an STI.
6. Summarize the nursing role in the prevention and control of STIs.
7. Describe the nursing management of patients with STIs.

KEY TERMS

chancre, Table 53-3, p. 1265
chlamydial infections, p. 1266
genital herpes, p. 1267
genital warts, p. 1269
gonorrhea, p. 1262
sexually transmitted infections (STIs), p. 1261
syphilis, p. 1264

Sexually transmitted infections (STIs) are infectious diseases that are commonly acquired through sexual contact (Table 53-1). They may also be contracted by other routes such as through blood, blood products, perinatal transmission, and autoinoculation. STI is becoming the more common term used for sexually transmitted disease.

Most infections start as lesions on the genitalia and other sexually exposed mucous membranes. Wide dissemination to other areas of the body can then occur. A latent or subclinical phase is present with all STIs. This can lead to a long-term persistent infection and the transmission of disease from an asymptomatic (but infected) person to another person. Having one STI increases the risk of acquiring another. A person can have different STIs at the same time.

In the United States all cases of gonorrhea and syphilis, and in most states chlamydial infection, must be reported to the state or local public health authorities for purposes of surveillance and partner notification. In spite of this requirement, many cases of these infections go unreported. An estimated 65 million Americans are currently infected with one or more STI. Every year an additional 19 million Americans are newly infected with an STI. About 50% of these new cases are in persons 15 to 24 years old.[1]

The most commonly diagnosed STIs are discussed in this chapter. Human immunodeficiency virus (HIV) infection is discussed in Chapter 15. Hepatitis B and C infections are discussed in Chapter 44.

Factors Affecting Incidence of Sexually Transmitted Infections

Many factors contribute to the current STI rates. Earlier reproductive maturity and increased longevity have resulted in a longer sexual life span. The increase in the total population has resulted in an increase in the number of susceptible hosts. Other factors include greater sexual freedom, lack of barrier methods (e.g., condoms) during sexual activity, and the media's increased emphasis on sexuality. Substance abuse contributes to unsafe sexual practices. In addition, increased

Hepatitis B and C	Hepatitis B and C viruses (see Chapter 44)
Encephalitis, esophagitis, retinitis, pneumonitis in immunocompromised patients	Cytomegalovirus (CMV)

leisure time, more national and international travel, and urbanization have brought together people with varying social behaviors and value systems.

Changes in the methods of contraception are also reflected in the incidence of STIs. The condom is considered to be the best form of protection (other than abstinence) against STIs. Although condom use has increased, condoms are still not used frequently in the general population.[2] Commonly used oral contraceptives cause the secretions of the cervix and the vagina to become more alkaline. This change produces a more favorable environment for the growth of organisms that cause STIs at these sites. Women who take oral contraceptives may have a lower risk of pelvic inflammatory disease (PID) as a result of the ability of the cervical mucus to act as a barrier against bacteria. However, the proliferation of *Chlamydia* organisms, the leading cause of nongonococcal PID, may be enhanced by oral contraceptive use.

Whether or not intrauterine device (IUD) users are at increased risk of PID is controversial, but it is clear that IUDs confer no protection against STIs. Long-acting contraceptives such as medroxyprogesterone (Depo-Provera) also offer no protection against STIs. Although these methods do not prevent transmission from partner to partner, they do prevent pregnancy and, therefore, transmission of the infection to the fetus.

BACTERIAL INFECTIONS

GONORRHEA

Gonorrhea is the second most frequently reported STI in the United States (chlamydial infections are the most common). In 2009 the gonorrhea rates were the lowest since recording of rates began. Since that time gonorrhea rates have increased slightly. A total of 309,341 cases of gonorrhea have been reported in the United States.[3] Gonorrhea rates are highest in adolescents of all racial and ethnic groups and among African Americans. Most states have enacted laws that permit examination and treatment of minors without parental consent.

CULTURAL & ETHNIC HEALTH DISPARITIES

Sexually Transmitted Infections

- *Chlamydial infection:* African Americans are 48% of cases.
- *Syphilis:* African Americans are 46% of cases, a rate 60 times higher than that of whites.
- *HSV-2:* More common in African Americans (46%) than whites (18%).
- *Gonorrhea:* African Americans are 77% of reported cases.
- *All STIs:* Hispanics have four times higher rate than whites.

HSV-2, Herpes simplex virus type 2.

Etiology and Pathophysiology

Gonorrhea is caused by *Neisseria gonorrhoeae,* a gram-negative diplococcus. The infection is spread by direct physical contact with an infected host, usually during sexual activity (vaginal, oral, or anal). Mucosal tissues in the genitalia (urethra in men, cervix in women), rectum, and oropharynx are especially sensitive to gonococcal infection. The delicate gonococcus is easily killed by drying, heating, or washing with an antiseptic solution. Consequently, indirect transmission by instruments or linens is rare.

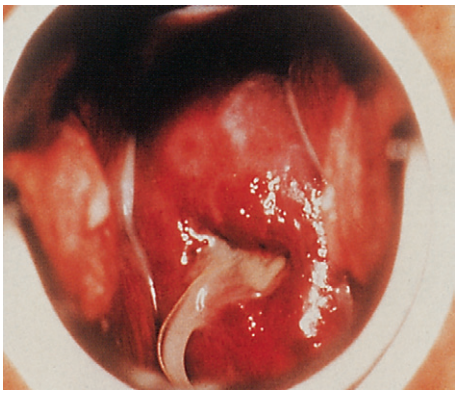
The incubation period is 3 to 8 days. The infection confers no immunity to subsequent reinfection. Gonococcal infection elicits an inflammatory response, which, if left untreated, leads to the formation of fibrous tissue and adhesions. This fibrous scarring is responsible for many complications in women such as strictures and tubal abnormalities, which can lead to tubal pregnancy, chronic pelvic pain, and infertility.

Clinical Manifestations

Men. The initial site of infection in men is usually the urethra. Symptoms of urethritis consist of dysuria and profuse, purulent urethral discharge developing 2 to 5 days after infection (Fig. 53-1). Painful or swollen testicles may also occur. Men generally seek medical evaluation early in the infection because their symptoms are usually obvious and distressing. It is unusual for men with gonorrhea to be asymptomatic.[4]

Women. Many women who contract gonorrhea are asymptomatic or have minor symptoms that are often overlooked, making it possible for them to remain a source of infection. A few women may complain of vaginal discharge, dysuria, or frequency of urination. Changes in menstruation may be a symptom, but the women often disregard these changes. After the incubation period, redness and swelling occur at the site of

FIG. 53-1 Profuse, purulent drainage in a patient with gonorrhea.



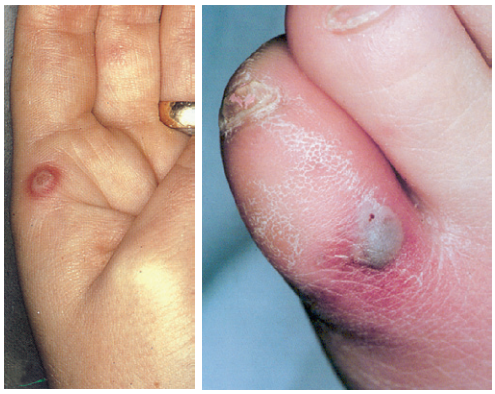


FIG. 53-2 Endocervical gonorrhea. Cervical redness and edema with discharge.

A B

contact, which is usually the cervix or urethra (Fig. 53-2). A greenish yellow purulent exudate often develops with a potential for abscess formation. The infection may remain local or can spread by direct tissue extension to the uterus, fallopian tubes, and ovaries. Although the vulva and vagina are uncommon sites for a gonorrheal infection, they may become involved when little or no estrogen is present, as in prepubertal girls and postmenopausal women. Because the vagina acts as a natural reservoir for infectious secretions, transmission is often more efficient from men to women than it is from women to men.

General. Anorectal gonorrhea may be present, usually as a result of anal intercourse. Symptoms may include mucopurulent anal discharge, bleeding, and tenesmus.[5] Most patients with anorectal infections and infections in the throat have few symptoms. A small percentage of individuals develop gonococcal pharyngitis from orogenital sexual contact. When the gonococcus can be demonstrated by a laboratory culture, individuals of either gender are infectious to their sexual partners.

Complications

Because men often seek treatment early in the course of the infection, they are less likely to develop complications. The complications that do occur in men are prostatitis, urethral strictures, and sterility from orchitis or epididymitis. Because women who are asymptomatic seldom seek treatment, complications are more common and usually constitute the reason for seeking medical attention. PID, Bartholin's abscess, ectopic pregnancy, and infertility are the main complications of gonorrhea in women. A small percentage of infected persons, mainly women, may develop a disseminated gonococcal infection (DGI). In DGI the appearance of skin lesions, fever, arthralgia, arthritis, or endocarditis usually causes the patient to seek medical help (Fig. 53-3).

Neonates can develop a gonococcal infection during delivery from an infected mother. Untreated infected infants develop permanent blindness. Almost all states have a health department regulation or law requiring the use of a prophylactic drug such as erythromycin ophthalmic ointment or silver nitrate aqueous solution in the eyes of all newborns. Therefore gonorrheal eye infections in newborns *(ophthalmia neonatorum)* are relatively rare today.

Diagnostic Studies

For men, a presumptive diagnosis of gonorrhea is made if there is a history of sexual contact with a new or infected partner

GENDER DIFFERENCES

Sexually Transmitted Infections

Men	Women
• Syphilis more common, especially in men who have sex with men • More likely to be symptomatic • Easier to diagnose because of less complex anatomy	• Chlamydial infection three times more common • Gonorrhea more common • HSV-2 more common • Have more frequent and serious complications related to STIs (e.g., pelvic inflammatory disease)

HSV-2, Herpes simplex type 2.

followed within a few days by a urethral discharge. Typical clinical manifestations, combined with a positive finding on a Gram-stained smear of the purulent discharge from the penis, give an almost certain diagnosis. A culture of the discharge is indicated for men whose smears are negative in the presence of strong clinical evidence. The nucleic acid amplification test (NAAT) (using ligase or polymerase chain reaction) is a nonculture test with sensitivity similar to culture tests for *N. gonorrhoeae.* It can be done on a wide variety of samples, including vaginal, endocervical, urethral, and urine specimens.[6]

For women, making a diagnosis of gonorrhea on the basis of symptoms is difficult because most women are symptom free or have complaints that may be confused with other conditions. Smears and purulent discharge do not establish a diagnosis of gonorrhea because the female genitourinary tract normally harbors a large number of organisms that resemble *N. gonorrhoeae.* A culture must be performed to confirm the diagnosis. Although the cervix is the most common site of sampling, specimens for culture may also be taken from the urethra, anus, or oropharynx. A urine specimen can reveal gonorrhea if it is present in the cervix or urethra.

Collaborative Care

Drug Therapy. Because of a short incubation period and high infectivity, treatment is generally instituted without awaiting culture results. The treatment of gonorrhea in the early stage is curative with a cephalosporin antibiotic. Treatment for gonorrhea is an intramuscular (IM) dose of ceftriaxone (Rocephin) or cefixime (Suprax) orally (Table 53-2).

Over the years, *N. gonorrhoeae* has developed a resistance to multiple classes of antimicrobial drugs, including fluoroquinolones (ciprofloxacin [Cipro], ofloxacin [Floxin], levofloxacin

TABLE 53-2 COLLABORATIVE CARE

Gonorrhea

Diagnostic

History and physical examination

Nucleic acid amplification test (NAAT) to detect *N. gonorrhoeae*
Testing for other STIs (syphilis, HIV, chlamydial infection)

Collaborative Therapy

Uncomplicated gonorrhea: ceftriaxone (Rocephin) IM or cefixime (Suprax) orally
If chlamydial infection is not ruled out: azithromycin (Zithromax) or doxycycline (Vibramycin)
Treatment of sexual contacts
Instruction on abstinence from sexual intercourse and alcohol during treatment
Reexamination if symptoms persist or recur after completion of treatment

Source: Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2010. Retrieved from *www.cdc.gov/STD/treatment*.

[Levaquin]) and tetracyclines (doxycycline [Vibramycin]). Gonococcal resistance to cephalosporin has recently been reported.[7]

The high frequency (up to 20% in men and 40% in women) of coexisting chlamydial and gonococcal infections has led to the addition of azithromycin (Zithromax) or doxycycline to the treatment regimen. Patients with coexisting syphilis are likely to be treated with the same drugs used for gonorrhea.

DRUG ALERT: Doxycycline (Vibramycin)

- Patients on this drug should avoid unnecessary exposure to sunlight.
- Do not take with antacids, iron products, or dairy products.

All sexual contacts of patients with gonorrhea must be evaluated and treated to prevent reinfection after resumption of sexual relations. The "ping-pong" effect of reexposure, treatment, and reinfection can end only when infected partners are treated simultaneously. Additionally, counsel the patient to abstain from sexual intercourse and alcohol during treatment. Sexual intercourse allows the infection to spread and can delay complete healing. Alcohol has an irritant effect on the healing urethral walls. Caution men against squeezing the penis to look for further discharge. Reinfection, rather than treatment failure, is the main cause of infections after treatment has ended.

SYPHILIS

The incidence of syphilis reported in the United States in 2000 was at its lowest rate since reporting started in 1941. During the past decade, syphilis rates increased until 2010 when the rate slightly decreased.[1] Many new cases of syphilis are being seen in men who have sex with men.

Etiology and Pathophysiology

Syphilis is caused by *Treponema pallidum,* a spirochete. This bacterium is thought to enter the body through very small breaks in the skin or mucous membranes. Its entry is facilitated by the minor abrasions that often occur during sexual intercourse. Syphilis is a complex disease in which many organs and tissues of the body can become infected by *T. pallidum.* The infection causes the production of antibodies that also react with normal tissues.

After a short period of protection, antibody levels decrease and a person is susceptible to reinfection. Not all people who are exposed to syphilis acquire the infection, since about one third become infected after intercourse with an infected person. In addition to sexual contact, syphilis may be spread through contact with infectious lesions and sharing of needles among IV drug users.

T. pallidum is extremely fragile and easily destroyed by drying, heating, or washing. The incubation period for syphilis ranges from 10 to 90 days (average 21 days). Congenital syphilis is transmitted from an infected mother to the fetus in utero after the tenth week of pregnancy. An infected pregnant woman has a high risk of a stillbirth or a baby dying shortly after birth.[8] Pregnant women need to be tested for syphilis at their first prenatal visit. Some states require all women to be screened at delivery.

Persons at high risk for acquiring syphilis are also at an increased risk for acquiring HIV infection. Often, both infections are present. Syphilitic lesions (chancres) on the genitalia enhance HIV transmission. Patients with HIV and syphilis appear to be at greatest risk for clinically significant central nervous system (CNS) involvement and may require more intensive treatment than do other patients with syphilis. Therefore the evaluation of all patients with syphilis should also include testing for HIV (with the patient's consent). Conversely, HIV patients should be tested at least annually for syphilis.

Clinical Manifestations

Syphilis has a variety of signs and symptoms that can mimic a number of other diseases. Consequently, compared with other STIs, it is more difficult to recognize syphilis. If it is not treated, specific clinical stages are characteristic of the progression of the disease (Table 53-3).

Complications

Complications of the disease occur mostly in late syphilis. The gummas of benign late syphilis may produce irreparable damage to bone, liver, or skin. In cardiovascular syphilis, the resulting aneurysm may press on structures such as the intercostal nerves, causing pain. The possibility of a rupture exists as the aneurysm increases in size. Scarring of the aortic valve results in aortic valve insufficiency and eventually heart failure.

Neurosyphilis causes degeneration of the brain with mental deterioration. Problems related to sensory nerve involvement are a result of *tabes dorsalis* (progressive locomotor ataxia). There may be sudden attacks of pain anywhere in the body, which can confuse the diagnosis with other conditions. Loss of vision and sense of position in the feet and legs can also occur. Walking may become even more difficult as joint stability is lost. (Late syphilis is also discussed in Chapter 59.)

Diagnostic Studies

The first step in diagnosis is to obtain a detailed and accurate sexual history. Asking if the patient has sex with men, women, or both can be more effective than asking directly about sexual orientation, since some men do not identify themselves as gay or homosexual. In addition, inquire about vaginal, oral, or anal sex. A physical examination should be done to identify any suspicious lesions or other significant signs and symptoms. Since syphilis is "the great imitator" of other conditions, it is easily missed. Oral sex is an important transmission route that is sometimes overlooked.

TABLE 53-3 STAGES OF SYPHILIS

Manifestations	Communicability
Primary	
Chancre (painless indurated lesion of penis, vulva, lips, mouth, vagina, and rectum) (Fig. 53-4) occurs 10 to 90 days after inoculation. Regional lymphadenopathy (draining of the microorganisms into the lymph nodes). Genital ulcers. *Duration of stage:* 3-8 wk	Exudate from chancre highly infectious; blood is infectious. Most infectious stage, but transmission can occur at any stage if there are moist lesions.
Secondary	
Occurs a few weeks after chancre appears. Systemic manifestations: flu-like symptoms (e.g., malaise, fever, sore throat, headaches, fatigue, arthralgia, headache, generalized adenopathy). Cutaneous lesions bilateral. Symmetric rash that begins on the trunk and involves the palms and soles. Mucous patches in the mouth (Fig. 53-5), tongue, or cervix. *Condylomata lata* (moist, weeping papules) in the anal and genital area. Weight loss, alopecia. *Duration of stage:* 1-2 yr	Exudate from skin and mucous membrane lesions highly infectious.
Latent	
Absence of signs or symptoms. Diagnosis based on positive specific treponemal antibody test together with normal CSF and absence of clinical manifestations. *Duration of stage:* Throughout life or progression to late stage	Noninfectious after 4 yr. Possible placental transmission. Almost 25% of persons with latent syphilis develop late syphilis, in some cases many years later.
Late (tertiary)*	
Appearance 3-20 yr after initial infection. Gummas (chronic, destructive lesions affecting any organ of body, especially skin, bone, liver, mucous membranes) (Fig. 53-6). *Cardiovascular:* Aneurysms, heart valve insufficiency, heart failure, aortitis. *Neurosyphilis:* General paresis (personality changes from minor to psychotic, tremors, physical and mental deterioration), tabes dorsalis (ataxia, areflexia, paresthesias, lightning pains, damaged joints), speech disturbances. *Duration of stage:* Chronic (without treatment), possibly fatal	Noninfectious. Spinal fluid possibly containing organism.

*Several forms such as cardiovascular syphilis and neurosyphilis occur together in approximately 25% of untreated cases.

CSF, Cerebrospinal fluid.

FIG. 53-4 Primary syphilis chancre.

FIG. 53-5 Secondary syphilis. Mucous patch in the mouth.

FIG. 53-6 Destructive skin gummas associated with tertiary syphilis.

Diagnostic studies for syphilis are presented in Table 53-4. The presence of spirochetes on dark-field microscopy and direct fluorescent antibody (DFA) tests of lesion exudate or tissue can confirm a clinical diagnosis of syphilis. However, syphilis is more commonly diagnosed by a serologic test.[4] Tests for syphilis may be classified as those performed for screening and those performed for confirmation of a positive screening test. Nonspecific antitreponemal antibodies can be detected by tests such as the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin (RPR) test. These nontreponemal tests are suitable for screening purposes, and usually become positive 10 to 14 days after the appearance of a chancre. The fluorescent treponemal antibody absorption (FTA-Abs) test and the *T. pallidum* particle agglutination (TP-PA) test detect specific antitreponemal antibodies and are used for confirming the diagnosis.

False-negative and false-positive test results do occur with the nontreponemal tests (VDRL, RPR). A false-negative result may be obtained during primary syphilis if the test is done before the individual has had time to produce antibodies. A false-positive finding may occur if patients have other diseases or conditions such as hepatitis, infectious mononucleosis, collagen diseases (e.g., systemic lupus erythematosus), pregnancy, or aging. Positive nontreponemal test results should be confirmed by more specific treponemal tests to rule out other causes. In the cerebrospinal fluid (CSF), changes such as increased white blood cell count, increased total protein, and a positive treponemal antibody test are diagnostic of neurosyphilis.

TABLE 53-4 COLLABORATIVE CARE

Syphilis

Diagnostic
- History and physical examination
- Dark-field microscopy
- Nontreponemal and/or treponemal serologic testing
- Testing for other STIs (HIV, gonorrhea, chlamydial infection)

Collaborative Therapy
- Antibiotic therapy
  - penicillin G benzathine (Bicillin) or aqueous procaine penicillin G
  - doxycycline (Vibramycin) or tetracycline (when penicillin is contraindicated)
- Confidential counseling and testing for HIV infection
- Surveillance
  - Repeat of nontreponemal tests at 6 and 12 mo
  - Examination of cerebrospinal fluid at 1 yr*

*If treatment involves alternative antibiotics or treatment failure has occurred.

If treatment with antibiotics is initiated early in the course of the disease on the basis of the history and the symptoms, the serologic testing may not indicate syphilis. Once a person has positive serologic findings for syphilis, indicating the presence of antibodies, these findings may remain positive for an indefinite period in spite of successful treatment.

Collaborative Care

Table 53-4 describes collaborative care of syphilis. Specific management is based on the symptoms.

Drug Therapy. Management of syphilis is aimed at eradicating all syphilitic organisms. Penicillin G benzathine (Bicillin) or aqueous procaine penicillin G is the treatment of choice for all stages of syphilis.[9] When penicillin is contraindicated, doxycycline or tetracycline may be used. However, treatment cannot reverse damage that is already present in the late stage of the disease. It is also important that all sexual contacts in the last 90 days be treated.

Patients having persistent or recurring symptoms after drug therapy has ended should be reevaluated. All patients with neurosyphilis must be carefully monitored, with periodic serologic testing, clinical evaluation at 6-month intervals, and repeat CSF examinations for at least 3 years.

CHLAMYDIAL INFECTIONS

Chlamydial infections are the most commonly reported STI in the United States. Infection rates have increased over the past 20 years, with more than 1.3 million cases reported in 2010.[1] This increase may be due in part to better and more intensive screening for the infection. Underreporting is significant because many people are asymptomatic and do not seek testing.

The incidence of chlamydia is higher in women than men, which may be because more women are screened for this infection. Women younger than 25 years old are five times more likely to have a chlamydial infection than women over age 30. Women infected with *Chlamydia* may also be at high risk for acquiring HIV from an infected partner.

Etiology and Pathophysiology

Chlamydial infections are caused by *Chlamydia trachomatis,* a gram-negative bacterium. *Chlamydia* can be transmitted during vaginal, anal, or oral sex. Numerous different serotypes, or strains, of *C. trachomatis* cause urogenital infections (e.g., nongonococcal urethritis [NGU] in men and cervicitis in women), ocular trachoma, and lymphogranuloma venereum. Risk factors for chlamydial infection are presented in Table 53-5. As with gonorrhea, chlamydial infections result in a superficial mucosal infection that can become more invasive.

TABLE 53-5 RISK FACTORS FOR CHLAMYDIAL INFECTION

- Women and adolescents
- New or multiple sexual partners
- Sexual partners who have had multiple partners
- History of STIs and cervical ectopy
- Coexisting STIs
- Inconsistent or incorrect use of condom

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

What Strategies Improve Screening Rates for Repeat Chlamydial Infections?

Clinical Question

In patients with repeat chlamydial infections (P), what is the effect of reminders and mailed screening kits (I) versus no intervention (C) on rescreening rates (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs) and observational studies

Critical Appraisal and Synthesis of Evidence
- Eight trials (n = 25 to 5863/trial) compared patient rescreening rates for repeat chlamydial infections.
- Interventions were mailed screening kits, motivational interviewing, financial incentives, and reminders.
- Rescreening occurred 3 wk to 12 mo after the initial chlamydial infection.
- Mailed screening kits for sample self-collection and phone call, postcard, and e-mail reminders significantly increased rescreening rates.

Conclusion
- Mailed screening kits, reminders, and a combination of both methods increased rescreening rates.

Implications for Nursing Practice
- Repeat chlamydial infections are common and increase the risk of complications.
- Remind patient of importance of rescreening.
- To increase rescreening rates, tailor interventions to meet patient needs and preferences.
- Text message and automated phone calling reminders may also be effective.

Clinical Manifestations

Chlamydial infection is known as a silent disease because symptoms may be absent or minor in most infected women and in

FIG. 53-7 Chlamydial epididymitis. Red, swollen scrotum.

many men.[10] In men, signs and symptoms include urethritis (dysuria, urethral discharge), proctitis (rectal discharge and pain during defecation), and epididymitis (unilateral scrotal pain, swelling, tenderness, fever) (Fig. 53-7).

In women, signs and symptoms include cervicitis (mucopurulent discharge, hypertrophic ectopy [area that is edematous and bleeds easily]), urethritis (dysuria, frequent urination, pyuria), bartholinitis (purulent exudate), dyspareunia (pain with intercourse), and menstrual abnormalities.

Because chlamydial infections are closely associated with gonococcal infections, clinical differentiation may be difficult. In men, urethritis, epididymitis, and proctitis may occur with both infections. In women, bartholinitis, cervicitis, and salpingitis (inflammation of the fallopian tube) can occur in both chlamydial and gonococcal infections. Therefore both infections are usually treated concurrently even without diagnostic proof. The incubation period of 1 to 3 weeks for chlamydial infection is longer than that for gonorrhea, and the symptoms are often milder.

Complications

Complications often develop from poorly managed, inaccurately diagnosed, or undiagnosed chlamydial infections. The infection is often not diagnosed until complications appear.

In men, epididymitis can lead to rare complications, including abscess, sepsis, infertility, and reactive arthritis (a systemic condition accompanied by skin lesions and inflammation of the eye and urethra).

In women, chlamydial infections can cause fallopian tube damage, a leading cause of ectopic pregnancy and infertility. Complications from chlamydial infections in women may result in PID, which can lead to chronic pelvic pain.[11] PID can also cause nausea, vomiting, fever, malaise, and abnormal vaginal bleeding.

Diagnostic Studies

Chlamydial infections in men and women can be diagnosed by testing urine or collecting swab specimens from the endocervix or vagina (women) or urethra (men). Rectal swab specimens are tested in persons engaging in anal sex. Table 53-6 outlines collaborative care for chlamydial infections.

Cell culture can be used to detect *Chlamydia* organisms. The most common diagnostic tests include the NAAT, DFA test, and enzyme immunoassay (EIA). These tests do not require special handling of specimens and are easier to perform than cell cultures. Amplification tests are the most sensitive diagnostic methods available and require fewer organisms. In addition, these tests can be used with urine samples rather than urethral and cervical swabs.

TABLE 53-6 COLLABORATIVE CARE

Chlamydial Infection

Diagnostic

- History and physical examination
- Nucleic acid amplification test (NAAT)
- Direct fluorescent antibody (DFA) test
- Enzyme immunoassay (EIA)
- Testing for other STIs (gonorrhea, HIV, syphilis)

Collaborative Therapy

- doxycycline (Vibramycin) or azithromycin (Zithromax)
- Alternative regimen: erythromycin, ofloxacin (Floxin), or levofloxacin (Levaquin)
- Instruction on abstinence from sexual intercourse for 7 days after completing treatment
- Treatment of all sexual partners

Collaborative Care

The Centers for Disease Control and Prevention (CDC) recommends that all sexually active women 25 years of age or younger be routinely screened for *Chlamydia*.[9] The CDC further recommends annual screening of all women older than 25 years of age with one or more risk factors for the infection (see Table 53-5).

Drug Therapy. To avoid complications from chlamydial infection, treatment should not be delayed. Doxycycline or azithromycin is used to treat patients and their partners. Treatment of pregnant women usually prevents transmission to the fetus. Patients treated for chlamydial infections should abstain from sexual intercourse for 7 days after treatment and until all sexual partners have completed a full course of treatment. Follow-up care includes advising the patient to return if symptoms persist or recur, treating sexual partners, and encouraging condom use during all sexual contacts.

The high incidence of recurrence may be due to failure to treat the sexual partners of infected people. Because of the high prevalence of asymptomatic infections, screening of high-risk populations is needed to identify those who are infected.

VIRAL INFECTIONS

GENITAL HERPES

Genital herpes is caused by herpes simplex virus (HSV). It is not a reportable infection in most states. Its true incidence is difficult to determine because most people have few to no symptoms. In the United States at least 50 million people are infected with HSV type 2. In people ages 14 to 49 approximately one out of six have genital herpes.[12]

Etiology and Pathophysiology

HSV enters through the mucous membranes or breaks in the skin during contact with an infected person. The virus then reproduces inside the cell and spreads to the surrounding cells. The virus next enters the peripheral or autonomic nerve endings and ascends to the sensory or autonomic nerve ganglion, where

it often becomes dormant. Viral reactivation (recurrence) may occur when the virus descends to the initial site of infection, either the mucous membranes or skin. When a person is infected with HSV, the virus usually persists within the individual for life. Transmission of HSV occurs through direct contact with skin or mucous membranes when an infected individual is symptomatic or through asymptomatic viral shedding.

Two different strains of HSV cause infection. In general, HSV type 1 (HSV-1) causes infection above the waist, involving the gingivae, the dermis, the upper respiratory tract, and the CNS. HSV type 2 (HSV-2) most frequently infects the genital tract and the perineum (i.e., locations below the waist). However, either strain can cause infection on the mouth or the genitalia. Although the majority of genital herpes cases are from HSV-2 infection, the incidence of anogenital herpes from HSV-1 is increasing among young women and men who have sex with men.

Clinical Manifestations

Primary Episode. In the *primary (initial) episode* of genital herpes the patient may complain of burning, itching, or tingling at the site of inoculation. Multiple small, vesicular, and sometimes painless lesions may appear on the inner thigh, penis, scrotum, vulva, perineum, perianal region, vagina, or cervix.[13] The vesicles contain large quantities of infectious viral particles (Fig. 53-8). The lesions rupture and form shallow, moist ulcerations. Finally, crusting and epithelialization of the erosions occur. Primary infections tend to be associated with local inflammation and pain, accompanied by systemic manifestations of fever, headache, malaise, myalgia, and regional lymphadenopathy.

Urination may be painful from the urine touching active lesions. Urinary retention may occur as a result of HSV urethritis or cystitis. A purulent vaginal discharge may develop with HSV cervicitis.

Primary lesions are generally present for 17 to 20 days, but new lesions sometimes continue to develop for 6 weeks. The duration of symptoms is longer and the frequency of complications is greater in women. The lesions heal spontaneously unless secondary infection occurs.

Recurrent Episodes. *Recurrent genital herpes* occurs in about 50% to 80% of individuals during the year following the primary episode. Common trigger factors include stress, fatigue, sunburn, general illness, immunosuppression, and menses. Many patients can predict a recurrence by noticing the prodromal symptoms of tingling, burning, and itching at the site where the lesions will eventually appear.[13]

The symptoms of recurrent episodes are less severe, and the lesions usually heal within 8 to 12 days. With time, the recurrent lesions generally occur less frequently. In extreme cases this can indicate immunosuppression and may signal a need to test for HIV.

Complications

Autoinoculation of the virus to extragenital sites such as the fingers and lips ("cold sores") may occur (Fig. 53-9). Although most infections are relatively benign, complications of genital herpes may involve the CNS, causing aseptic meningitis and lower motor neuron damage. Neuron damage may result in atonic bladder, impotence, and constipation. Immunocompromised patients (e.g., HIV-infected patients) should be monitored closely for treatment failure and a slower healing time of HSV lesions.

Women with a primary episode of HSV near the time of delivery have the highest risk of transmitting genital herpes to the neonate. An active genital lesion at the time of delivery is usually an indication for cesarean delivery.[9] Acyclovir (Zovirax) may be given to pregnant women who are at least at 36 weeks of gestation to prevent neonatal transmission.[14]

Diagnostic Studies and Collaborative Care

A diagnosis of genital herpes is usually based on the patient's symptoms and history. Highly accurate serologic tests are available for the diagnosis of HSV-1 and HSV-2. These type-specific immunoassays test for antibodies to HSV. A viral culture of the active lesion can also be used to isolate the virus.

Encourage symptomatic treatment such as using good genital hygiene and wearing loose-fitting cotton undergarments. The lesions should be kept clean and dry. To ensure complete drying of the perineal area, women may use a hair dryer set on a cool setting. Frequent sitz baths may soothe the area and reduce inflammation. Drying agents such as colloidal oatmeal (Aveeno) and aluminum salts (Burow's solution) may

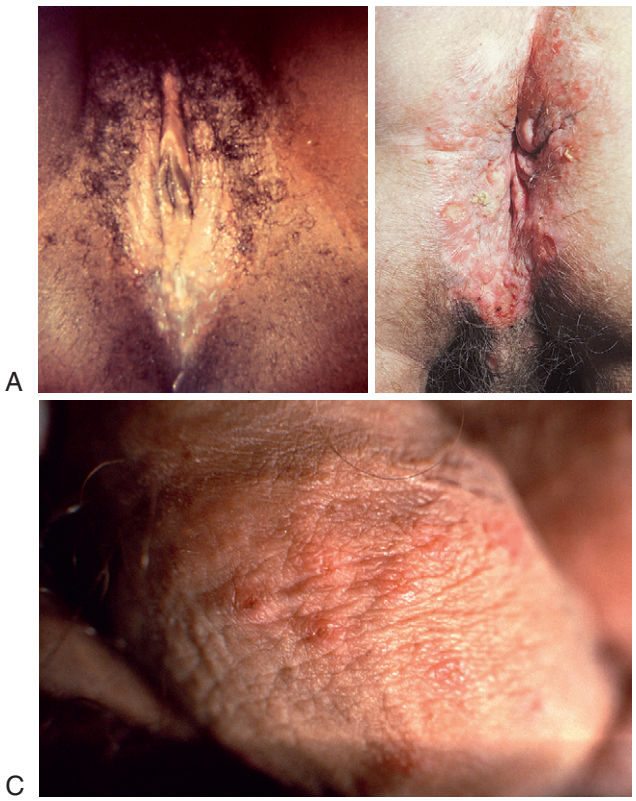

FIG. 53-8 Unruptured vesicles of herpes simplex virus type 2 (HSV-2). **A,** Vulvar area. **B,** Perianal area. **C,** Penile herpes simplex, ulcerative stage.

FIG. 53-9 Autoinoculation of herpes simplex virus (HSV) to the lips.

provide some relief from the burning and itching. Techniques to reduce pain on urination include pouring a pitcher of water onto the perineal area while voiding to dilute the urine, and voiding in a warm tub of water or shower. Pain may require a local anesthetic such as lidocaine (Xylocaine) or systemic analgesics such as codeine and aspirin.

Sexual transmission of HSV can occur during asymptomatic periods, and the use of barrier methods, especially condoms, should be encouraged. When lesions are present, the patient should avoid sexual activity altogether because even barrier protection is not satisfactory in eliminating infection transmission.

Drug Therapy. Treatment of HSV infection should be started before diagnostic results are available because early treatment reduces transmission and duration of the ulcers. Three antiviral agents are available for the treatment of HSV: acyclovir, valacyclovir (Valtrex), and famciclovir (Famvir). These drugs inhibit herpetic viral replication and are prescribed for primary and recurrent infections (Table 53-7). Acyclovir, valacyclovir, and famciclovir are also used to suppress frequent recurrences (six or more episodes per year).

Although not a cure, these drugs shorten the duration of viral shedding and the healing time of genital lesions and reduce outbreaks by 75%.[9] Continued use of oral acyclovir as suppressive therapy for up to 6 years is safe and effective for persons with frequent or severe recurrences. Adverse reactions are mild and include headache, occasional nausea and vomiting, and diarrhea. Acyclovir ointment has no clinical benefit in the treatment of recurrent lesions, either in speed of healing or in resolution of pain, and is not commonly recommended.

IV acyclovir is reserved for severe or life-threatening infections in which hospitalization is required for the treatment of disseminated infections, CNS infections (meningitis), or pneumonitis. Nephrotoxicity has been observed with high-dose IV use. Clinical trials are examining the effectiveness of a vaccine for HSV-2.[15]

TABLE 53-7 COLLABORATIVE CARE

Genital Herpes

Diagnostic
- History and physical examination
- Antibody assay for HSV type
- Viral isolation by tissue culture

Collaborative Therapy

Primary (Initial) Infection
- acyclovir (Zovirax), famciclovir (Famvir), or valacyclovir (Valtrex)

Recurrent Episodic Infection
- acyclovir, famciclovir, or valacyclovir
- Identify triggering factors
- Yearly Pap test
- Abstinence from sexual contact while lesions are present
- Symptomatic care
- Confidential counseling and testing for HIV

Suppressive Therapy
- acyclovir, famciclovir, or valacyclovir

Severe Infection
- acyclovir IV until clinical improvement, followed by oral antiviral therapy

GENITAL WARTS

Genital warts *(Condylomata acuminata)* are caused by the human papillomavirus (HPV). HPV is a highly contagious STI seen frequently in sexually active young adults. There are more than 100 types of papillomaviruses, many of which are sexually transmitted. Ninety percent of genital warts are caused by HPV types 6 and 11. Although genital warts are not malignant, other HPV types (e.g., types 16 and 18) are oncogenic and associated with cervical, vaginal, vulvar, anal, and penile cancers.[16] In most states, genital warts are not a reportable infection.

Minor trauma during intercourse can cause abrasions that allow HPV to enter the body. The epithelial cells infected with HPV undergo transformation and proliferation to form a warty growth. The incubation period of the virus is generally 3 to 4 months, but may be longer.

Clinical Manifestations and Complications

Most individuals who have HPV infection do not know that they are infected because symptoms are often not present. Genital warts are discrete single or multiple papillary growths that are white to gray and pink-flesh colored. They may grow and coalesce to form large, cauliflower-like masses. Most patients have 1 to 10 genital warts.

In men the warts may occur on the penis and scrotum, around the anus, or in the urethra. In women the warts may be located on the inner thighs, vulva, vagina, or cervix and in the perianal area (Fig. 53-10). There are usually no other signs or symptoms. Itching may occur with anogenital warts. Bleeding on defecation may occur with anal warts.

During pregnancy, genital warts tend to grow rapidly and increase in size. An infected mother may transmit the condition to her newborn. Cesarean delivery is not routinely indicated unless the birth canal becomes blocked by massive warts.

Diagnostic Studies and Collaborative Care

Up to two thirds of the early lesions caused by HPV are undetectable by visual examination. A diagnosis of genital warts can be made on the basis of the gross appearance of the lesions. Warts may be confused with condylomata lata of secondary syphilis, carcinoma, or benign neoplasms. Serologic and cytologic testing should be done to rule out these conditions. HPV deoxyribonucleic acid (DNA) tests help determine if women with abnormal Papanicolaou (Pap) test results need further follow-up. Currently, HPV cannot be confirmed by culture.

Prevention of genital warts is hampered by the high proportion of asymptomatic infections and lack of curative treatment. The primary goal when treating visible genital warts is the removal of symptomatic warts.

Treatment consists of chemical or ablative (removal with laser or electrocautery) methods. One common treatment is the use of 80% to 90% trichloroacetic acid (TCA) or bichloroacetic acid (BCA) applied directly to the wart surface. Petroleum jelly is applied to the surrounding normal skin to minimize irritation before a small amount of TCA is applied to the wart with a cotton swab. A sharp stinging pain is often felt with initial acid contact, but this quickly subsides. TCA is not washed off after treatment.

Podophyllin resin (10% to 25%), a cytotoxic agent, is recommended therapy for small external genital warts. When podophyllin is used, it is applied carefully to each wart, avoiding normal tissue, and is then thoroughly washed off in 1 to 4 hours. This substance encourages the sloughing of skin containing

FIG. 53-10 Genital warts. **A,** Severe vulvar warts. **B,** Perineal wart. **C,** Multiple genital warts of the glans penis.

viral particles. Podophyllin has local (e.g., pain, burning) and systemic (e.g., nausea, dizziness, leukopenia, respiratory distress) toxic symptoms. In general, warts located on moist surfaces respond better to topical treatment (e.g., TCA, podophyllin) than do warts on drier surfaces.

Patient-managed treatment is also an option. Podofilox (5%) liquid and gel are available by prescription (Condylox and Condylox Gel). The patient applies the solution or gel for 3 successive days followed by 4 days of no treatment. Treatment can be repeated for up to 4 weeks or until the lesions resolve. Imiquimod (5%) cream (Aldara) is an immune response modifier that is applied once daily at bedtime, three times a week for up to 16 weeks.

The removal of warts may or may not decrease infectivity. Genital warts are difficult to treat and often require multiple office visits.[17] The therapy should be modified if a patient has not improved after three treatments or if the warts have not completely disappeared after six treatments.

If the warts do not regress with any of these therapies, treatments such as cryotherapy with liquid nitrogen, electrocautery, laser therapy, intralesional use of α-interferon, and surgical excision may be indicated. Because treatment does not destroy the virus, merely the infected tissue, recurrences and reinfection are possible, and careful long-term follow-up is advised.

HPV Vaccines. Vaccines are available to protect against HPV types 6, 11, 16, and 18 (Gardasil) and HPV types 16 and 18 (Cervarix). The vaccine is given in three IM doses over a 6-month period and has few side effects.

For females, either Gardasil or Cervarix vaccine is recommended at age 11 or 12 years. It may be given to girls starting at age 9. The vaccine is also recommended for females 13 through 26 years of age who did not get all three doses when they were younger.

For males, Gardasil vaccine is recommended at ages 11 or 12 years. It may be given to boys starting at age 9. This vaccine is recommended for males 13 through 21 years of age who have not completed the three-dose series. This vaccine may be given to men 22 through 26 years of age who have not completed the three-dose series. It is recommended for men through age 26 who have sex with men or whose immune system is weakened because of HIV infection, other illness, or medications.[18]

Because of reported cases of syncope (fainting) during vaccine administration, the patient should remain seated or lying down and be closely observed for 15 minutes after vaccination. These vaccines do not treat active HPV infection. Ideally, individuals should receive the vaccine before the start of sexual activity, but those who are active or even infected still get protection from the HPV types not already acquired. HPV vaccine reduces the risk of anal cancer and may also protect against oropharynx cancer.[19]

NURSING MANAGEMENT SEXUALLY TRANSMITTED INFECTIONS

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a person with an STI are presented in Table 53-8.

NURSING DIAGNOSES

Nursing diagnoses for the patient with an STI include, but are not limited to, the following:

- Risk for infection *related to* lack of knowledge about mode of transmission, inadequate personal and genital hygiene, and failure to practice precautionary measures
- Anxiety *related to* impact of the condition on relationships, disease outcome, and lack of knowledge of disease
- Ineffective health maintenance *related to* lack of knowledge about disease process, inadequate follow-up measures, and possibility of reinfection

PLANNING

The overall goals are that the patient with an STI will (1) demonstrate understanding of the mode of transmission of STIs and the risk posed by STIs, (2) complete treatment and return for appropriate follow-up, (3) notify or assist in notification of sexual contacts about their need for testing and treatment, (4) abstain from intercourse until infection is resolved, and (5) demonstrate knowledge of safer sex practices.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Many approaches to stopping the spread of STIs have been advocated and have met with varying degrees of success. Be prepared to discuss "safe" sex practices with all patients, not only those who are perceived to be at risk. These practices include abstinence, monogamy, avoidance of certain high-risk sexual practices, and use of condoms and other barriers to limit contact with potentially infectious body fluids or lesions. Sexual abstinence is a certain method of avoiding all

EVIDENCE-BASED PRACTICE

Applying the Evidence

F.C. is a 19-yr-old man who is being seen in the health care center for signs and symptoms of a urinary tract infection. When asked, he shares with you that he is sexually active. After reviewing his health history, you learn that he has not received the human papillomavirus (HPV) vaccine. You discuss the risks and benefits of the vaccine and suggest that he consider getting it.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Males ages 9-26 can get vaccinated with Gardasil to reduce the incidence of anogenital HPV infections, which are caused by HPV types 6, 11, 16, or 18. Gardasil protects against the two HPV types (6 and 11) that cause 90% of genital warts.	Approximately 90% of anal cancers have been linked to HPV infection. Males may be unaware of the expanded recommendations for Gardasil, which was originally approved to prevent cervical, vulvar, and vaginal cancer caused by HPV types 6, 11, 16, and 18 in females ages 9 through 26.	F.C. states that he never has unprotected sex and does not like injections.

Your Decision and Action

After listening carefully, F.C. decides to talk to a few of his friends before making a decision about the vaccine. He tells you that he had no idea that he could get HPV infections. If he decides to get the vaccine, he will be back. You document your discussion in his chart.

Advisory Committee on Immunization Practices: Recommendations on the use of quadrivalent human papillomavirus vaccine in males—advisory committee on immunization practices (ACIP) 2011, Centers for Disease Control and Prevention. Retrieved from *www.cdc.gov/mmwr/preview/mmwrhtml/mm6050a3.htm*.

HEALTHY PEOPLE

Health Impact of Responsible Sexual Behavior

- Greatly reduces the risk of contracting sexually transmitted infections, including infection from human immunodeficiency virus, gonorrhea, chlamydial infection, syphilis, and herpes
- Greatly reduces the risk of spreading viruses such as human papillomavirus that could potentially cause cervical, vulvar, vaginal, penile, anal, and oropharyngeal cancers

TABLE 53-8 NURSING ASSESSMENT

Sexually Transmitted Infections

Subjective Data

Important Health Information

Past health history: Contact with individuals with STIs, multiple sexual partners

Medications: Oral contraceptives; allergy to any antibiotics, especially penicillin

Functional Health Patterns

Health perception–health management: Shared needles during IV drug use; malaise

Nutritional-metabolic: Nausea, vomiting, anorexia; pharyngitis, oral lesions, itching at infected site; chills; alopecia

Elimination: Dysuria, urinary frequency, retention; urethral discharge; tenesmus, proctitis

Cognitive-perceptual: Arthralgia; headache; painful, burning lesions

Sexuality-reproductive: Dyspareunia; vaginal discharge, menstrual abnormalities; genital or perianal lesions

Objective Data

General

Fever, lymphadenopathy (generalized or inguinal)

Integumentary

Syphilis: Primary: Painless, indurated genital, oral, or perianal lesions
Secondary: Bilateral, symmetric rash on palms, soles, or entire body; mucous patches on mouth or tongue; alopecia

Genital herpes: Painful genital or anal vesicular lesions

Genital warts: Single or multiple gray or white genital or anal warts (possibly becoming massive)

Gastrointestinal

Purulent rectal discharge (indicator of gonorrhea), rectal lesions, proctitis

Urinary

Urethral discharge, erythema

Reproductive

Cervical discharge, lesions, inflamed Bartholin's glands

Possible Diagnostic Findings

Gonorrhea: Positive Gram stain, smears, cultures, and DNA amplification for *Neisseria gonorrhoeae*

Syphilis: Positive findings on VDRL and RPR, spirochetes on dark-field microscopy

Chlamydia: Positive culture or DNA amplification for *Chlamydia*

Genital herpes: Positive HSV-1 or HSV-2 antibody titer; positive tissue culture for HSV-1 or HSV-2

DNA, Deoxyribonucleic acid; *HSV-1,* herpes simplex virus type 1; *HSV-2,* herpes simplex virus type 2; *RPR,* rapid plasma reagin; *STIs,* sexually transmitted infections; *VDRL,* Venereal Disease Research Laboratory.

STIs, but few people consider this a feasible alternative to sexual expression. Limiting sexual intimacies outside of a well-established monogamous relationship can reduce the risk of contracting an STI. A teaching guide for the patient with an STI is presented in Table 53-9.

All sexually active women should be screened for cervical cancer using a Pap test. Women with a history of STIs are at greater risk for cervical cancer. Anal Pap tests should also be done for all individuals who are recipients of anal sex. (Pap tests are discussed in Chapter 54.)

Measures to Prevent Infection. An inspection of the sexual partner's genitalia before coitus is recommended. Discharge, sores, blisters, or rash should be viewed with concern. A patient who is aware of specific signs and symptoms of infection can intelligently make the decision to continue the sexual interaction with modifications or elect not to have sexual relations. The patient should remember that, when engaging in sex, he or she is exposed to the infections of everyone with whom the partner has ever had sex.

Tell men that some protection is provided if they void immediately after intercourse and wash their genitalia and the adjacent areas with soap and water. Women may also benefit from postcoital voiding and washing. However, emphasize that these practices do not provide adequate protection against STIs after exposure to infection.

Spermicidal jellies and creams have not been shown to reduce the risk of contracting STIs.[20] These same barriers may serve as supplementary lubrication, thereby decreasing irritation and friction. They also reduce the chance that a minor laceration could serve as the entry point for an infectious organism.

TABLE 53-9 PATIENT TEACHING GUIDE

Sexually Transmitted Infections

When teaching the patient with sexually transmitted infections:

1. Explain precautions to take such as
   - voiding and washing genitalia and surrounding area after coitus to flush out some organisms and reduce the occurrence of infection
   - using condoms
   - being monogamous
   - asking potential partners about sexual history
   - avoiding sex with partners who use IV drugs or who have visible oral, inguinal, genital, perineal, or anal lesions
2. Explain the importance of taking all antibiotics and/or antiviral agents as prescribed. Symptoms will improve after 1-2 days of therapy, but organisms may still be present.
3. Teach patient about the need for treatment of sexual partners to prevent transmission of infection.
4. Instruct patient to abstain from sexual intercourse during treatment and to use condoms when sexual activity is resumed to prevent spread of infection and reinfection.
5. Explain the importance of follow-up examination and reculture at least once after treatment if appropriate to confirm complete cure and prevent relapse.
6. Allow patient and partner to verbalize concerns to clarify areas that need explanation.
7. Instruct patient about symptoms of complications and need to report problems to ensure proper follow-up and early treatment of reinfection.
8. Inform patient regarding state of infectivity to prevent a false sense of security, which might result in careless sexual practices and poor personal hygiene.

Proper use of a condom provides a highly effective mechanical barrier to infection. The condom should be undamaged and correctly in place throughout all phases of sexual activity. A deterrent to barrier usage is alcohol and drug use. Use of barrier contraceptives requires planning and motivation, both of which are impaired with alcohol or drug ingestion. Give specific verbal and written instructions on the proper use of condoms (see eTable 15-4 available at the website for Chapter 15). Partners should discuss any objections to condom usage, such as interference with spontaneity and the presence of a barrier. Information about the mechanics of sexual arousal and incorporating a condom into lovemaking can help in overcoming the individual's or partner's resistance to its use. Female condoms are lubricated polyurethane sheaths designed for vaginal use but are considerably more expensive than male condoms (see eTable 15-5 available at the website for Chapter 15).

Among couples with one infected partner, consistent and scrupulous condom use can reduce transmission to the uninfected partner. Unprotected anal intercourse and other high-risk behaviors should be eliminated, and condoms should be used if sexual contact continues.

Initiate a discussion to assess the risk for contracting an STI. Questions to ask include number of partners, type of birth control used, use of condoms, history of an STI, use of IV drugs, and sexual preference. Instead of asking if a patient is homosexual or asking only about sexual preference, it can be more revealing to ask, "Do you have sex with men or women or both?" Some men who have sex with men do not identify themselves as homosexual or bisexual, which is a major contributor to infection of wives and female or male partners. Although the majority of STIs are transmitted between men having sex with men and heterosexual contact, it is possible to transmit an STI between women.[21]

Plan teaching based on the response to these questions. Interpersonal skills necessary for this interview include respect, compassion, and a nonjudgmental attitude. Tailor your counseling to the individual. Do not assume that older people are not at risk, since an increasing number of older people are becoming infected.

Screening Programs. Screening programs can help prevent certain STIs. For many years, there have been various screening programs to identify cases of syphilis. Many institutions offer voluntary prenatal HIV and syphilis testing and counseling for pregnant women.

Screening programs have been developed and implemented for detection of gonorrhea and chlamydial infection. These programs are targeted to women because women are more likely to have asymptomatic gonorrhea and thereby serve as sources of infection. Routine gonorrheal and chlamydial testing during pelvic examinations and prenatal visits are a major part of these programs. Mass application of screening programs for genital chlamydial infections, genital herpes, and HPV infections (warts) may also be possible with the advent of rapid, cost-effective tests.

Case Finding. Interviewing and case finding are other methods used to control STIs. These activities are directed toward locating and examining all contacts of each known patient with an STI as soon after sexual exposure as possible so that effective treatment can be initiated. Trained interviewers may often find cases even if they are supplied with only limited information. The caseworkers, who are often nurses, are aware of the social implications of these diseases and the need for discretion. Sexual contacts are often not informed about the origin of the information naming them as a contact so that greater cooperation and privacy are ensured.

Partner notification and treatment impose a heavy burden on public health departments and, as a result, the notification often becomes the responsibility of the infected partner. The infected partner may choose not to inform sexual partners, and the partners may choose not to seek treatment. *Expedited partner therapy* (EPT) is a safe, effective tool for treating STIs that allows a health care provider to provide prescriptions or medications to a patient to take to his or her partner, without examining the partner. EPT has been shown to be useful in ensuring partner treatment among men and reducing repeat infections among women.[22] Several states have adopted legislation to allow health care providers to dispense antibiotic therapy for sex partners of individuals with chlamydial infection or gonorrhea. The legality of treating without evaluating the patient is uncertain in some states, and it is illegal in others.

Educational and Research Programs. Actively encourage your community to provide better education about STIs for its citizens. Teenagers, who are known to have a high incidence of infection, should be a prime target for such educational programs. STI rates are also rising in older adults.[23] Older adults are less likely to use condoms and in general have a harder time initiating discussion of sexual health issues.

Knowledge and understanding can decrease the STI epidemic. The HPV vaccine that protects against genital warts and cervical cancer should be encouraged before the start of sexual activity. Accurate and current information may help reduce parental fears related to the vaccine. Consider stressing the prevention of cancer as a reason for the vaccine, which may be more productive and less controversial, thus making the parent and adolescent more receptive. Efforts are being made to

develop vaccines for syphilis, gonorrhea, genital herpes, and HIV. Many clinicians view the development of effective vaccines as a prerequisite for the eradication of STIs.

ACUTE INTERVENTION

Psychologic Support. The diagnosis of an STI may be met with a variety of emotions, such as shame, guilt, anger, and a desire for vengeance. Provide counseling and encourage the patient to verbalize feelings. Couples in marital or committed relationships are confronted with an added problem when an STI is diagnosed, and they must face the implication of sexual activity outside the relationship. The acute problem raises other concerns about their relationship and may serve as an incentive for further problem solving. The couple needs support and counseling. A referral for professional counseling to explore the ramifications of an STI in their relationship may be indicated.

A patient who has genital herpes is faced with the fact that repeated infections can occur and that no cure is available. This can be frustrating and disruptive to the patient's physical, emotional, social, and sexual life. Help the patient identify and avoid any factors that may precipitate the condition. Inform the patient that the frequency and severity of recurrences will probably decrease over time.

HPV infections involve a prolonged course of treatment. The patient can become frustrated and distressed because of frequent office visits, associated costs, potential for unpleasant side effects as a result of treatment, and effects of the infection on future health and sexual relationships. Support and a willingness to listen to the patient's concerns are needed. Support groups are also available.

Follow-up. If you work in public health facilities, clinics, or other outpatient settings, you are more likely to care for a patient with an STI than if you work in a hospital setting. Whatever the setting, as a nurse you are in a position to explain and interpret treatment measures such as the purpose and possible side effects of prescribed drugs and the need for follow-up care.

Frequently, single-dose treatment for gonorrhea, chlamydial infection, and syphilis helps prevent the problems associated with nonadherence with drug therapy. Give special instructions to the patient requiring multiple-dose therapy to complete the prescribed regimen. Also inform the patient about problems resulting from nonadherence. All patients should return to the treatment center for a repeat culture from the infected sites or for serologic testing at designated times to determine the effectiveness of the treatment. Explaining to the patient that cures are not always obtained on the first treatment can reinforce the need for a follow-up visit. Also advise the patient to inform sexual partners of the need for testing and treatment, regardless of whether they are free of symptoms or experiencing symptoms.

Hygiene Measures. Emphasize to the patient with an STI the importance of certain hygiene measures. An important component is frequent hand washing and bathing. Bathing and cleaning of the involved areas can provide local comfort and prevent secondary infection. Because douching may spread the infection or undermine local immune responses, it is contraindicated. The synthetic materials used in most undergarments frequently increase or exacerbate local irritations by trapping moisture. Cotton undergarments provide better absorption and are cooler and more comfortable for the patient with an STI.

Sexual Activity. Sexual abstinence is indicated during the communicable phase of the infection. If sexual activity occurs before treatment has been completed, emphasize to the patient the importance of using condoms to help prevent the spread of infection and reinfection. Also encourage condom usage after treatment to prevent future exposure to infection. The patient can also choose to relate to a partner in an intimate way that avoids both coitus and oral-genital contact. Note that even single-dose treatments can take up to 1 week to be effective and thus the patient is infectious during this period.

ETHICAL/LEGAL DILEMMAS

Confidentiality and HIPAA

Situation

P.H., a 22-yr-old woman, is informed of the positive results of a test for chlamydial infection. You advise her to tell her sexual partners that she has this disease. She refuses to tell her boyfriend because he will know that she has had sex with another partner. You later learn that the nursing student who was in the clinic for the day, who is a friend of the boyfriend, hinted to him that he should have STI testing.

Ethical/Legal Points for Consideration

- Each state has requirements for reporting communicable diseases and other health-related data. Inform the patient of the reporting requirements for communicable diseases.
- Nurses and other health care professionals have both a legal and an ethical obligation to maintain confidentiality of patient information. The Health Insurance Portability and Accountability Act (HIPAA) ensures the privacy of personal health information.
- Your primary obligation is to the patient seeking care. Patient teaching is one way to establish a partnership with this woman. Share information about the effects of the disease if it is not treated, the consequences of reinfection, and the effect of the disease on others who may not know that they are infected. Then encourage the patient to inform her partners of the diagnosis for the good of everyone.

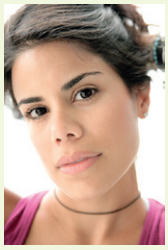
Discussion Questions

1. What are your state's requirements for reportable conditions?
2. In your opinion, what is the best way to balance the needs of an individual patient with those of the general public?
3. What are the risks to the institution for the breach of confidentiality and HIPAA?

AMBULATORY AND HOME CARE

Because many STIs are cured with a single dose or short course of antibiotic therapy, many persons are casual about the outcome of these infections. The consequences of this attitude can include delays in treatment, nonadherence with instructions, and subsequent development of complications. The complications are serious and costly. They can result in disfigurement and destruction of important tissues and organs.

Surgery and prolonged therapy are indicated for many patients with infection-related complications. Major surgical procedures such as resection of an aneurysm or aortic valve replacement may be necessary to treat cardiovascular problems caused by syphilis. Pelvic surgery and procedures to correct fertility problems secondary to an STI may include lysis of adhesions, dilation of strictures, reconstructive tuboplasty, and in vitro fertilization.



EVALUATION

Expected outcomes for the patient with an STI are that the patient will

- Describe modes of transmission
- Use appropriate hygienic measures
- Experience no reinfection
- Demonstrate compliance with follow-up protocol

CASE STUDY

Gonorrhea and Chlamydial Infection

Eyecandy Images/ Thinkstock

Patient Profile

C.R. is a 24-yr-old Hispanic woman who is seen at the outpatient clinic with complaints of a purulent yellow-white discharge and frequent urination over the past 2 wk. She is sexually active with a new partner after breaking up with a long-term boyfriend. She was treated in the past for *Chlamydia* at age 20.

Subjective Data

- Her sexual partner does not use a condom or spermicide with intercourse
- Her last menstrual period was 3 wk ago
- Her sexual partner was recently treated for epididymitis
- Appears very nervous

Objective Data

- Cervical ectopy noted during Pap test
- Mucopurulent cervical discharge
- Urine pregnancy test is negative
- Nucleic acid amplification test is positive for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*

Collaborative Care

- ceftriaxone 250 mg IM once
- doxycycline 100 mg bid for 7 days

Discussion Questions

1. What were C.R.'s risk factors for acquiring gonorrhea and chlamydial infection?
2. What complications could occur if C.R.'s infections are not treated?
3. ***Priority Decision:*** What is the priority of care for C.R.?
4. What instructions should C.R. receive to ensure successful treatment? To prevent reinfection? To prevent further transmission of the infection?
5. ***Delegation Decision:*** Which nursing personnel should be responsible for teaching C.R. what she needs to know about other sexually transmitted infections (STIs): registered nurse, licensed practical/vocational nurse, unlicensed assistive personnel?
6. What impact is her diagnosis likely to have on C.R.'s self-image? On her relationship with her sexual partner?
7. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Evidence-Based Practice:*** C.R. mentions she is using the spermicide nonoynol-9 (N-9) to protect herself against STIs. Would you advise her to continue to use it?

evolve Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The individual with the lowest risk for sexually transmitted pelvic inflammatory disease is a woman who uses
   a. oral contraceptives.
   b. barrier methods of contraception.
   c. an intrauterine device for contraception.
   d. a Norplant implant or injectable Depo-Provera for contraception.
2. The nurse is obtaining a subjective data assessment from a woman reported as a sexual contact of a man with chlamydial infection. The nurse understands that symptoms of chlamydial infection in women
   a. are frequently absent.
   b. are similar to those of genital herpes.
   c. include a macular palmar rash in the later stages.
   d. may involve chancres inside the vagina that are not visible.
3. A primary HSV infection differs from recurrent HSV episodes in that *(select all that apply)*
   a. only primary infections are sexually transmitted.
   b. symptoms are less severe during recurrent episodes.
   c. transmission of the virus to a fetus is less likely during primary infection.
   d. systemic manifestations such as fever and myalgia are more common in primary infection.
   e. lesions from recurrent HSV are more likely to transmit the virus than lesions from primary HSV.
4. Explain to the patient with gonorrhea that treatment will include both ceftriaxone and doxycycline because
   a. most patients need both drugs to eradicate the organism.
   b. coverage with more than one antibiotic will prevent reinfection.
   c. no single agent successfully eradicates both primary and recurrent infections.
   d. the high rate of coexisting chlamydial infection and gonorrhea indicates coverage with both drugs.
5. In assessing patients for STIs, the nurse needs to know that many STIs can be asymptomatic. Which STIs can be asymptomatic *(select all that apply)?*
   a. Syphilis
   b. Gonorrhea
   c. Genital warts
   d. Genital herpes
   e. Chlamydial infection
6. To prevent the infection and transmission of STIs, the nurse's teaching plan would include an explanation of
   a. the appropriate use of oral contraceptives.
   b. sexual positions that can be used to avoid infection.
   c. the necessity of annual Pap tests for patients with HPV.
   d. sexual practices that are considered high-risk behaviors.

7. Provide emotional support to a patient with an STI by
   a. offering information on how safer sexual practices can prevent STIs.
   b. showing concern when listening to the patient who expresses negative feelings.
   c. reassuring the patient that the disease is highly curable with appropriate treatment.
   d. helping the patient who received an STI from his or her sexual partner in forgiving the partner.

1. b, 2. a, 3. b, d, 4. d, 5. a, b, c, d, e, 6. d, 7. b

LEARNING OUTCOMES

1. Summarize the etiologies of infertility and the strategies for diagnosis and treatment of the infertile woman.
2. Describe the etiology, clinical manifestations, and nursing and collaborative management of menstrual problems and abnormal vaginal bleeding.
3. Identify the risk factors, clinical manifestations, and collaborative care of ectopic pregnancy.
4. Describe the changes related to menopause and the nursing and collaborative management of the patient with menopausal symptoms.
5. Differentiate among the common problems that affect the vulva, vagina, and cervix and the related nursing and collaborative management.
6. Describe the assessment, collaborative care, and nursing management of women with pelvic inflammatory disease and endometriosis.
7. Explain the clinical manifestations, diagnostic studies, collaborative care, and surgical therapy for cervical, endometrial, ovarian, and vulvar cancers.
8. Summarize the preoperative and postoperative nursing management for the patient requiring surgery of the female reproductive system.
9. Differentiate among the common problems that occur with cystoceles, rectoceles, and fistulas and the related nursing and collaborative management.
10. Summarize the clinical manifestations of sexual assault and the appropriate nursing and collaborative management of the patient who has been sexually assaulted.

INFERTILITY

Infertility is the inability to conceive after at least 1 year of regular unprotected intercourse.[1] Approximately 15% of couples in North America are infertile. Understandably, infertility can be both a physical and an emotional crisis.

Etiology and Pathophysiology

Infertility may be caused by either female or male or combined factors. (Conditions that cause male infertility are discussed in Chapter 55.) In some cases, the cause of infertility may not be identified.

The factors usually causing female infertility include problems with ovulation (anovulation or inadequate corpus luteum), tubal obstruction or dysfunction (endometriosis or damage from pelvic infection), and uterine or cervical factors (fibroid tumors or structural anomalies). Risk factors for infertility include tobacco and illicit drug use and being obese or thin. In women the risk for infertility starts about age 30 and increases after age 40.[2]

Reviewed by Brenda Pavill, RN, PhD, FNP, Associate Professor–Nursing, Misericordia University, Dallas, Pennsylvania; and Beth Perry Black, RN, PhD, Professor of Nursing, UNC at Chapel Hill School of Nursing, UNC School of Nursing, Chapel Hill, North Carolina.

TABLE 54-1 COLLABORATIVE CARE

Infertility

Diagnostic

- History and physical examination of both partners, including psychosocial functioning
- Review of menstrual and gynecologic history
- Assessment of possible sexually transmitted infections
- Hormone levels
  - Serum hormone levels (e.g., FSH, LH, prolactin)
  - Urinary LH
- Pap test
- Ovulatory study
- Tubal patency study
  - Hysterosalpingogram
- Postcoital test
  - Cervical mucus
  - Sperm penetration assay

- Drug therapy (see Table 54-2)
- Intrauterine insemination
- Assisted reproductive technologies (ARTs)

FSH, Follicle-stimulating hormone; *LH,* luteinizing hormone.

TABLE 54-2 DRUG THERAPY

Infertility

Drug	Mechanism of Action
Selective Estrogen Receptor Modulator	
clomiphene (Clomid, Serophene)	Stimulates hypothalamus to ↑ production of GnRH, which ↑ release of LH and FSH. End result is stimulation of ovulation.
Menotropins (Human Menopausal Gonadotropin)	
Pergonal Repronex Humegon	Product made of FSH and LH to promote the development and maturation of follicles in the ovaries.
Follicle-Stimulating Hormone Agonists	
urofollitropin (Fertinex, Bravelle) follitropin (Gonal-f, Follistim)	Stimulate follicle growth and maturation by mimicking the body's natural FSH.
GnRH Antagonists	
cetrorelix (Cetrotide) ganirelix (Antagon)	Prevent premature LH surges and premature ovulation in women undergoing ovarian stimulation.
GnRH Agonists	
leuprolide (Lupron) nafarelin (Synarel)	Suppress release of LH and FSH with continuous use. May also be used in the treatment of endometriosis.
Human Chorionic Gonadotropin (hCG)	
Pregnyl Profasi Novarel	Induces ovulation by stimulating the release of eggs from follicles.

FSH, Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone.

Diagnostic Studies

A detailed history and a general physical examination of the woman and her partner provide the basis for selecting diagnostic studies (Table 54-1). The possibility of medical, genetic, or gynecologic diseases is explored before tests are performed to determine problems affecting general health and fertility. These tests include hormone levels, ovulatory studies, tubal patency studies, and postcoital studies. Other screening tests for infertility include semen analysis and pelvic ultrasound.

Ovulatory Studies. A basal body temperature record is kept to determine whether there is regular ovulation. The woman is instructed to take and graph her temperature, referred to as basal body temperature, on awakening before any activity. As ovulation approaches, the production of estrogen increases, which may cause a drop in temperature of about 2°F. When ovulation occurs, progesterone is produced, causing a rise in temperature. Thus a temperature graph helps detect ovulation and suggests the timing of intercourse if pregnancy is desired. Ovulation prediction kits are now available for use by women at home. Other tests for ovulation include cervical and vaginal smears, endometrial biopsy, and plasma progesterone levels.

Tubal Patency Studies. Tubal factors (occlusion or deformity) are most commonly assessed using a hysterosalpingogram. This procedure consists of the radiographic visualization of the uterus and fallopian tubes by injecting a radiopaque dye through the cervix. Tubal patency, shape, position, and any distortions of the endometrial cavity can be determined. Laparoscopy may be used when hysterosalpingogram is contraindicated or other pelvic pathologic conditions appear likely.

Postcoital Studies. A postcoital test can determine whether the cervical environment is favorable for the sperm. The couple is asked to have intercourse about the time ovulation is expected and 2 to 12 hours before the office visit. Douching or bathing should be avoided before the test. The cervical and vaginal secretions are aspirated and examined for the number and motility of sperm present.

NURSING AND COLLABORATIVE MANAGEMENT
INFERTILITY

The management of infertility problems depends on the cause. If infertility is secondary to an alteration in ovarian function, supplemental hormone therapy to restore and maintain ovulation may be used. Drug therapy to treat infertility is presented in Table 54-2. Chronic cervicitis and inadequate estrogenic stimulation are cervical factors causing infertility. Antibiotic therapy is indicated for cervicitis. Inadequate estrogenic stimulation is treated using estrogen.

When a couple has not succeeded in conceiving while under infertility management, an option is intrauterine insemination with sperm from the partner or a donor. If this technique does not succeed, assisted reproductive technologies (ARTs) may be used. ARTs include in vitro fertilization (IVF), gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), donor gametes, and embryo cryopreservation. IVF is the removal of mature oocytes from the woman's ovarian follicle via laparoscopy, followed by in vitro fertilization of the ova with the partner's sperm. When fertilization and cleavage have occurred, the resulting embryos are transferred into the woman's uterus. The procedure requires 2 to 3 days to complete and is used in cases of fallopian tube obstruction, diminished sperm count, and unexplained infertility. Frequently, multiple attempts are

needed for successful implantation. IVF is financially costly and emotionally stressful.[3]

Assist women experiencing infertility by providing information about the physiology of reproduction and the infertility evaluation, and by addressing the psychologic and social distress that can accompany infertility. Reducing psychologic stress can improve the emotional climate, making it more conducive to achieving a pregnancy.

Teaching and providing emotional support are major responsibilities throughout infertility testing and treatment. Feelings of anger, frustration, grief, and helplessness may heighten as additional diagnostic tests are performed. Infertility can generate great tension in a marriage as the couple exhausts financial and emotional resources. Few insurance carriers cover the high cost of infertility testing and treatment. Encourage couples to participate in a support group for infertile couples, as well as individual therapy.

ABORTION

An **abortion** is the loss or termination of a pregnancy before the fetus has developed to a state of viability (ability to survive outside the uterus). Abortions are classified as *spontaneous* (those occurring naturally) or *induced* (those occurring as a result of mechanical or medical intervention). *Miscarriage* is the common term for the unintended loss of a pregnancy.

Spontaneous Abortion

Spontaneous abortion is the natural loss of pregnancy before 20 weeks of gestation. Fetal chromosomal anomalies may account for many miscarriages before 8 weeks of gestation. Other causes of spontaneous abortions include endocrine abnormalities, maternal infection, acquired anatomic abnormalities (e.g., uterine fibroids, endometriosis), immunologic factors, and environmental factors. About 10% to 15% of all pregnancies end as a result of spontaneous abortion.

Uterine cramping coupled with vaginal bleeding often indicates a spontaneous abortion. Serial measurements of serum β-human chorionic gonadotropin (β-hCG) hormone and vaginal ultrasound examination of the pelvis are the most reliable indicators of viability of the pregnancy.

Treatment to prevent a possible spontaneous abortion is limited. Although bed rest and avoidance of vaginal intercourse are often recommended, there is no evidence that these measures improve the outcome. The woman is advised to report any bleeding to her health care provider. Most women proceed to abortion regardless of treatment. If the products of conception do not pass completely or bleeding becomes excessive, a *dilation and curettage* (D&C) procedure is generally performed.[4] The D&C involves dilating the cervix and scraping the endometrium of the uterus to empty the contents of the uterus.

Women who are experiencing bleeding and cramping during pregnancy may be admitted to the hospital. Vital signs and estimated blood loss are monitored. Women are distressed and experience both physical and emotional pain. Arrange for someone to stay with the patient, since emotional support is important. Be aware of the grieving process that results from the loss of a pregnancy.

Induced Abortion

Induced abortion is an intentional or elective termination of a pregnancy. Induced abortion is done for personal reasons (at the request of the woman) and for medical reasons. Several techniques are used to induce abortion, including menstrual extraction, suction curettage, dilation and evacuation (D&E), and drug therapy (Table 54-3). Deciding on which technique to use to terminate a pregnancy depends on the gestational age (length of the pregnancy) and the woman's condition. Suction curettage may be performed up to 14 weeks of gestation and accounts for more than 90% of abortion procedures.

Drug therapy is another method to induce abortion (medical abortion) early in pregnancy. These agents must be given within the first 49 days of pregnancy (day 1 being the first day of the last menstrual period).

Once the decision is made to have an abortion, the woman and her significant others need support and acceptance.

TABLE 54-3 METHODS FOR INDUCING ABORTION

Method	Length of Pregnancy	Description
Early Abortion		
Menstrual extraction	Usually up to 2 wk after first missed period	Catheter is inserted through cervix into uterus, and suction is applied. Endometrium and contents of uterus are aspirated.
Suction aspiration (curettage)	Up to 14 wk	Cervix is usually dilated, uterine aspirator is introduced, and suction is applied, removing endometrial tissue and implanted pregnancy.
Dilation and evacuation (D&E)	10-16 wk (approximate)	Cervix is dilated, and products of conception are removed by vacuum cannula and use of other instruments as needed.
mifepristone (Mifeprex, RU-486) with misoprostol (Cytotec)	Up to 7 wk	Mifepristone is administered orally. Misoprostol (prostaglandin) is administered orally or intravaginally 2 days later.
methotrexate with misoprostol	Up to 7 wk	Methotrexate is administered intramuscularly. Misoprostol is given intravaginally 5-7 days later.
Late Abortion		
Instillation of Drugs		
Hypertonic saline solution	After 16 wk	About 200 mL of amniotic fluid is withdrawn, with similar amount of 20% normal saline solution injected. Uterus is irritated and begins to contract within 12-36 hr. Contractions may be assisted with IV oxytocin.
Prostaglandins • carboprost (Hemabate) • dinoprostone (Prostin E2, Cervidil)	After 16 wk	Amniocentesis is done, and prostaglandin is inserted into amniotic sac, resulting in stimulation of smooth muscle of uterus. Expulsion of uterine contents occurs within 24 hr.
Hysterotomy	16-20 wk	Miniature cesarean delivery is performed. Incision is made into uterus and contents are removed.

Prepare the patient for what to expect both emotionally and physically. Grief and sadness are normal emotions after an abortion. The patient needs to understand the procedure, including instructions for preprocedure and postprocedure care. Your caring attitude can be a positive factor in the patient's experience.

After the procedure, teach the patient the signs and symptoms of possible complications, such as abnormal vaginal bleeding, severe abdominal cramping, fever, and foul-smelling drainage. Also stress to the patient to avoid intercourse and vaginal insertions until reexamination, which needs to be in 2 weeks. Contraception can be started the day of the procedure or during the patient's return visit in accordance with her needs and desires.

PROBLEMS RELATED TO MENSTRUATION

The normal menstrual cycle is discussed in Chapter 51. The hormonal changes related to the menstrual cycle are shown in Fig. 51-7. Menstruation may be irregular during the first few years after menarche and the years preceding menopause. Once established, a woman's menstrual cycles usually have a predictable pattern. However, considerable normal variation exists among women in cycle length and in duration, amount, and character of the menstrual flow (see Table 51-2).

PREMENSTRUAL SYNDROME

Premenstrual syndrome (PMS) is a symptom complex related to the luteal phase of the menstrual cycle. The symptoms can be severe enough to impair interpersonal relationships or interfere with usual activities. Because many symptoms may be associated with PMS, it is difficult to define. However, PMS symptoms always occur cyclically during the luteal phase before the onset of menstruation and are not present at other times of the month. About 40% of all women have been significantly affected by PMS during their lifetime.[5]

Etiology and Pathophysiology

The etiology and pathophysiology of PMS are not well understood. It may have a biologic trigger with compounding psychosocial factors. Neurotransmitters, such as serotonin, could also be involved. Some women may have a genetic predisposition to PMS. Other proposed causes of PMS include hormone imbalance and nutritional deficiencies. *Premenstrual dysphoric disorder* (PMDD) is the term applied when women with PMS have a severe mood disorder.

Clinical Manifestations

PMS is extremely variable in its clinical manifestations between women and, for an individual woman, from one cycle to another. Common physical symptoms include breast discomfort, peripheral edema, abdominal bloating, sensation of weight gain, episodes of binge eating, and migraine headache. Abdominal bloating and breast swelling are caused by fluid shifts because total body weight does not generally change. Anxiety, depression, irritability, and mood swings are some of the emotional symptoms that women may experience.

Diagnostic Studies and Collaborative Care

PMS can be diagnosed only when other possible causes for the symptoms have been ruled out. A focused health history and physical examination are done to identify any underlying conditions such as thyroid dysfunction, uterine fibroids, or depression that may account for the symptoms. No definitive diagnostic test is available for PMS. When PMS or PMDD is a possible diagnosis, a woman is given a symptom diary to record her symptoms prospectively for two or three menstrual cycles. Diagnosis is based on an evaluation of the woman's symptoms.

TABLE 54-4 COLLABORATIVE CARE

Premenstrual Syndrome (PMS)

Diagnostic
- History and physical examination
- Symptom diary

Collaborative Therapy
- Stress management and relaxation therapy
- Nutritional therapy
- Aerobic exercise
- Drug therapy
  - Diuretics
  - Prostaglandin inhibitors (e.g., ibuprofen [Advil, Motrin])
  - Selective serotonin reuptake inhibitors (e.g., sertraline [Zoloft])
  - Combined oral contraceptives

Nondrug and drug strategies can relieve some PMS symptoms (Table 54-4). However, no single treatment is available. The goal of treatment is to reduce the severity of symptoms and enhance the woman's sense of control and quality of life.

Several conservative approaches to managing PMS symptoms are considered helpful, including stress management, diet changes, exercise, education, and counseling. Techniques for stress reduction include yoga, meditation, and biofeedback. To decrease autonomic nervous system arousal, women should avoid caffeine, reduce dietary intake of refined carbohydrates, exercise on a regular basis, and practice relaxation techniques. Eating complex carbohydrates with high fiber, foods rich in vitamin B_6, and sources of tryptophan (dairy and poultry) are thought to promote serotonin production, which improves the symptoms. Vitamin B_6 may be found in such foods as pork, milk, and legumes.

Exercise results in a release of endorphins, leading to mood elevation. Aerobic exercise can also have a relaxing effect. Because fatigue tends to exaggerate the symptoms of PMS, adequate rest in the premenstrual period is a priority.

Explanations about PMS help the woman understand the complexity of the disorder and ways that she can regain a sense of control. Assure the patient that her symptoms are real, PMS exists, and she is not "crazy." Acknowledgment that she has PMS can itself be therapeutic. Teaching the woman's partner about the nature of PMS helps the partner better understand PMS and its effects.

Drug Therapy. Drug therapy is considered when symptoms persist or interfere with daily functioning. Currently no single drug can treat all the symptoms associated with PMS. One therapy may be tried for a time; if no improvement is noted, another approach is tried. Many treatments are symptom specific. For fluid retention, diuretics such as spironolactone (Aldactone) are used. For reducing cramping pain, backache, and migraine headache, prostaglandin inhibitors such as ibuprofen (Motrin, Advil) are used. To improve negative mood, vitamin B_6 supplementation (50 mg/day) may be used. Calcium and magnesium supplementation may also be effective in alleviating psychologic and physiologic symptoms. For anxiety, buspirone

(BuSpar) taken during the luteal phase has helped some women. Women with PMDD may benefit from antidepressants, including fluoxetine (Prozac, Sarafem) and tricyclic antidepressants (e.g., amitriptyline [Elavil]).

Selective serotonin reuptake inhibitors (SSRIs) (e.g., sertraline [Zoloft]) have provided significant relief to women with severe PMS. Other treatments include oral contraceptives containing estrogen and progesterone. Evening primrose oil may help in reducing menstrual cramping for some women.

DRUG ALERT: Oral Contraceptives (Both Estrogen and Progesterone)

- May increase the risk of cervical, liver, and perhaps breast cancer
- May elevate blood pressure and cholesterol (related to estrogen)
- Increase risk of cardiac disease if patient is also smoking
- May impair effectiveness of concurrent use of antibiotics
- Are contraindicated in patients with migraine headaches and depression

DYSMENORRHEA

Dysmenorrhea is abdominal cramping pain or discomfort associated with menstrual flow. The degree of pain and discomfort varies with the individual. The two types of dysmenorrhea are *primary* (no pathologic condition exists) and *secondary* (pelvic disease is the underlying cause).[5] Dysmenorrhea is one of the most common gynecologic problems.

Etiology and Pathophysiology

Primary dysmenorrhea is not a disease. It is caused by an excess of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and/or an increased sensitivity to it. Stimulation of the endometrium by estrogen, followed by progesterone, results in a dramatic increase in prostaglandin production by the endometrium. With the onset of menses, degeneration of the endometrium releases prostaglandin. Locally, prostaglandins increase myometrial contractions and constriction of small endometrial blood vessels. This causes tissue ischemia and increased sensitization of the pain receptors, resulting in menstrual pain. Primary dysmenorrhea begins in the first few years after menarche, typically with the onset of regular ovulatory cycles.

Secondary dysmenorrhea is usually acquired after adolescence, occurring most commonly at 30 to 40 years of age. Common pelvic conditions that cause secondary dysmenorrhea include endometriosis, chronic pelvic inflammatory disease, and uterine fibroids. Because secondary dysmenorrhea can be caused by many conditions, symptoms vary. However, painful menses is present in all situations.

Clinical Manifestations

Primary dysmenorrhea starts 12 to 24 hours before the onset of menses. The pain is most severe the first day of menses and rarely lasts more than 2 days. Characteristic manifestations include lower abdominal pain that is colicky in nature, frequently radiating to the lower back and upper thighs. The abdominal pain is often accompanied by nausea, diarrhea, fatigue, and headache.

Secondary dysmenorrhea usually occurs after the woman has experienced problem-free periods for some time. The pain, which may be unilateral, is generally more constant and continues longer than in primary dysmenorrhea. Depending on the cause, symptoms such as *dyspareunia* (painful intercourse), painful defecation, or irregular bleeding may occur at times other than menstruation.

NURSING AND COLLABORATIVE MANAGEMENT DYSMENORRHEA

Evaluation begins with distinguishing primary from secondary dysmenorrhea. Obtain a complete health history with special attention to menstrual and gynecologic history. A pelvic examination is performed by the health care provider. The probable diagnosis is primary dysmenorrhea if the history reveals an onset shortly after menarche, symptoms are associated only with menses, and the pelvic examination is normal. If a specific cause of dysmenorrhea is evident, the diagnosis is secondary dysmenorrhea.

Treatment for primary dysmenorrhea includes heat, exercise, and drug therapy. Heat is applied to the lower abdomen or back. Regular exercise is beneficial because it may reduce endometrial hyperplasia and subsequent prostaglandin production. Primary drug therapy is nonsteroidal antiinflammatory drugs (NSAIDs) such as naproxen (Naprosyn), which has antiprostaglandin activity. NSAIDs should be started at the first sign of menses and continued every 4 to 8 hours to maintain a sufficient level of the drug to inhibit prostaglandin synthesis for the usual duration of discomfort.

Oral contraceptives may also be used. They decrease dysmenorrhea by reducing endometrial hyperplasia. Acupuncture and transcutaneous nerve stimulation may be used for women who have inadequate relief from medications or who prefer not to take medications. Patients who are unresponsive to these treatments should be evaluated for chronic pelvic pain (discussed later in this chapter on p. 1289).

Treatment of secondary dysmenorrhea depends on the cause. Some individuals with secondary dysmenorrhea are helped by the approaches used for primary dysmenorrhea.

Instruct women on why dysmenorrhea occurs and how to treat it. This will provide women with a foundation for coping with this common problem and increase feelings of control and self-reliance.

Women often ask what can be done for minor discomforts associated with menstrual cycles. Advise women that during acute pain, relief may be obtained by applying heat to the abdomen or back and taking NSAIDs for analgesia. Also suggest noninvasive pain-relieving practices such as relaxation breathing and guided imagery.

Other health care measures to reduce the discomfort of dysmenorrhea include regular exercise and proper nutritional habits. Avoiding constipation, maintaining good body mechanics, and eliminating stress and fatigue, particularly before menstrual periods, can also decrease discomfort. Staying active and interested in activities may also help.

ABNORMAL VAGINAL BLEEDING

Abnormal vaginal or uterine bleeding is a common gynecologic concern. Abnormalities include *oligomenorrhea* (long intervals between menses, generally greater than 35 days), **amenorrhea** (absence of menstruation), *menorrhagia* (excessive or prolonged menstrual bleeding), and *metrorrhagia* (irregular bleeding or bleeding between menses). The cause of abnormal bleeding may vary from anovulatory menstrual cycles to more serious conditions such as ectopic pregnancy or endometrial cancer.

The woman's age provides direction for identifying the cause of bleeding. For example, a postmenopausal woman with

abnormal bleeding must always be evaluated for endometrial cancer but does not need to be evaluated for possible pregnancy. For a 20-year-old woman with abnormal bleeding, the possibility of pregnancy must always be considered, and endometrial cancer would be unlikely.

Abnormal bleeding may be caused by dysfunction of the hypothalamic-pituitary-ovarian axis such as a pituitary adenoma. Another possible cause is infection. Changes in lifestyle such as marriage, recent moves, a death in the family, financial stress, and other emotional crises can also cause irregular bleeding. Because psychologic factors can influence endocrine function, they should be considered when the patient is evaluated.

Types of Irregular Bleeding

Oligomenorrhea and Amenorrhea. Anovulation is the most common reason for missing menses once pregnancy has been ruled out. Additional causes of amenorrhea are listed in Table 54-5. *Primary amenorrhea* refers to the failure of menstrual cycles to begin by age 16 years or by age 14 years if secondary sex characteristics are present. *Secondary amenorrhea* refers to the cessation of menstrual cycles once they had been established.

Ovulation is often erratic for several years after menarche and before menopause. Thus oligomenorrhea due to anovulation is common for women at the beginning and end of menstruation. In anovulatory cycles the corpus luteum that produces progesterone does not form. This may result in a situation referred to as *unopposed estrogen*. When unopposed by progesterone, estrogen can cause excessive buildup of the endometrium. Persistent overgrowth of the endometrium increases a woman's risk for endometrial cancer. To reduce this risk, progesterone or oral contraceptives are prescribed to ensure that the patient's endometrial lining is shed at least four to six times per year.

Menorrhagia. The excessive bleeding associated with menorrhagia can be characterized as an increased duration (more than 7 days), increased amount (more than 80 mL), or both. Anovulatory uterine bleeding is the most common cause of menorrhagia. An unopposed estrogen state continues to build up the endometrium until it becomes unstable, resulting in menorrhagia. For young women with excessive bleeding, clotting disorders must be considered. Uterine fibroids (also called *leiomyomas*) and endometrial polyps are common causes of menorrhagia for women in their childbearing years.[6]

TABLE 54-5 CAUSES OF AMENORRHEA

Natural Amenorrhea
- Pregnancy
- Breastfeeding
- Menopause

Medications
- Antipsychotics
- Chemotherapy
- Antidepressants

Lifestyle
- Stress
- Excessive exercise
- Low body weight
- Acute and chronic illness

Hormonal Imbalance
- Polycystic ovary syndrome
- Pituitary tumors
- Premature menopause

Structural Problems
- Uterine scarring
- Structural abnormalities of vagina
- Damage to ovaries or uterus from radiation

Metrorrhagia. Metrorrhagia, also referred to as *spotting* or *breakthrough bleeding,* is bleeding between menstrual periods. For all reproductive-age women, pregnancy complications such as spontaneous abortion or ectopic pregnancy must be considered as a possible cause. Other causes include cervical or endometrial polyps, infection, and cancer. Spotting is common during the first three cycles of oral contraceptives. If spotting continues beyond that, a different pill formulation can be prescribed once other causes of metrorrhagia have been ruled out. Spotting with long-acting progestin therapy (e.g., Mirena intrauterine device [IUD]) or progestin-only pills (medroxyprogesterone [Depo-Provera, Provera]) is also common. For postmenopausal women, endometrial cancer must be considered whenever spotting is experienced. In postmenopausal women, exogenous estrogen administration during hormone therapy is a common cause of metrorrhagia.

Diagnostic Studies and Collaborative Care

Because abnormal vaginal bleeding has multiple causes, the diagnostic and collaborative care varies. A health history and physical examination directed at the most likely causes of vaginal bleeding for the woman's age-group is the first step. These findings provide the basis for selecting laboratory tests and diagnostic procedures. Treatment depends on the etiology of the problem (e.g., menorrhagia, amenorrhea), degree of threat to the patient's health, and whether children are desired in the future.

Combined oral contraceptives may be prescribed for a woman with amenorrhea to ensure regular shedding of the endometrium if she also wants contraception. Tranexamic acid (Lysteda) may be used to treat heavy menstrual bleeding. This drug stabilizes a protein that helps blood to clot. Side effects may include headache, back pain, abdominal pain, muscle and joint pain, anemia, and fatigue. Women using hormonal contraception should take tranexamic acid only if they have a strong medical need, since there is an increased risk of blood clots and stroke. Estradiol valerate/dienogest (Natazia) may be given to women with heavy menstrual bleeding who desire an oral contraceptive to prevent pregnancy.

The treatment goal for women with menorrhagia is to minimize further blood loss. If menorrhagia is the result of anovulatory cycles, the endometrium must be stabilized by a combination of oral estrogen and progesterone.

Balloon thermotherapy is a technique for menorrhagia that involves the introduction of a soft, flexible balloon into the uterus. The balloon is then inflated with sterile fluid (Fig. 54-1). The fluid in the balloon is heated and maintained for 8 minutes, thus causing ablation (removal) of the uterine lining. When the treatment is completed, the fluid is withdrawn from the balloon and the catheter is removed from the uterus. The uterine lining sloughs off in the next 7 to 10 days. Uterine balloon thermotherapy is contraindicated for women who desire to maintain their fertility and for women with any suspected uterine abnormalities such as fibroids, suspected endometrial cancer, prior cesarean delivery, or myomectomy. With severe bleeding, hospitalization is indicated. All patients with menorrhagia should be evaluated for anemia and treated as indicated.

Surgical Therapy. Surgery may be indicated depending on the underlying cause of the abnormal vaginal bleeding. D&C is used only in cases of acute excess bleeding or for older women when endometrial biopsy and ultrasonography have not pro-

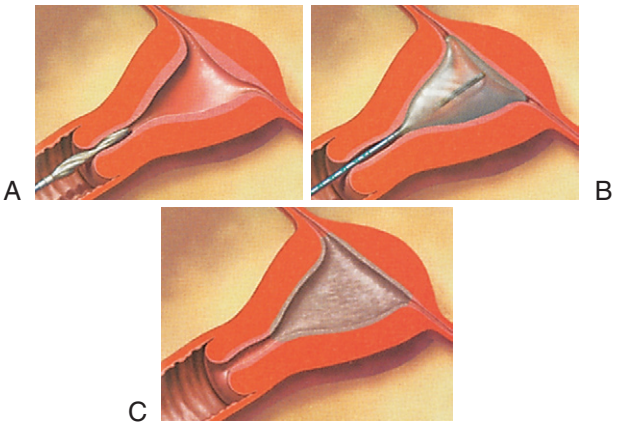

FIG. 54-1 Balloon thermotherapy for treatment of menorrhagia. **A,** Balloon-tipped catheter is inserted into the uterus through the vagina and the cervix. **B,** The balloon is inflated with a sterile fluid that expands to fit the size and shape of the uterus. The fluid is heated to 188° F (87° C) and maintained for 8 minutes while the uterine lining is treated. **C,** Fluid is withdrawn from the balloon and the catheter is removed. (Courtesy Ethicon, Inc, Cornelia, Ga.)

vided the necessary diagnostic information. Endometrial ablation for menorrhagia may be done by laser, thermal balloon, cryotherapy, or microwave energy for patients who do not want to have children.

If menorrhagia is caused by uterine fibroids, a **hysterectomy** (surgical removal of the uterus) may be performed. A *myomectomy* (removal of fibroids without removal of the uterus) may be performed if the patient wants to preserve her uterus. The myomectomy is done via laparotomy, laparoscopy, or hysteroscopy. Hormonal regimens and embolization of the blood vessels supplying the fibroid tumor are other treatment options.

NURSING MANAGEMENT
ABNORMAL VAGINAL BLEEDING

Teaching women about the characteristics of the menstrual cycle will enable them to identify normal variations. Table 51-2 includes characteristics of the menstrual cycle and related patient teaching. This knowledge can decrease apprehension and dispel misconceptions about the menstrual cycle. If the patient's menstrual cycle pattern does not fall within the normal range, urge her to discuss this with her health care provider.

The selection of internal or external sanitary protection is a matter of personal preference. Tampons are convenient and make menstrual hygiene easier, whereas pads may provide better protection. Using a combination of tampons and pads and avoiding prolonged use of superabsorbent tampons may decrease the risk of *toxic shock syndrome* (TSS). TSS is an acute life-threatening condition caused by a toxin from *Staphylococcus aureus*. TSS causes high fever, vomiting, diarrhea, weakness, myalgia, and a sunburn-like rash.[7]

Whenever excessive, the amount of the vaginal bleeding should be assessed as accurately as possible. The patient should record and report the number and size of pads or tampons used and the degree of saturation. The patient's fatigue level, along with variations in blood pressure and pulse, should be monitored because anemia and hypovolemia may be present. For the patient requiring a surgical procedure, provide the appropriate preoperative and postoperative care.

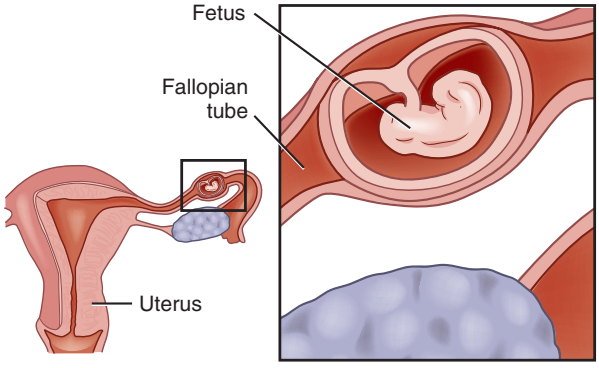

FIG. 54-2 Ectopic pregnancy occurring in the fallopian tube.

ECTOPIC PREGNANCY

An **ectopic pregnancy** is the implantation of the fertilized ovum anywhere outside the uterine cavity. Approximately 3% of all pregnancies are ectopic, and approximately 98% of these occur in the fallopian tube[8] (Fig. 54-2). The remaining 2% to 3% may be ovarian, abdominal, or cervical. Ectopic pregnancy is a life-threatening condition. Earlier identification has contributed to decreased mortality rates.

Etiology and Pathophysiology

Any blockage of the fallopian tube or reduction of tubal peristalsis that impedes or delays the zygote passing to the uterine cavity can result in tubal implantation. After implantation, the growth of the gestational sac expands the tubal wall. Eventually the tube ruptures, causing acute peritoneal symptoms. Less acute symptoms usually begin within 6 to 8 weeks after the last normal menstrual period and weeks before rupture would occur.

Risk factors for ectopic pregnancy include a history of pelvic inflammatory disease, prior ectopic pregnancy, current progestin-releasing IUD, progestin-only birth control failure, and prior pelvic or tubal surgery. Additional risk factors for ectopic pregnancy include procedures used in infertility treatment, including IVF, embryo transfer, and ovulation induction.

Clinical Manifestations

The classic manifestations of ectopic pregnancy are abdominal or pelvic pain, missed menses, and irregular vaginal bleeding. Other manifestations include morning sickness, breast tenderness, gastrointestinal disturbance, malaise, and syncope. Pain is almost always present and is caused by distention of the fallopian tube. It may start unilaterally and then spread to become bilateral. The character of the pain varies among women and can be colicky or vague. If tubal rupture occurs, the pain is intense and may be referred to the shoulder as a result of irritation of the diaphragm by blood released into the abdominal cavity. Symptom severity does not necessarily correlate with the extent of external bleeding present. With rupture, the risk of hemorrhage and hypovolemic shock is present. Suspected rupture is treated as an emergency.

The vaginal bleeding that may accompany ectopic pregnancy is usually described as spotting. However, bleeding may be heavier and can be confused with menses.

Diagnostic Studies

Ectopic pregnancy can be a diagnostic challenge because of its similarity to other pelvic and abdominal disorders, such as

salpingitis, spontaneous abortion, ruptured ovarian cyst, appendicitis, and peritonitis. A serum (radioimmunoassay) pregnancy test should be performed. If the test is negative, an ectopic pregnancy is not likely. If ectopic pregnancy cannot be excluded by the pregnancy test, further evaluation is warranted. If the patient is in stable condition, a combination of serial measurements of serum β-hCG and vaginal ultrasonography is used.[9] Absence of a normal intrauterine pregnancy means that the diagnosis is probably a spontaneous abortion or an ectopic pregnancy. With a spontaneous abortion, serial serum β-hCG levels will decrease over time. A complete blood count is obtained when there is any concern regarding the amount of blood loss or if surgery is contemplated.

NURSING AND COLLABORATIVE MANAGEMENT
ECTOPIC PREGNANCY

Surgery remains the primary approach for treating ectopic pregnancies and should be performed immediately. However, medical management with methotrexate (Folex) is being used with increasing success in patients who are hemodynamically stable and have a mass less than 3 cm in size.[10] A conservative surgical approach limits damage to the reproductive system as much as possible. Removal of the fetus from the tube is preferred to removing the tube. Laparoscopy is preferable to laparotomy because it decreases blood loss and the length of the hospital stay (Fig. 54-3). If the tube ruptures, conservative surgical approaches may not be possible. The patient may need a blood transfusion and supplemental IV fluid therapy to relieve shock and restore a satisfactory blood volume for safe anesthesia and surgery. The use of laparoscopy has resulted in fewer repeated ectopic pregnancies and a higher rate of future successful pregnancies.

Nursing care depends on the patient's condition. Before the diagnosis has been confirmed, be alert to patient signs of increasing pain and vaginal bleeding, which may indicate that the tube has ruptured. Monitor vital signs closely and observe for signs of shock. Give explanations and prepare the patient for diagnostic procedures when appropriate. Preparation of the patient for abdominal surgery may follow rapidly. Provide reassurance and support for the surgery to the patient and her family. Postoperatively, the patient may express a fear of future ectopic pregnancies and have many questions about the impact of this experience on her fertility.

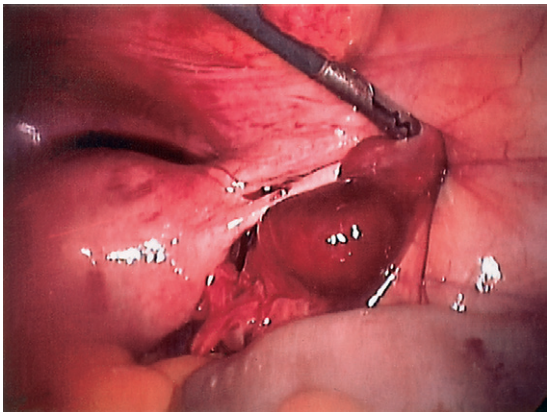

FIG. 54-3 Laparoscopic treatment of ectopic pregnancy in the right fallopian tube.

PERIMENOPAUSE AND POSTMENOPAUSE

Perimenopause is a normal life transition that begins with the first signs of change in menstrual cycles and ends after cessation of menses.[11] **Menopause** is the physiologic cessation of menses associated with declining ovarian function. It is usually considered complete after 1 year of *amenorrhea* (absence of menstruation). Menopause starts gradually and is usually associated with changes in menstruation, including menstrual flows that are increased, decreased, or irregular. Eventually complete cessation of menses occurs. *Postmenopause* is a term that refers to the time in a woman's life after menopause.

The age at which menopause occurs ranges from 44 to 55 years, with an average age of 51 years. Menopause may occur earlier due to illness, surgical removal of the uterus or both ovaries, side effects of radiation therapy or chemotherapy, or drugs. The age at which menopause occurs is not affected by age at menarche, physical characteristics, number of pregnancies, date of last pregnancy, or oral contraceptive use. However, genetic factors, autoimmune conditions, cigarette smoking, and racial or ethnic factors are related to an earlier age at menopause.

Changes within the ovary start the cascade of events that finally result in menopause. The regression of the follicles within each ovary begins at puberty and accelerates after age 35. With age, fewer follicles remain that are responsive to follicle-stimulating hormone (FSH). FSH normally stimulates the dominant follicle to secrete estrogen. When the follicles can no longer respond to FSH, the production of estrogen and progesterone from the ovary declines. However, perimenopausal women can get pregnant until menopause has occurred, since many women have long anovulatory cycles interspersed with shorter, ovulatory cycles.

With decreased ovarian function, decreased levels of estrogen cause a gradual increase in FSH and luteinizing hormone (LH) as a result of the negative feedback process. By the time menopause occurs, there is a 10- to 20-fold increase in FSH. The elevated FSH level may take several years to return to the premenopausal level. The reduced estrogen level also causes a decrease in the frequency of ovulation and results in changes in the reproductive organs and tissues (e.g., atrophy of vaginal tissue).

Clinical Manifestations

Clinical manifestations of perimenopause and postmenopause are presented in Table 54-6. Perimenopause is a time of erratic hormonal fluctuation. Irregular vaginal bleeding is common.

TABLE 54-6 MANIFESTATIONS OF PERIMENOPAUSE AND POSTMENOPAUSE

Perimenopause	Postmenopause
• Irregular menses	• Cessation of menses
• Occasional vasomotor symptoms	• Vasomotor instability (hot flashes and night sweats)
• Atrophy of genitourinary tissue with decreased support	• Atrophy of genitourinary tissue (e.g., vaginal epithelium)
• Stress and urge incontinence	• Stress and urge incontinence
• Osteoporosis	• Breast tenderness
• Mood changes	

TABLE 54-7 MANIFESTATIONS OF ESTROGEN DEFICIENCY

Vasomotor
- Hot flashes
- Night sweats

Genitourinary
- Atrophic vaginitis
- Dyspareunia secondary to poor lubrication
- Incontinence

Psychologic
- Emotional lability
- Change in sleep pattern
- Decreased REM sleep

Musculoskeletal
- Increased fracture rate, especially vertebral bodies but also humerus, distal radius, and upper femur

Cardiovascular
- Decreased high-density lipoproteins (HDLs)
- Increased low-density lipoproteins (LDLs)

Other
- Diminished collagen content of skin
- Breast tissue changes

REM, Rapid eye movement.

With decreasing estrogen, hot flashes and other symptoms begin. The signs and symptoms of diminished estrogen are listed in Table 54-7. The loss of estrogen plays a significant role in the cause of age-related alterations. Changes most critical to a woman's well-being are the increased risks for coronary artery disease (CAD) and osteoporosis (secondary to bone density loss). Other changes include a redistribution of fat, a tendency to gain weight more easily, muscle and joint pain, loss of skin elasticity, changes in hair amount and distribution, and atrophy of external genitalia and breast tissue.

Hallmarks of perimenopause include *vasomotor instability* (hot flashes) and irregular menses. A hot flash (occurs in up to 80% of all women) is described as a sudden sensation of intense heat along with perspiration and flushing.[12] These sensations may last from several seconds to 5 minutes and occur most often at night, thereby disturbing sleep. The cause of hot flashes, or vasomotor instability, is not clearly understood. It has been theorized that temperature regulators in the brain are in proximity to the area where gonadotropin-releasing hormone (GnRH) is released. The lowered estrogen levels are correlated with dilation of cutaneous blood vessels, resulting in hot flashes and increased sweating. The more sudden the withdrawal of estrogen (e.g., surgical removal of the ovaries), the more likely the symptoms will be severe if no hormone replacement is provided. Symptoms usually subside over time and typically last from 5 to 10 years with or without treatment.[13] Hot flashes can be triggered by stress and situations that affect body temperature, such as eating a hot meal, hot weather, or warm clothing. Women who smoke are at higher risk for hot flashes because smoking affects estrogen metabolism. African American women report the highest incidence of hot flashes, whereas Asian American women report the lowest number.[13]

Atrophic vaginal changes secondary to decreased estrogen include thinning of the vaginal mucosa and disappearance of rugae. Vaginal secretions also decrease and become more alkaline. As a result of these changes, the vagina is easily traumatized and more susceptible to infection, including a higher risk for human immunodeficiency virus (HIV) infection if exposed. *Dyspareunia* (painful intercourse) may also occur. This can lead to unnecessary and premature cessation of sexual activity. Dryness is a problem that can be corrected with water-soluble lubricants or, if needed, with hormonal creams or systemic hormone therapy.

Atrophic changes in the lower urinary tract also occur with a decrease in estrogen. Bladder capacity decreases, and the bladder and urethral tissue lose tone. These changes can cause symptoms that mimic a bladder infection (e.g., dysuria, urgency, frequency) when no infection is present.

Whether decreasing estrogen causes the psychologic changes associated with perimenopause is unclear. Depression, irritability, and cognitive problems, which are often attributed to menopause, could result from life stressors or sleep deprivation from hot flashes. Depressive symptoms appear to improve when hormone levels stabilize.

Collaborative Care

The diagnosis of perimenopause should be made only after careful consideration of other possible causes for the woman's symptoms. Depression, thyroid dysfunction, anemia, or anxiety can cause the same symptoms. Review a woman's history of menstrual patterns as part of establishing the diagnosis. Because of the hormonal fluctuations that occur before menopause, routine testing of the serum FSH level to establish a diagnosis is not indicated.

Drug Therapy. Hormone therapy (HT) was once standard therapy in the United States for treating menopausal symptoms. HT includes estrogen for women without a uterus or estrogen and progesterone for women with a uterus. Findings from the Women's Health Initiative (WHI) clinical trials changed this practice.[14] The data showed that women who had taken estrogen plus progestin (Prempro) had an increased risk of breast cancer, stroke, heart disease, and emboli. However, these women had fewer hip fractures and a lower risk of developing colorectal cancer. Women who took only estrogen (Premarin) had an increased risk of stroke and emboli. However, these women had decreased risk for fractures with no increased risk for heart disease or breast or colorectal cancer. A recent systematic review has updated and validated the results of the WHI trials.[15]

If women wish to consider taking HT for the short-term treatment (4 to 5 years) of menopausal symptoms, the risks and benefits of therapy (e.g., minimizes bone loss, hot flashes, vaginal atrophic changes) should be considered carefully. The woman and her health care provider should thoroughly discuss the decision to take HT, and which ones to take. If a woman chooses to use HT, the lowest effective dose should be used. The age that a woman starts HT may determine her risk of heart disease. The risk appears to increase the further a woman moves away from menopause.

The side effects of estrogen include nausea, fluid retention, headache, and breast enlargement. Side effects of progesterone include increased appetite, weight gain, irritability, depression, spotting, and breast tenderness. A commonly used estrogen preparation is 0.625 mg of conjugated estrogen (Premarin) daily. For symptom relief, a higher dose may be needed. To receive the protective benefit of progesterone, 5 to 10 mg of medroxyprogesterone is indicated for 12 days of each month on a cyclic regimen, or 2.5 mg on a continuous regimen. If the estrogen is increased for symptom relief, the progesterone should also be increased. Other forms of progesterone include norethindrone (Aygestin) and micronized progesterone creams, dermal patches, gels, and lotions; rings placed around the cervix; and subcutaneous pellets. Vaginal creams are especially useful for urogenital symptoms (e.g., dryness). Transdermal estrogen (skin patch or spray [EvaMist]) has the advantage of bypassing the liver, but the disadvantage of causing skin irritation.

DRUG ALERT: Medroxyprogesterone (Depo-Provera, Provera)

- Report immediately the development of sudden loss of vision, severe headache, chest pain, hemoptysis, pain in calves (especially with swelling, redness), numbness in arm or leg, and abdominal pain or tenderness.

SSRI antidepressants, including paroxetine (Paxil), fluoxetine, and venlafaxine (Effexor), are an effective alternative to HT in reducing hot flashes. This effect is noted even if the user is not depressed. The mechanism of action is unknown. Clonidine (Catapres), an antihypertensive drug, and gabapentin (Neurontin), an antiseizure drug, have also been shown to relieve hot flashes.

Selective estrogen receptor modulators (SERMs), such as raloxifene (Evista), are also used to treat menopausal problems. These drugs have some of the positive benefits of estrogen, such as preventing bone loss, without the negative effects such as endometrial hyperplasia. Raloxifene competes with estrogen for estrogen receptor sites.[16] It decreases bone loss and serum cholesterol with minimal effects on breast and uterine tissue.

Bisphosphonates, including alendronate (Fosamax) and risedronate (Actonel), are also used to decrease the risk for osteoporosis in postmenopausal women. These drugs enhance bone mineral density by suppressing resorption. SERMs and bisphosphonates are discussed further in Chapter 64 with respect to their role in the management of osteoporosis.

Nonhormonal Therapy. Because of the risks associated with HT, many women try other therapies to relieve menopausal symptoms. Paroxetine (Brisdelle) is a newer nonhormonal treatment that may be used for moderate to severe hot flashes associated with menopause. This drug is a selective serotonin reuptake inhibitor.

Hot flash frequency and severity can be reduced through measures that lead to a decrease in heat production and an increase in heat loss. Keeping a cool environment and limiting caffeine and alcohol intake lower heat production. Relaxation techniques (e.g., relaxation breathing, imagery) may also help. To promote heat loss at night when hot flashes can disrupt sleep, increase air circulation in the room and avoid bedding that traps the heat (e.g., heavy quilts). Loose-fitting clothes do not retain body heat, whereas clothes with tight necks and wrists do. Cool cloths applied to flushed areas also aid in heat loss.

Daily intake of vitamin E in doses up to 800 IU may also help reduce hot flashes in some women. Changing sleep patterns may be helped by avoiding alcohol and controlling hot flashes. Relaxation techniques can promote a better night's sleep by decreasing anxiety. A regular moderate program (three to four times per week) of aerobic and weight-bearing exercises can slow the process of bone loss and a tendency toward weight gain.

Nutritional Therapy. Good nutrition can decrease the risk of cardiovascular disease and osteoporosis in addition to assisting with vasomotor symptoms. A daily intake of about 30 cal/kg of body weight is recommended. A decrease in metabolic rate and careless eating habits can cause the weight gain and fatigue often attributed to menopause. An adequate intake of calcium and vitamin D helps maintain healthy bones and counteracts loss of bone density. Postmenopausal women not receiving supplemental estrogen should have a daily calcium intake of at least 1500 mg, whereas those taking estrogen replacement need at least 1000 mg/day. Calcium supplements are best absorbed when taken with meals. Either dietary calcium or calcium supplements may be used (see Tables 64-14 and 64-15).

COMPLEMENTARY & ALTERNATIVE THERAPIES

Herbs and Supplements for Menopause

Herb	Scientific Evidence	Nursing Implications
Black cohosh	Mixed evidence for use in the treatment of menopausal symptoms*	• Generally well tolerated in recommended doses for up to 6 mo. • Should not be used in people with a liver disorder.
Soy	Mixed evidence for treatment of menopausal symptoms*	• Women with a history of breast, ovarian, or uterine cancer or endometriosis should consult their health care provider before using soy or soy products. • Soy may interact with warfarin. Patients taking warfarin should consult their health care provider before using soy or soy products.

*In general, the evidence for use of these herbs as treatments for menopause symptoms is limited by a lack of well-designed, controlled trials (*www.naturalstandard.com*).

The diet should be high in complex carbohydrates and vitamin B complex, especially B_6. Phytoestrogens (soy, tofu, chickpeas, sunflower seeds) have been used to reduce menopausal symptoms. Herbal remedies, such as black cohosh, have become popular in treating menopausal symptoms (see Complementary & Alternative Therapies box above). Consultation with an experienced herbal practitioner is recommended before initiating therapy.

NURSING MANAGEMENT
PERIMENOPAUSE AND POSTMENOPAUSE

Foster a positive image of perimenopause as a time of vitality and attractiveness. Perimenopause can provide women with a renewed incentive to enhance self-care and well-being. Provide teaching and reassurance to perimenopausal women who experience difficulty in managing their symptoms. Tell them that symptoms are normal and often are temporary. Discuss nondrug approaches to managing symptoms.

Dry skin can be improved by the use of moisturizing soaps and body lotions. Kegel exercises may help decrease stress incontinence (see Table 46-19). Sexual function can continue with little change in the vast majority of postmenopausal women. Cessation of menstruation and ability to bear children should not be equated with cessation of sexual capability. For some women, menopause may be liberating.

Femininity and libido do not disappear with menopause. A water-soluble lubricant (e.g., Replens, Astroglide, K-Y jelly) is often effective in managing atrophic changes in vaginal epithelium. An active sex life helps increase lubrication and maintains the pliability of vaginal tissues. Provide the patient with an opportunity to candidly discuss concerns related to sexual functioning.

CULTURALLY COMPETENT CARE

MENOPAUSE

Although all women experience menopause, the perception of menopause varies by culture. Ethnic groups have different traditions and beliefs regarding menopause, including the use of complementary and alternative therapies to manage symp-

toms.[17] Be aware of the attitudes and beliefs regarding menopause among women from various ethnic and cultural backgrounds. In many cultures, menopause is considered a normal part of aging, and little emphasis is placed on the physical and emotional symptoms that accompany the loss of fertility. In cultures where older adults are revered, menopause may be seen as a liberating transition to a state of being a "wise woman."

American culture generally has a negative attitude toward aging and places a high value on youth. Menopause is often considered a disorder that requires treatment. Menopausal symptoms may be viewed as troublesome, with a strong need to treat hot flashes and mood swings. Numerous substances, from HT to herbal preparations, are often used to treat menopausal symptoms.

Menopause is a milestone in a woman's life that is embedded in her own personality and her culture. Approaching the menopausal woman with this understanding is important to provide culturally competent care.

CONDITIONS OF VULVA, VAGINA, AND CERVIX

Etiology and Pathophysiology

Infection and inflammation of the vagina, cervix, and vulva commonly occur when the natural defenses of the acid vaginal secretions (maintained by sufficient estrogen levels) and the presence of *Lactobacillus* are disrupted. The woman's resistance may also be decreased as a result of aging, poor nutrition, and drugs that alter the bacterial flora or mucosa. Organisms gain entrance to the areas through contaminated hands, clothing, douching, and intercourse. Table 54-8 presents the causes, manifestations, diagnostic methods, and collaborative care of common infections and inflammations.

Most lower genital tract infections are related to sexual intercourse. Intercourse can transmit organisms, injure tissues, and alter the acid-base balance of the vagina. Vulvar infections caused by viruses such as herpes and genital warts can be sexually transmitted when no lesions are apparent. Oral contraceptives, antibiotics, and corticosteroids may produce changes in the vaginal pH and trigger an overgrowth of the organisms present. For example, *Candida albicans* may be present in small numbers in the vagina. An overgrowth of this organism causes vulvovaginitis.

Clinical Manifestations

Abnormal vaginal discharge and reddened vulvar lesions are common clinical manifestations. In addition to a thick white curdlike discharge, women with vulvovaginal candidiasis (VVC) often experience intense itching and dysuria, which is the result of urine coming into contact with fissures and irritated areas on the vulva. The hallmark of bacterial vaginosis is the fishy odor of the discharge. Women with cervicitis may notice spotting after intercourse.

Common vulvar lesions include herpes infection and genital warts. Initial or primary herpes infections may be extremely painful. Herpes begins as a small vesicle followed by a superficial red ulcer. Most herpes lesions are painful. Genital warts, caused by the human papillomavirus (HPV), vary in appearance. Irregularly shaped "cauliflower" lesions are common. Genital warts are painless unless traumatized. (Herpes infection and genital warts are discussed in Chapter 53.)

Postmenopausal women may develop gynecologic problems such as *lichen sclerosis*.[18] This chronic inflammatory condition is associated with intense itching in the genital skin area (e.g., labia minora, clitoris). The lesions are white with a "tissue

TABLE 54-8 INFECTIONS OF THE LOWER GENITAL TRACT

Infection and Etiology	Manifestations and Diagnostic Methods	Drug Therapy
Vulvovaginal Candidiasis (VVC) (Monilial Vaginitis)		
Candida albicans (fungus)	Commonly found in mouth, gastrointestinal tract, and vagina. Pruritus, thick white curdlike discharge. KOH microscopic examination: pseudohyphae, pH 4.0-4.7.	Antifungal agents (e.g., miconazole [Monistat], clotrimazole [Gyne-Lotrimin, Mycelex] [available over the counter, in cream or suppository]) Fluconazole (Diflucan).
Trichomonas Vaginitis		
Trichomonas vaginalis (protozoa)	Sexually transmitted. Pruritus, frothy greenish or gray discharge. Hemorrhagic spots on cervix or vaginal walls. Saline microscopic examination: swimming trichomonads, pH >4.5.	Metronidazole (Flagyl) for patient and partner.
Bacterial Vaginosis		
Gardnerella vaginalis *Corynebacterium vaginale*	Mode of transmission unclear. Watery discharge with fishy odor. May or may not have other symptoms. Saline microscopic examination: epithelial cells, pH >4.5.	Oral or vaginal metronidazole (Flagyl) or clindamycin (Clindesse). Examine and treat partner. Lactobacillus acidophilus taken orally by diet (e.g., yogurt, fermented soy products) or supplements can decrease unwanted vaginal bacteria.
Cervicitis		
Chlamydia trachomatis	Sexually transmitted; mucopurulent discharge with postcoital spotting from cervical inflammation. Culture for *Chlamydia* and *Neisseria gonorrhoeae*.	Azithromycin (Zithromax). Treat patient and partner.
Severe Recurrent Vaginitis		
C. albicans (most often)	May be indication of HIV infection. All women who are unresponsive to first-line treatment should be offered HIV testing.	Drug appropriate to opportunistic organism.

KOH, Potassium hydroxide.

paper" appearance initially, although scratching produces changes in the appearance. The cause is unknown. High-potency topical corticosteroid ointment such as clobetasol (Temovate) helps relieve itching.

Collaborative Care

Evaluate genital problems by taking a history, performing a physical examination, and obtaining the appropriate laboratory and diagnostic studies. Because many problems relate to sexual activity, a sexual history is essential. The nature of the problem determines the extent of the evaluation. When ulcerative lesions are present, do a culture for herpes and a blood test for syphilis. Genital warts are usually identified by their clinical appearance. Vulvar dystrophies may be examined via colposcopy with a biopsy taken for diagnosis.

Problems involving vaginal discharge are evaluated by microscopy and cultures. The most common vaginal conditions (i.e., bacterial vaginosis, VVC, and trichomoniasis) are diagnosed by a procedure called a *wet mount*. The findings characteristic of each condition are shown in Table 54-8. To assess for cervicitis, endocervical cultures are obtained for chlamydial infection and gonorrhea. If purulent discharge is observed coming from the cervix, a sample of endocervical cells may be taken to conduct a Gram stain. The Gram-stained slide is examined with a microscope to identify white blood cells and gram-negative diplococci (indicative of gonorrhea). (Sexually transmitted infections [STIs] are discussed in Chapter 53.)

Drug therapy is based on the diagnosis (see Table 54-8). Antibiotics taken as directed will cure bacterial infections. Treatment duration and medications vary with specific STIs. Teach patients how to properly take their medications and to follow up to verify a cure. Partners should be treated so that reinfection does not occur.

Women with vaginal conditions or cervical infection should abstain from intercourse for at least 1 week. Douching should be avoided because it has been adversely linked to pelvic inflammatory disease, STIs, and ectopic pregnancy. Sexual partners must be evaluated and treated if the patient is diagnosed with trichomoniasis, chlamydial infection, gonorrhea, syphilis, or HIV.

Treatment of vulvar dystrophies is symptomatic because no cures are available. Treatment involves controlling the itching and hence the scratching. Interrupting the "itch-scratch cycle" prevents further secondary damage to the skin.

NURSING MANAGEMENT
CONDITIONS OF VULVA, VAGINA, AND CERVIX

Teach women about common genital conditions and how to reduce their risks. Recognize symptoms that indicate a problem, and help women seek care in a timely manner. Discussing problems that concern the patient's genitalia or sexual intercourse is frequently difficult. Use a nonjudgmental attitude to make women feel more comfortable while empowering them to ask questions.

When a woman is diagnosed with a genital condition, ensure that she fully understands the directions for treatment. Taking the full course of medication is especially important to decrease the chance of relapse. Because genitalia are such a private area, the use of graphs and models is especially helpful for patient teaching. When a woman is using a vaginal medication for the first time, show her the applicator and how to fill it. Also teach where and how the applicator should be inserted using visual aids or models. Vaginal creams should be inserted before going to bed so that the medication will remain in the vagina for a long period. Women using vaginal creams or suppositories may wish to use panty liners during the day when the residual medication may drain out.

PELVIC INFLAMMATORY DISEASE

Pelvic inflammatory disease (PID) is an infectious condition of the pelvic cavity that may involve the fallopian tubes (salpingitis), ovaries (oophoritis), and pelvic peritoneum (peritonitis). A tubo-ovarian abscess may also form (Fig. 54-4). In the United States it is estimated that 1 million women experience an acute episode of PID annually.[19] PID is referred to as "silent" when women do not perceive any symptoms. Other women with PID are in acute distress. PID may also be a cause of chronic pelvic pain (discussed on p. 1289).

Etiology and Pathophysiology

PID is often the result of untreated cervicitis. The organism infecting the cervix ascends higher into the uterus, fallopian tubes, ovaries, and peritoneal cavity. *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are the most common causative organisms of PID. These organisms, as well as anaerobes, mycoplasma, streptococci, and enteric gram-negative rods, gain entrance during sexual intercourse or after pregnancy termination, pelvic surgery, or childbirth. It is important to remember that not all cases of PID are the result of an STI.

Women at increased risk for chlamydial infections (those younger than 24 years of age, who have multiple sex partners, or who have a new sex partner) should be routinely tested for chlamydia. Chlamydial infections can be asymptomatic and unknowingly transmitted during intercourse. Silent PID is a major cause of female infertility.

Clinical Manifestations

Women with PID usually go to a health care provider because they are experiencing lower abdominal pain. The pain typically starts gradually and then becomes constant. The intensity may vary from mild to severe. Movement such as walking can increase the pain. The pain is also frequently associated with intercourse. Spotting after intercourse and purulent cervical or

FIG. 54-4 Pelvic inflammatory disease. Acute infection of the fallopian tubes and the ovaries. The tubes and the ovaries have become an inflamed mass attached to the uterus. A tubo-ovarian abscess is also present.

vaginal discharge may also be noted. Fever and chills may be present. Women with less acute symptoms often notice increased cramping pain with menses, irregular bleeding, and some pain with intercourse. Women who have mild symptoms may go untreated either because they did not seek care or the health care provider misdiagnosed their complaints.

A pelvic examination assists in the diagnosis of PID. Women with PID have lower abdominal tenderness, adnexal tenderness, and positive cervical motion tenderness. Additional criteria useful for diagnosis may include fever and abnormal discharge (vaginal or cervical). Cultures for *N. gonorrhoeae* and *C. trachomatis* are also obtained, and a pregnancy test is done to rule out an ectopic pregnancy. Drug therapy begins when minimal diagnostic criteria are met. Thus treatment is not delayed for culture results. When the patient's pain or obesity compromises the pelvic examination and a tubo-ovarian abscess may be present, a vaginal ultrasound is indicated.

Complications

Immediate complications of PID include septic shock and *Fitz-Hugh-Curtis syndrome,* which occurs when PID spreads to the liver and causes acute perihepatitis. The patient has symptoms of right upper quadrant pain, but liver function tests are normal. Tubo-ovarian abscesses may "leak" or rupture, resulting in pelvic or generalized peritonitis. As the general circulation is flooded with bacterial endotoxins from the infected areas, septic shock may result. Embolisms may occur as the result of thrombophlebitis of the pelvic veins.

PID can cause adhesions and strictures in the fallopian tubes. Ectopic pregnancy may result when a tube is partially obstructed because the sperm can pass through the stricture, but the fertilized ovum cannot reach the uterus. After one episode of PID, the risk of having an ectopic pregnancy increases 10-fold. Further damage can obstruct the fallopian tubes and cause infertility.

Collaborative Care

PID is usually treated on an outpatient basis. The patient is given a combination of antibiotics such as cefoxitin (Mefoxin) and doxycycline (Vibramycin) to provide broad coverage against the causative organisms.[19] With effective antibiotic therapy, the pain should subside. The patient must have no intercourse for 3 weeks. Her partner(s) must be examined and treated. An important part of care is physical rest and oral fluids. Reevaluation in 48 to 72 hours, even if symptoms are improving, is an essential part of outpatient care.

If outpatient treatment is unsuccessful or if the patient is acutely ill or in severe pain, admission to the hospital is indicated. If a tubo-ovarian abscess is present, hospitalization is also indicated. Maximum doses of parenteral antibiotics are given in the hospital. Corticosteroids may be added to the antibiotic regimen to reduce inflammation, allowing for faster recovery and optimizing the chances for subsequent fertility. Application of heat to the lower abdomen or sitz baths may improve circulation and decrease pain. Bed rest in a semi-Fowler's position promotes drainage of the pelvic cavity by gravity and may prevent the development of abscesses high in the abdomen. Analgesics to relieve pain and IV fluids to prevent dehydration are also used.

Surgery is indicated for abscesses that fail to resolve with IV antibiotics. The abscess may be drained by laparoscopy or laparotomy. In extreme cases of infection or severe chronic pelvic pain, a hysterectomy may be performed. When surgery is necessary, the capacity for childbearing is preserved whenever possible.

NURSING MANAGEMENT
PELVIC INFLAMMATORY DISEASE

Subjective and objective data that should be obtained from the woman with PID are presented in Table 54-9. Prevention, early recognition, and prompt treatment of vaginal and cervical infections can help prevent PID and its serious complications. Provide accurate information about factors that place a woman at increased risk for PID. Urge women to seek medical attention for any unusual vaginal discharge or possible infection of their reproductive organs. Inform patients that not all discharge indicates infection, but that early diagnosis and treatment of an infection, if present, can prevent serious complications. Teach patients methods to decrease the risk of getting STIs and to recognize the signs of infection in their partner(s).

The patient may feel guilty about having PID, especially if it is associated with an STI. She may also be concerned about the complications associated with PID, such as adhesions and strictures of the fallopian tubes, infertility, and the increased incidence of ectopic pregnancy. Discuss with the patient her feelings and concerns to help her cope with them more effectively.

For patients requiring hospitalization, you have an important role in implementing drug therapy, monitoring the patient's health status, and providing symptom relief and patient teaching. Record vital signs and the character, amount, color, and odor of the vaginal discharge. Explain the need for limiting

TABLE 54-9 NURSING ASSESSMENT

Pelvic Inflammatory Disease

Subjective Data

Important Health Information

Past health history: Use of IUD; previous PID, gonorrhea, or chlamydial infection; multiple sexual partners; exposure to partner with urethritis; infertility
Medications: Use of and allergy to any antibiotics
Surgery or other treatments: Recent abortion or pelvic surgery

Functional Health Patterns

Health perception–health management: Malaise
Nutritional-metabolic: Nausea, vomiting; chills, fever
Elimination: Urinary frequency, urgency
Cognitive-perceptual: Lower abdominal and pelvic pain; low back pain; onset of pain just after a menstrual cycle; dysmenorrhea, dyspareunia, dysuria, vulvar pruritus
Sexuality-reproductive: Abnormal vaginal bleeding and menstrual irregularity; vaginal discharge

Objective Data

Reproductive

Mucopurulent cervicitis, vulvar maceration, vaginal discharge (heavy and purulent to thin and mucoid), tenderness on motion of cervix and uterus; presence of inflammatory masses on palpation

Possible Diagnostic Findings

Leukocytosis; ↑ erythrocyte sedimentation rate; positive culture of secretions or endocervical fluid; pelvic inflammation and positive endometrial biopsy on laparoscopic examination; abscess or inflammation on ultrasonography

IUD, Intrauterine device; *PID,* pelvic inflammatory disease.

activity, being in a semi-Fowler's position, and increasing fluid intake. Assess the degree of abdominal pain to determine the effectiveness of drug therapy.

CHRONIC PELVIC PAIN

Chronic pelvic pain refers to pain in the pelvic region (below the umbilicus and between the hips) that lasts 6 months or longer.[20] It accounts for 10% of all visits to gynecologists and is the reason for 20% to 30% of all laparoscopies. Up to one third of women who have PID have chronic pelvic pain.[21]

The cause of chronic pelvic pain is often hard to find. Many different conditions can cause pelvic pain. Gynecologic etiologies include dysmenorrhea, endometriosis, PID, ovarian cysts, uterine fibroids, pelvic adhesions, and ectopic pregnancies. Abdominal etiologies include irritable bowel syndrome, interstitial cystitis, appendicitis, and colitis. Psychologic factors (e.g., depression, chronic stress, history of sexual or physical abuse) may increase the risk of developing chronic pelvic pain. Emotional distress makes pain worse, and living with chronic pain contributes to emotional distress.

Chronic pelvic pain has many different clinical manifestations, including severe and steady pain, intermittent pain, dull and achy pain, pelvic pressure or heaviness, and sharp pain or cramping. In addition, pain may occur during intercourse or while having a bowel movement.

Determining the cause of chronic pelvic pain often involves a process of elimination. In addition to a detailed history and physical examination (including a pelvic examination), the patient may be asked to keep a journal of the onset of symptoms and any precipitating factors.

Diagnostic tests may include cultures from cervix or vagina (used to detect STIs), ultrasound, computed tomography (CT) scan, or magnetic resonance imaging (MRI) to detect abnormal structures or growths. Laparoscopy may be used to visualize the pelvic organs. This procedure is especially useful in detecting endometriosis and chronic PID.

If the cause of chronic pelvic pain is found, treatment focuses on that cause. If no cause can be found, treatment involves managing the pain. Over-the-counter pain medications (e.g., aspirin, ibuprofen, acetaminophen) may provide some relief. Sometimes stronger pain drugs may be needed. Birth control pills or other hormonal medications may help relieve cyclic pelvic pain related to menstrual cycles. If an infection is the source of the problem, antibiotics are used.

Tricyclic antidepressants (e.g., amitriptyline, nortriptyline [Pamelor]) have pain-relieving and antidepressant effects. These drugs may help improve chronic pelvic pain even in women who do not have depression. The patient may be encouraged to get counseling for any emotional issues.

Laparoscopic surgery may be used to remove pelvic adhesions or endometrial tissue. As a last resort, a hysterectomy may be done.

ENDOMETRIOSIS

Endometriosis is the presence of normal endometrial tissue in sites outside the endometrial cavity.[22] The most frequent sites are in or near the ovaries, uterosacral ligaments, and uterovesical peritoneum (Fig. 54-5). However, endometrial tissues can be in many other locations such as stomach, lungs, intestines, and spleen. The tissue responds to the hormones of the ovarian cycle and undergoes a "mini-menstrual cycle" similar to the uterine endometrium.

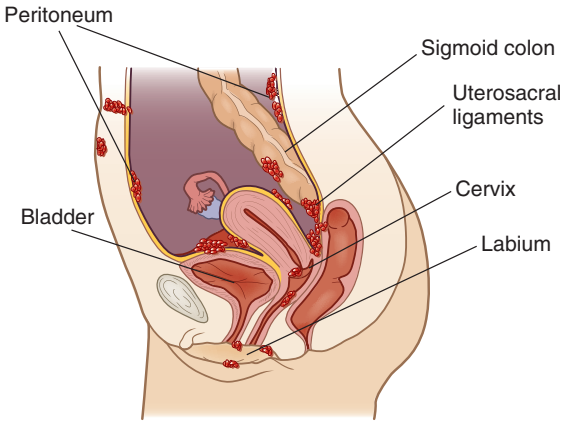

FIG. 54-5 Common sites of endometriosis.

The typical patient with endometriosis is in her late twenties or early thirties and has never had a full-term pregnancy. Although it is not a life-threatening condition, endometriosis can cause considerable pain. It is also a common cause of infertility and increases the risk of ovarian cancer. Endometriosis is one of the most common gynecologic problems, affecting more than 5.5 million women in North America.[23]

Etiology and Pathophysiology

Although the etiology of endometriosis is poorly understood, many theories have been proposed. A widely held view is that retrograde menstrual flow passes through the fallopian tubes carrying viable endometrial tissues into the pelvis. The tissue attaches to various sites (see Fig. 54-5). Another theory suggests that undifferentiated embryonic peritoneal cavity cells remain dormant in the pelvic tissue until the ovaries produce sufficient hormones to stimulate their growth. Other proposed causes include a genetic predisposition and altered immune function.

Clinical Manifestations

Patients with endometriosis have a wide range of clinical manifestations and severity. The magnitude of a woman's symptoms does not necessarily correlate with the clinical extent of her endometriosis. Dysmenorrhea after years of relatively pain-free menses and infertility may serve as clues to the presence of endometriosis. The most common manifestations are secondary dysmenorrhea, infertility, pelvic pain, dyspareunia, and irregular bleeding. Less common manifestations include backache, painful bowel movements, and dysuria. With menopause, estrogen is no longer produced in the ovaries, and the symptoms may disappear.

When the ectopic endometrial tissues "menstruate," the blood collects in cystlike nodules that have a characteristic bluish black color. When a cyst ruptures, the pain may be acute, and the resulting irritation promotes the formation of adhesions, which attach and fix the affected area to another pelvic structure. Endometrial lesions may become severe enough to cause a bowel obstruction or painful micturition.

Collaborative Care

Endometriosis may be suspected based on a woman's history of the characteristic symptoms and the health care provider's palpation of firm nodular lumps in the adnexa on bimanual

TABLE 54-10 COLLABORATIVE CARE

Endometriosis

Diagnostic
- History and physical examination
- Pelvic examination
- Laparoscopy
- Pelvic ultrasound
- MRI

Collaborative Therapy
- Conservative therapy (watch and wait)

Drug Therapy
- Nonsteroidal antiinflammatory drugs (NSAIDs)
- Oral contraceptives
- danazol (Danocrine)
- GnRH agonists (e.g., leuprolide [Lupron])

Surgical Therapy
- Laparotomy to remove implanted tissue and adhesions
- Total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO)

GnRH, Gonadotropin-releasing hormone; *MRI,* magnetic resonance imaging.

examination. However, laparoscopy is necessary for a definitive diagnosis. The treatment of endometriosis is influenced by the patient's age, desire for pregnancy, symptom severity, and extent and location of the disease. When symptoms are not disruptive, a "watch and wait" approach is used (Table 54-10). When endometriosis is identified as a probable cause of infertility, therapy proceeds more rapidly.

Drug Therapy. Drug therapy is used to reduce symptoms. Pain may be relieved with NSAIDs such as ibuprofen and diclofenac (Voltaren). Drugs to inhibit estrogen production by the ovary are often used to shrink the endometrial tissue. These drugs imitate a state of pregnancy or menopause. Continuous use (for 9 months) of combined oral contraceptives causes regression of endometrial tissue. Ovulation is suppressed by progestin agents such as medroxyprogesterone. Another approach to hormonal treatment is danazol (Danocrine), a synthetic androgen that inhibits the anterior pituitary. This drug causes atrophy of ectopic endometrial tissue. Subjective relief of symptoms is noted within 6 weeks of danazol use. The side effects of weight gain, acne, hot flashes, and hirsutism and the expense of this drug restrict its use.

Another class of drugs used is GnRH agonists (e.g., leuprolide [Lupron], nafarelin [Synarel]). These drugs result in amenorrhea. Side effects are usually the same as those of menopause (hot flashes, vaginal dryness, emotional lability). Loss of bone density has also been reported in women who remain on the therapy longer than 6 months. Endometriosis is controlled but not cured by HT. Persistent lesions give rise to subsequent recurrences once the menstrual cycle is reestablished.

DRUG ALERT: Leuprolide (Lupron)
- Assess patient for pregnancy before initiating therapy.
- Monitor patient for dysrhythmias, palpitations.
- Instruct patient to use nonhormonal contraceptive measures during therapy.

Surgical Therapy. The only cure for endometriosis is surgical removal of all the endometrial implants. Surgical therapy may be conservative or definitive. Conservative surgery is done to confirm the diagnosis or to remove implants. It involves removal or destruction of endometrial implants and lysing or excision of adhesions by means of laparoscopic laser surgery or laparotomy. GnRH agonist therapy (e.g., leuprolide) can be administered for 4 to 6 months to reduce the size of the lesions before surgery. By reducing the extent of the surgery, this preoperative drug treatment helps reduce the development of adhesions that may further threaten fertility. Definitive surgery involves removal of the uterus, fallopian tubes, ovaries, and as many endometrial implants as possible.

For women wishing to get pregnant, conservative surgical therapy is used to remove implants blocking the fallopian tube. Adhesions are removed from the tubes, ovaries, and pelvic structures. Efforts are made to conserve all tissues necessary to maintain fertility.

The individual woman should be actively involved in making the decision about preserving part or all of her ovaries, if surgically possible. Explore her feelings about maintaining her ovarian function. The health care provider should assess the woman's risk for ovarian cancer and provide this information for her consideration.

NURSING MANAGEMENT ENDOMETRIOSIS

Teach and reassure the patient that endometriosis is not life threatening. This may permit her to accept a conservative and progressive treatment approach. When the symptoms are less severe, teach about nondrug comfort measures that may be helpful. Assist patients in understanding the drugs that have been ordered to treat their condition. Explain the action and possible side effects of the prescribed drug. Psychologic support may be needed for women experiencing severe disabling pain, sexual difficulties secondary to dyspareunia, and infertility.

If conservative surgery is the treatment selected, care is similar to the general preoperative and postoperative care of a patient undergoing laparotomy (see Chapter 43, p. 971). If definitive surgery is planned, the care is similar to that for the patient undergoing an abdominal hysterectomy (see eNursing Care Plan 54-1 on the website for this chapter). Know the extent of the procedure so that appropriate preoperative teaching can be done.

BENIGN TUMORS OF THE FEMALE REPRODUCTIVE SYSTEM

LEIOMYOMAS

Etiology and Pathophysiology

Leiomyomas (uterine fibroids) are benign smooth-muscle tumors that occur within the uterus. Leiomyomas are common benign tumors of the female genital tract (Fig. 54-6). By 50 years of age, 60% of all women will have had at least one uterine leiomyoma.[24] The cause of leiomyomas is unknown. They appear to depend on ovarian hormones because they grow slowly during the reproductive years and undergo atrophy after menopause.

Clinical Manifestations

The majority of women with leiomyomas do not have any symptoms. When present, the most common symptoms include abnormal uterine bleeding, pain, and symptoms associated with pelvic pressure. Increased bleeding is associated with increased

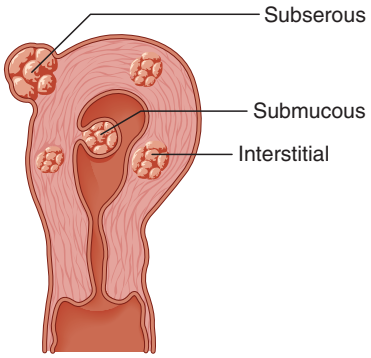

FIG. 54-6 Leiomyomas. Uterine section showing whorl-like appearance and locations of leiomyomas.

endometrial surface area caused by leiomyomas. Pain occurs with infection or twisting of the pedicle from which the tumor is growing. Devascularization and blood vessel compression may also contribute to pain. Pressure on surrounding organs may result in rectal, bladder, and lower abdominal discomfort. Large tumors may cause a general enlargement of the lower abdomen. These tumors are sometimes associated with miscarriage and infertility.

Collaborative Care

Clinical diagnosis is based on the characteristic pelvic findings of an enlarged uterus distorted by nodular masses. Treatment depends on the symptoms, the patient's age, her desire to bear children, and the location and size of the tumors. If the symptoms are minimal, the health care provider may elect to follow the patient closely for a time.

Persistent heavy menstrual bleeding causing anemia and large or rapidly growing tumors are indications for surgery. The leiomyomas are removed by hysterectomy or by myomectomy for women who wish to have children. In this case, only the fibroids are removed to preserve the uterus. Small tumors may be removed using a hysteroscope and laser resection instruments.

Uterine artery embolization is an increasingly used alternative treatment for uterine fibroids.[25] Embolic material (small plastic or gelatin beads) is injected into the uterine artery and carried to the fibroid branches.

Cryosurgery is another option. In cases of large leiomyomas, a GnRH agonist (e.g., leuprolide) may be used preoperatively to shrink the tumor. However, the risks and benefits of this drug should be fully discussed, including the potential for irreversible loss of bone mass. The treatment should not be used on women planning to have children.

Another treatment option uses MRI-guided focused ultrasound to target and destroy uterine fibroids. Treatment requires repeated targeting and heating of the fibroid tissue while the patient lies inside the MRI machine. The procedure can last as long as 3 hours.

CERVICAL POLYPS

Cervical polyps are benign pedunculated lesions that generally arise from the endocervical mucosa and are seen protruding through the cervical os during a speculum examination. Polyps are a characteristic bright cherry-red and are soft and fragile in consistency. They are generally small, measuring less than 3 cm in length, and may be single or multiple. Their cause is unknown.

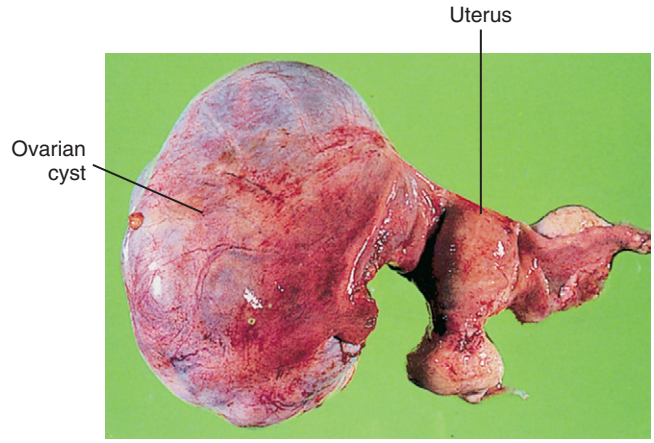

FIG. 54-7 Large ovarian cyst.

Symptoms are usually not present, but metrorrhagia and bleeding after straining for a bowel movement and coitus can occur. Polyps are prone to infection. When the polyp is small, it can be excised in an outpatient procedure. If the point of attachment of the polyp cannot be identified and is not accessible to cautery, a polypectomy is performed in an operating room. All tissue removed is sent for pathologic review because polyps occasionally undergo malignant changes.

BENIGN OVARIAN TUMORS

There are many different types of benign tumors. The cause of most of them is unknown. They can be divided into cysts and neoplasms. *Cysts* are usually soft, are surrounded by a thin capsule, and may be detected during the reproductive years. Follicle and corpus luteum cysts are common ovarian cysts (Fig. 54-7). Multiple small ovarian follicles may occur in a condition called *polycystic ovary syndrome* (PCOS) (discussed in the next section). Epithelial ovarian neoplasms may be cystic or solid, and small or extremely large. Cystic teratomas, or dermoid cysts, originate from germ cells and can contain bits of any type of body tissue, such as hair or teeth.

Ovarian masses are often asymptomatic until they are large enough to cause pressure in the pelvis. Constipation, menstrual irregularities, urinary frequency, a full feeling in the abdomen, anorexia, an increase in abdominal girth, and peripheral edema may occur, depending on the tumor's size and location. Pelvic pain may be present if the tumor is growing rapidly. Severe pain results when the cyst twists on its pedicle (ovarian torsion).

In some cases, an ovarian cyst can rupture. A ruptured ovarian cyst is not only extremely painful, but it can lead to serious complications, such as hemorrhage and infection.

Pelvic examination reveals a mass or an enlarged ovary that demands further investigation. If the mass is cystic and smaller than 8 cm, the patient is asked to return for reexamination in 4 to 6 weeks. If the mass is cystic and greater than 8 cm or is solid, laparoscopic surgery or laparotomy is performed. Immediate surgery is necessary if ovarian torsion occurs, causing the ovary to rotate and cutting off circulation. Surgical techniques are used to save as much of the ovary as possible.

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a chronic disorder in which many benign cysts form on the ovaries. It most commonly occurs in women under 30 years old and is a cause of

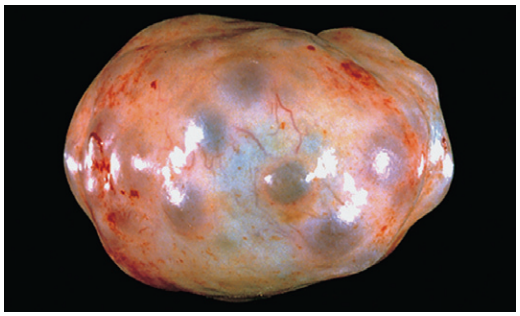

FIG. 54-8 Polycystic ovary syndrome. Multiple fluid-filled cysts in the ovary.

infertility. It affects about 3% to 7% of women of reproductive age.[26] PCOS is due to hormonal abnormalities in which the ovaries produce estrogen and excess testosterone but not progesterone. Fluid-filled cysts develop from mature ovarian follicles that fail to rupture (thereby releasing an egg) each month (Fig. 54-8). This problem affects both ovaries.

Classic manifestations include irregular menstrual periods, amenorrhea, hirsutism, and obesity. Of these manifestations, obesity in particular has been associated with severe symptoms such as excess androgens, oligorrhea, amenorrhea, and infertility. Many women start with normal menstrual periods, which after 1 to 2 years become irregular and then infrequent. If PCOS is left untreated, cardiovascular disease and abnormal insulin resistance with type 2 diabetes mellitus may develop.[27,28]

Pelvic ultrasound reveals enlarged ovaries with multiple small cysts. Successful management includes early diagnosis and treatment to improve quality of life and decrease the risk of complications. Oral contraceptives are useful in regulating menstrual cycles. Hirsutism may be treated with spironolactone. Hyperandrogenism can be treated with flutamide (Eulexin) and a GnRH agonist such as leuprolide. Metformin (Glucophage) reduces hyperinsulinemia and has been shown to improve hyperandrogenism and restore ovulation. For women wishing to become pregnant, fertility drugs (e.g., clomiphene [Clomid]) may be used to induce ovulation. If all other treatments are unsuccessful, a hysterectomy with bilateral salpingectomy and oophorectomy may be performed.

DRUG ALERT: Clomiphene (Clomid)

Instruct the patient to notify her physician immediately if

- Lower abdominal pain occurs.
- Pregnancy is suspected.

Teach the patient the importance of weight management and exercise to decrease insulin resistance. Obesity exacerbates the problems related to PCOS. Monitor lipid profile and fasting glucose levels. Hirsutism is cosmetically distressing for many women. Support the patient as she explores measures to remove unwanted hair (e.g., depilating agents, electrolysis). Stress the importance of regular follow-up care to monitor the effectiveness of therapy and to detect any complications.

CANCERS OF THE FEMALE REPRODUCTIVE SYSTEM

CERVICAL CANCER

Approximately 12,000 women in the United States are diagnosed with cervical cancer and 4200 women die from cervical cancer annually.[29] Noninvasive cervical cancer (in situ) is about four times more common than invasive cervical cancer. The mortality rate for cervical cancer in the United States is twice as high for African American women as it is for white women. An increased risk of cervical cancer is associated with low socioeconomic status, early sexual activity (before 17 years of age), multiple sexual partners, infection with HPV, immunosuppression, and smoking.

The number of deaths from cervical cancer in the United States has fallen steadily over the past 50 years because of better and earlier diagnosis with the widespread use of the Papanicolaou (Pap) test. In addition to cancer, the Pap test screens for precancerous changes. Treatment of precancerous lesions can prevent progression to cervical cancer.

CULTURAL & ETHNIC HEALTH DISPARITIES

Cancers of the Female Reproductive System

Ovarian Cancer

- Japanese women have a low incidence of ovarian cancer.
- However, second- and third-generation Japanese women in the United States have much higher rates, similar to those of white women born in the United States.

Endometrial Cancer

- Incidence is higher for white women and African American women.
- Mortality rate for African American women is nearly twice that of white women.

Cervical Cancer

- Incidence is higher among Hispanic, African American, and Native American women than among white women.
- Mortality rates are more than twice as high among African American women as among white women.

Etiology and Pathophysiology

The progression from normal cervical cells to dysplasia and then to invasive cervical cancer appears to be related to repeated injuries to the cervix. The progression occurs slowly over years. A strong relationship exists between dysplasia and HPV infections. HPV types 16 and 18 together cause about 70% of cervical cancers. Cancer rates are expected to decline further with vaccines (e.g., Gardasil, Cervarix) now being used for the prevention of HPV.[30]

Clinical Manifestations

Precancerous changes are asymptomatic. This highlights the importance of routine screening. The peak incidence of noninvasive cervical cancer is in women in their early thirties. The average age for women with invasive cervical cancer is 50 (Fig. 54-9). Early cervical cancer is generally asymptomatic, but leukorrhea and intermenstrual bleeding eventually occur. The discharge is usually thin and watery but becomes dark and foul smelling as the disease advances, suggesting an infection. The vaginal bleeding is initially only spotting. As the tumor enlarges, bleeding becomes heavier and more frequent. Pain is a late symptom and is followed by weight loss, anemia, and cachexia.

Diagnostic Studies

The American Cancer Society recommends the following guidelines for annual Pap testing:[31]

- Begin testing at age 21 regardless of when a woman becomes sexually active.

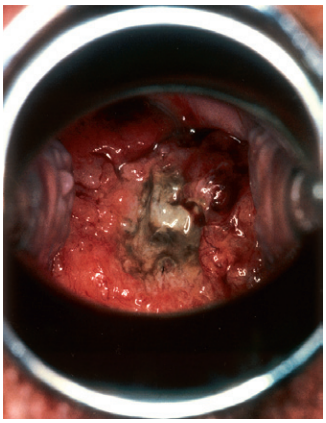

FIG. 54-9 Cervical cancer. View through a speculum inserted into the vagina.

- Women ages 21 to 65 years old should be screened with the Pap test every 3 years.
- Women who have had a total hysterectomy (uterus and cervix removed) for reasons not related to cervical cancer do not need to be tested.
- Women 65 and older should no longer be screened after having two or three consecutive negative Pap tests within the last 2 years.

Women with a history of cervical cancer should continue with screening as recommended by their health care provider for at least 20 years. A woman who has been vaccinated against HPV needs to continue following the screening guidelines for her age-group.

The two types of HPV that have been associated with most cases of cervical cancer (types 16 and 18) can be identified through deoxyribonucleic acid (DNA) testing. HPV DNA tests help determine if women with abnormal Pap test results need further follow-up. Women ages 30 to 65 who have the HPV DNA test and the Pap test (co-testing) can be screened every 5 years rather than every 3 years.

Pap tests are less than 100% accurate in screening for cervical cell abnormalities. Problems occur with both false-positive and false-negative reports. ThinPrep, a liquid-based technique for Pap tests, has reduced the number of inaccurate test results.

The finding of an abnormal Pap test indicates the need for follow-up. Women with minor changes may be followed with a repeated Pap test in 4 to 6 months for 2 years. Up to 80% may revert to normal spontaneously. Women with more prominent changes receive additional procedures, such as colposcopy and biopsy, before a definitive diagnosis can be made. Colposcopy helps identify possible epithelial abnormalities and suggests areas for biopsy. Biopsies are sent for pathologic evaluation. Colposcopy and biopsy have improved diagnosis and allow more focused treatments.

The type and extent of the biopsy vary with the abnormality seen. A punch biopsy may be done on an outpatient basis with a special punch biopsy forceps. The excision of a cone-shaped section of the cervix may be used for both diagnosis and treatment. Conization is accomplished using one of several techniques, depending on the health care provider's experience and the availability of equipment. *Cryotherapy* (freezing) and laser cone vaporization destroy the tissue. Laser cone excision and the *loop electrosurgery excision procedure* (LEEP) remove the identified tissue and allow for histologic examination to ensure that all microinvasive tissue has been removed. These can be performed as outpatient procedures with mild analgesics or sedation. Complications of these procedures include excessive bleeding and possible cervical stenosis after healing.

TABLE 54-11 STAGING AND TREATMENT OF CERVICAL CANCER

Stage	Extent	Treatment
0	In situ	Cervical conization, hysterectomy, cryosurgery, laser surgery
I	Confinement to cervix	Radiation, radical hysterectomy
II	Spread beyond cervix to upper two thirds of vagina but not to tissues around uterus	Radiation, cisplatin-based chemotherapy, radical hysterectomy
III	Spread to pelvic wall, involvement of lower third of vagina, and/or has caused kidney problems	Radiation, cisplatin-based chemotherapy
IV	Spread to other parts of the body such as bladder, rectum, liver, lungs, and bones	Radiation, surgery (e.g., pelvic exenteration), cisplatin-based chemotherapy

Modified from National Cancer Institute: Cancer cervical treatment: stages of cervical cancer. Retrieved from *www.cancer.gov/cancertopics/pdq/treatment/cervical/Patient/page2*.

Collaborative Care

Vaccines against HPV reduce the incidence of both cervical-related neoplasia and cervical cancer due to infection from HPV types 16 and 18. Vaccination against HPV is recommended for females and males beginning at ages 11 or 12 years. (Vaccines are discussed further in Chapter 53, p. 1270.)

The treatment of cervical cancer is guided by the stage of the tumor and the patient's age and general state of health (Table 54-11). There are four procedures in which fertility can be preserved. Conization may be the only type of therapy needed for noninvasive cervical cancer if analysis of removed tissue demonstrates that a wide area of normal tissue surrounds the excised tissue. Laser treatments can be used in which a directed infrared beam is employed to destroy abnormal tissue. Cautery and cryosurgery may also be used.

Invasive cancer of the cervix is treated with surgery, radiation, and chemotherapy as single treatments or in combination. Surgical procedures include hysterectomy, radical hysterectomy (involving adjacent structures), and, rarely, pelvic exenteration. (Surgical therapy is discussed on p. 1297.) Radiation may be by external (e.g., cobalt) or internal implants (e.g., cesium, radium). Standard radiation treatment is 4 to 6 weeks of external radiation followed by one or two treatments with internal implants (brachytherapy). (Radiation therapy is discussed in Chapter 16.) Cisplatin-based chemotherapy regimens benefit patients with cancer spread beyond the cervix.

ENDOMETRIAL CANCER

Cancer of the endometrium is the most common gynecologic malignancy. Approximately 47,000 newly diagnosed cases of

EVIDENCE-BASED PRACTICE

Applying the Evidence

H.K. is a 33-yr-old African American woman who had a tubal ligation in the outpatient surgery unit. As you prepare her for discharge, you remind her that she needs to have regular Pap tests to screen for cervical cancer. She expresses concern over the expense of this procedure. She tells you that her health care insurance will not pay for diagnostic tests, and she does not remember when she last had a Pap test done.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
For women after age 30 who have had three normal Pap tests, the American Cancer Society recommends screening every 2-3 yr.	You know that the incidence and death rate of cervical cancer is twice as high for African Americans as for whites.	H.K. is concerned about the costs related to her current procedure and future Pap tests. She adds that no one in her family has ever had cervical cancer.

Your Action and Decision

As her nurse, you explain the American Cancer Society recommendations and her increased risk for cervical cancer. She tells you that she understands and will schedule a follow-up appointment, but unless the cost of the Pap test is reasonable, she will probably not be able to get yearly Pap tests unless her health care plan improves.

Reference for Evidence

American Cancer Society: American Cancer Society guidelines for the early detection of cancer. Retrieved from *www.cancer.org/Healthy/FindCancerEarly/CancerScreeningGuidelines*.

endometrial cancer and 8000 deaths occur annually. Endometrial cancer has a relatively low mortality rate, since most cases are diagnosed early. The survival rate is over 95% if the cancer has not spread at the time of diagnosis.

Etiology and Pathophysiology

The major risk factor for endometrial cancer is estrogen, especially unopposed estrogen.[32] Additional risk factors include increasing age, nulliparity, late menopause, obesity, smoking, diabetes mellitus, and a personal or family history of hereditary nonpolyposis colorectal cancer (HNPCC) (see the Genetics in Clinical Practice box for HNPCC in Chapter 43 on p. 986). Obesity is a risk factor because adipose cells store estrogen, thus increasing endogenous estrogen. Pregnancy and oral contraceptives are protective factors.

Endometrial cancer arises from the lining of the endometrium. Most tumors are adenocarcinomas. The precursor may be a hyperplastic state that progresses to invasive carcinoma. Hyperplasia occurs when estrogen is not counteracted by progesterone. The cancer directly extends into the cervix and through the uterine serosa. As invasion of the myometrium occurs, regional lymph nodes, including the paravaginal and para-aortic, become involved. Hematogenous metastases develop concurrently. The usual sites of metastases are lung, bone, liver, and eventually the brain. Malignant cells can be found in the peritoneal cavity, probably after transport through the fallopian tubes.

Prognostic factors include histologic differentiation, myometrial invasion, peritoneal cytology, lymph node and adnexal metastases, and tumor size. Endometrial cancer grows slowly, metastasizes late, and is curable with therapy if diagnosed early.

Clinical Manifestations

The first sign of endometrial cancer is abnormal uterine bleeding, usually in postmenopausal women. Because perimenopausal women have sporadic periods for a time, it is important that this sign not be ignored or attributed to menopause.

Pain occurs late in the disease process. Other manifestations that may arise are related to metastasis to other organs. Metastatic spread occurs in a characteristic pattern. Spread to the pelvic and para-aortic nodes is common. When distant metastasis occurs, it most commonly involves the lungs, liver, bones, brain, and vagina.

Collaborative Care

Endometrial biopsy is the primary diagnostic test for endometrial cancer. Endometrial biopsy is done on an outpatient basis. Any abnormal or unexpected bleeding in a postmenopausal woman requires obtaining a tissue sample to exclude endometrial cancer. For women who have or are at risk of developing HNPCC, the American Cancer Society recommends annual screening with endometrial biopsy beginning at 35 years of age. The Pap test is not a reliable diagnostic tool for endometrial cancer, but it can rule out cervical cancer.

Most cases of endometrial cancer are diagnosed at an early stage when surgery alone may result in cure. Treatment of endometrial cancer is a total hysterectomy and bilateral salpingo-oophorectomy with lymph node biopsies. The lack of estrogen and progesterone receptors is a poor prognostic indicator. Surgery may be followed by radiation, either to the pelvis or the abdomen externally or intravaginally, to decrease local recurrence.

No tumor markers with high sensitivity and high specificity for endometrial cancer are known at present, although CA-125 is often used in clinical practice. CA-125 has been used in surveillance of advanced endometrial cancer. In patients who have increased CA-125 values pretreatment, this test might prove useful in posttreatment surveillance.

Treatment of advanced or recurrent disease is difficult. Progesterone HT (e.g., megestrol [Megace]) can be used when the progesterone receptor status is positive and the tumor is well differentiated.[32] Tamoxifen (Nolvadex), either alone or in combination with progesterone therapy, is also effective in women with advanced or recurrent endometrial cancer. Chemotherapy is considered when progesterone therapy is unsuccessful. Agents used include doxorubicin (Adriamycin), cisplatin (Platinol), 5-fluorouracil (5-FU), carboplatin (Paraplatin), and paclitaxel (Taxol).

OVARIAN CANCER

Ovarian cancer is a malignant tumor of the ovaries. About 22,280 new cases of ovarian cancer are diagnosed in the United States each year, and about 15,000 women die from the disease annually. It is the fifth leading cause of cancer deaths in women in the United States. Most women with ovarian cancer have advanced disease at diagnosis.[33] It occurs most frequently in women between 55 and 65 years of age. White women are at greater risk for ovarian cancer than African American women.

Etiology and Pathophysiology

Genetic Link

The cause of ovarian cancer is not known. Women who have mutations of the *BRCA* genes have an increased susceptibility

GENETICS IN CLINICAL PRACTICE

Ovarian Cancer

Genetic Basis
- Mutations in *BRCA1* and/or *BRCA2* genes.
- Normally these genes are tumor suppressor genes involved in DNA repair.
- Autosomal dominant transmission.
- Mutations passed down from either mother or father.

Incidence
- About 10% of cases of ovarian cancer are related to hereditary factors.
- Women with *BRCA1* mutations have a 25%-40% lifetime risk of developing ovarian cancer.
- Women with *BRCA2* mutations have a 10%-20% lifetime risk of developing ovarian cancer.
- Family history of both breast and ovarian cancer increases the risk of having a *BRCA* mutation.
- *BRCA* mutations occur in 10%-20% of patients with ovarian cancer who have no family history of breast or ovarian cancer.

Genetic Testing
- DNA testing is available for *BRCA1* and *BRCA2* genetic mutations.

Clinical Implications
- Bilateral oophorectomy reduces the risk of ovarian cancer in women with *BRCA1* and *BRCA2* mutations.
- Genetic counseling and testing for *BRCA* mutations should be considered for women whose personal or family history puts them at high risk for a genetic predisposition to ovarian cancer.

to ovarian cancer. The *BRCA* genes are tumor suppressor genes that inhibit tumor growth when functioning normally. When they mutate, they lose their tumor suppressor ability. This results in an increased risk for women to develop ovarian or breast cancer (see the Genetics in Clinical Practice box).

The major risk factor for ovarian cancer is family history (one or more first-degree relatives). A family history of breast or colon cancer is also a risk factor. Other risk factors include a personal history of breast or colon cancer and HNPCC (see the Genetics in Clinical Practice box on HNPCC in Chapter 43 on p. 986).

Women who have never been pregnant (nulliparity) are also at higher risk. Other risk factors include increasing age, high-fat diet, increased number of ovulatory cycles (usually associated with early menarche and late menopause), HT, and possibly the use of infertility drugs.

Breastfeeding, multiple pregnancies, oral contraceptive use (more than 5 years), and early age at first birth seem to reduce the risk of ovarian cancer. These factors may have a protective effect because they reduce the number of ovulatory cycles, and thus reduce the exposure to estrogen.

About 90% of ovarian cancers are epithelial carcinomas that arise from malignant transformation of the surface epithelial cells. Germ cell tumors account for another 10%. Histologic grading is an important prognostic determinant. Tumor cells are graded according to the level of differentiation, ranging from well differentiated (grade I) to poorly differentiated (grade III) to undifferentiated (grade IV). Grade IV cells carry a poorer prognosis than the other grades.

Intraperitoneal dissemination is a common characteristic of ovarian cancer. It metastasizes to the uterus, bladder, bowel, and omentum. In advanced disease, it can spread to the stomach, colon, liver, and other parts of the body.

  - Adjuvant and palliative
- Radiation therapy
  - Adjuvant and palliative

Clinical Manifestations

Symptoms are vague in the early stages. An accumulation of fluid initially causes abdominal enlargement. Nonspecific symptoms that warrant further evaluation include pelvic or abdominal pain, bloating, urinary urgency or frequency, and difficulty eating or feeling full quickly.[33] Women who have one or more of these symptoms, especially if they are new, persistent (occur at least 12 days per month), or worsening, need to see their health care provider. Vaginal bleeding rarely occurs, and pain is not an early symptom. Later signs are increased abdominal girth, unexplained weight loss or gain, and menstrual changes.

Diagnostic Studies

No screening test exists for ovarian cancer. Because early ovarian cancer has vague symptoms, yearly bimanual pelvic examinations should be performed to identify an ovarian mass (Table 54-12). Postmenopausal women should not have palpable ovaries, so a mass of any size should be suspected as possible ovarian cancer. An abdominal or a transvaginal ultrasound can be done to detect ovarian masses. An exploratory laparotomy may be used to establish the diagnosis and stage the disease.

A test called OVA1 can help detect whether a pelvic mass is benign or malignant before it is surgically removed. OVA1 uses a blood sample to test for levels of five biomarkers that change due to ovarian cancer. It is not intended for ovarian cancer screening or for a definitive diagnosis of ovarian cancer.

For women with a high risk for ovarian cancer, screening using a combination of the tumor marker (CA-125) and ultrasound is often recommended in addition to a yearly pelvic examination. CA-125 is positive in 80% of women with epithelial ovarian cancer and is used to monitor the course of the disease. However, levels of CA-125 may be elevated with other malignancies (e.g., pancreatic cancer) or with benign conditions such as fibroids or endometriosis. A large recent clinical trial has reported that screening by CA-125 and ultrasound did not result in fewer deaths from ovarian cancer.[34] Currently only 20% of ovarian cancers are diagnosed at an early stage.

Collaborative Care

Women identified as being at high risk based on family and health history may require counseling regarding options such as prophylactic oophorectomy and oral contraceptives. It is important to note that although oophorectomy significantly

reduces the risk of ovarian cancer, it does not completely eliminate the possibility of the disease.

Ovarian cancer staging is critical for guiding treatment decisions. Stage I describes disease limited to the ovaries; stage II, disease limited to the pelvis; stage III, disease limited to the abdominal cavity; and stage IV, distant metastatic disease. The overall survival rate is 90% with early disease, 36% with local spread, and 20% with distant metastases.

Most patients with ovarian cancer have widespread disease at presentation. The initial treatment for all stages of ovarian cancer is surgery, which is usually a total abdominal hysterectomy and bilateral salpingo-oophorectomy with omentectomy and removal of as much of the tumor as possible (i.e., tumor debulking). Surgery facilitates chemotherapy by reducing the number of cells that the chemotherapy has to kill.

Depending on the differentiation of the cells and the stage of cancer, other treatment options include intraperitoneal and systemic chemotherapy, intraperitoneal instillation of radioisotopes, and external abdominal and pelvic radiation therapy. If a patient is clinically free of symptoms after completing treatment, a "second-look" surgical procedure is often performed to determine whether there is any evidence of disease. If no disease is found, the patient is monitored for recurrent disease.

Chemotherapy usually consists of a combination of a platinum compound, such as cisplatin or carboplatin, and a taxane, such as paclitaxel or docetaxel (Taxotere). The typical course of chemotherapy involves three to six cycles. A cycle is a schedule that allows regular doses of a drug, followed by a rest period.

Other chemotherapy drugs used include altretamine (Hexalen), topotecan (Hycamtin), etoposide (VePesid), gemcitabine (Gemzar), and oxaliplatin (Eloxatin). These drugs may be used to treat recurrent disease or as a palliative measure to shrink the tumor to relieve pressure and pain.

VAGINAL CANCER

Primary vaginal cancers are rare, with about 2680 new cases reported annually. The peak incidence is between ages 50 and 70. Vaginal tumors are usually secondary sites or metastases of other cancers such as cervical or endometrial carcinomas. The most common type of vaginal cancer is squamous cell carcinoma. Intrauterine exposure to diethylstilbestrol (DES) places a woman at risk for clear cell adenocarcinoma of the vagina.

Treatment of vaginal cancer depends on the type of cells involved, the stage of the disease, and the size and location of the tumor. Squamous cell carcinomas can be treated with both surgery and radiation.

VULVAR CANCER

Cancer of the vulva is relatively rare, with about 4490 new cases reported annually. Similar to cervical cancer, preinvasive lesions referred to as vulvar intraepithelial neoplasia (VIN) precede invasive vulvar cancer. The invasive form occurs mainly in women over 60 years of age, with the highest incidence being in women in their seventies.

Patients with vulvar neoplasia may have symptoms of vulvar itching or burning, pain, bleeding, or discharge. Women who are immunosuppressed and/or have diabetes mellitus, hypertension, or chronic vulvar dystrophies are at a higher risk for developing vulvar cancers. Several subtypes of HPV have been identified in some but not all vulvar cancers. Vaccines (Gardasil, Cervarix) are now available to protect against some vaginal and vulvar cancers that are caused by these HPV subtypes. (Vaccines for HPV are discussed in Chapter 53, p. 1270.)

Diagnosis of vulvar cancer is based on physical examination, colposcopy, and biopsy results of the suspicious lesion. VIN can be treated topically with imiquimod cream (Aldara) or surgery.

Laser therapy may be used to kill cancer cells. Surgery is the most common treatment for cancer of the vulva. The goal of surgery is to remove all the cancer without any loss of the woman's sexual function. A local excision with removal of the lesion and surrounding tissue may be done. For more extensive lesions, vulvectomy may be done (various types of vulvectomies are presented in Table 54-13). If the cancer is

TABLE 54-13 SURGICAL PROCEDURES INVOLVING THE FEMALE REPRODUCTIVE SYSTEM

Type of Surgery	Description
Abdominal Hysterectomy	
Total hysterectomy	Uterus and cervix removed using large abdominal incision (bikini cut).
Total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO)	Uterus, cervix, fallopian tubes, and ovaries removed using large abdominal incision.
Radical hysterectomy	Panhysterectomy, partial vaginectomy, and dissection of lymph nodes in pelvis.
Vaginal Hysterectomy	Uterus and cervix removed through a cut in the top of vagina.
Laparoscopic Hysterectomy	Laparoscope (video camera and small surgical instruments).
Laparoscopic-assisted vaginal hysterectomy (LAVH)	Incision made at top of vagina. Uterus and cervix removed through the vagina. Laparoscope inserted into abdomen to assist in the procedure.
Laparoscopic supracervical hysterectomy	Uterus removed using only laparoscopic instruments. Cervix is left intact.
Robotic-Assisted Surgery	Robot (special machine) used to do surgery through small abdominal incisions. Most often used when a patient has cancer or is very overweight and vaginal surgery is not safe.
Vulvectomy	Surgical procedure to remove part or all of the vulva.
Skinning vulvectomy	Removal of top layer of vulvar skin where the cancer is found. Skin grafts from other parts of the body may be needed to cover the area.
Simple vulvectomy	Entire vulva is removed
Radical vulvectomy	Entire vulva, including clitoris, labia majora and minora, and nearby tissue, is removed. Nearby lymph nodes may also be removed.
Vaginectomy	Removal of vagina.
Pelvic Exenteration	Radical hysterectomy, total vaginectomy, removal of bladder with diversion of urinary system and resection of colon and rectum with colostomy.

extensive, a pelvic exenteration may be done. As adjuvant measures, the patient may have *chemotherapy* or *radiation therapy* after surgery.

SURGICAL PROCEDURES: FEMALE REPRODUCTIVE SYSTEM

A variety of surgical procedures are performed when benign or malignant tumors of the genital tract are found (see Table 54-13). A *hysterectomy* (removal of the uterus) is performed for excision of cancerous tumors of the female reproductive system. A hysterectomy may be done abdominally, vaginally, or laparoscopically. The abdominal route is used when large tumors are present and the pelvic cavity is to be explored or when the tubes and ovaries are to be removed at the same time (Fig. 54-10). The abdominal route can present more postoperative problems because it involves an incision and the opening of the abdominal cavity.

A vaginal route is often used when vaginal repair is done in addition to removal of the uterus. In both vaginal and abdominal hysterectomies, the ligaments that support the uterus are attached to the vaginal cuff to maintain the normal depth of the vagina. Laparoscopic procedures have the advantage of quicker recovery time and fewer complications.[35]

Depending on the findings and reason for the hysterectomy, the cervix may be left in place and not removed. Preserving the cervix may decrease the risk of pelvic floor prolapse and urinary incontinence. The patient needs to continue to get Pap tests if the cervix is left in place or the surgery was done to treat cancer.

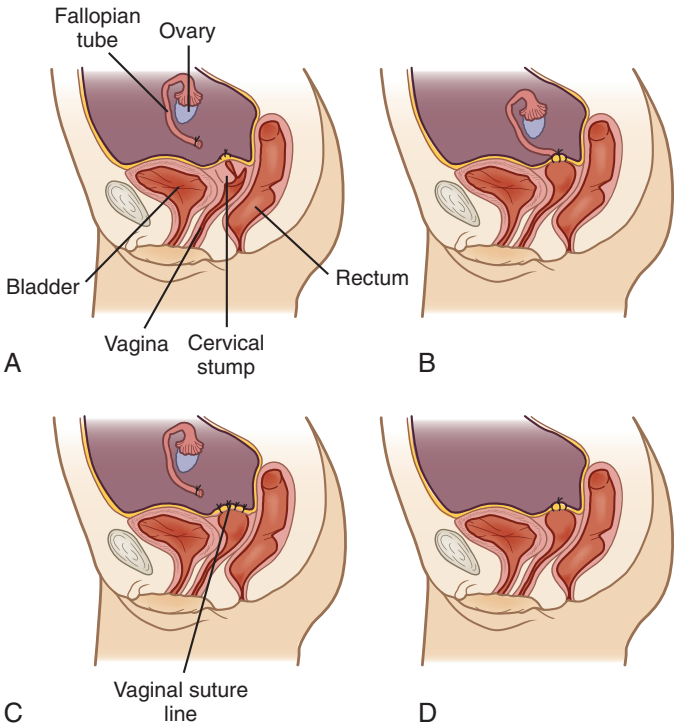

FIG. 54-10 **A,** Cross section of subtotal hysterectomy. Note that cervical stump, fallopian tubes, and ovaries remain. **B,** Cross section of total hysterectomy. Note that fallopian tubes and ovaries remain. **C,** Cross section of vaginal hysterectomy. Note that fallopian tubes and ovaries remain. **D,** Total hysterectomy, salpingectomy, and oophorectomy. Note that uterus, fallopian tubes, and ovaries are completely removed.

RADIATION THERAPY: CANCERS OF FEMALE REPRODUCTIVE SYSTEM

Radiation is used to cure or control or as a palliative measure for cancers of the female reproductive system, either alone or in combination with other treatments. The goal of radiation therapy is to deliver a specific amount of high-energy (or ionizing) radiation to the cancer with minimal damage to the normal surrounding tissue. Radiation therapy may be external or internal (brachytherapy).

External Radiation Therapy

With external radiation therapy, a source outside of the body delivers electromagnetic radiation in the form of waves. (External radiation therapy and related nursing care are discussed in Chapter 16.)

Brachytherapy

Brachytherapy allows the radiation to be placed internally near or into the tumor. This method can deliver a high dose of radiation directly to the tumor.[36] The dose decreases sharply farther away from the source, causing less damage to the surrounding normal tissue. A variety of forms are used to deliver the therapy, including wires, capsules, needles, tubes, and seeds. Brachytherapy is used in the management of cervical and endometrial cancer because of the accessibility of these body parts and the favorable results obtained. Radium and cesium are two commonly used isotopes.

To prepare the patient for the treatment, give a cleansing enema to prevent straining at stool, which could cause displacement of the isotope. Insert an indwelling catheter to prevent a distended bladder from coming into contact with the radioactive source.

A variety of applicators have been developed for intrauterine treatment. Applicators are inserted into the endometrial cavity and vagina in the operating room. When the applicator contains the radioactive material, this is known as *preloading*. In *afterloading* the applicator is implanted in the operating room but is not loaded with the radioactive material until its correct placement is verified and the patient has returned to her room.

Radiation exposure to the patient is precisely controlled. The radiation exposure to the physician and other personnel involved in the implantation is reduced when the afterload technique is used. The applicator is secured with vaginal packing and is left in place for 24 to 72 hours.

During treatment the patient is placed in a lead-lined private room and is on absolute bed rest. She may be turned from side to side. The presence of an intrauterine applicator produces uterine contractions that may require analgesics. The destruction of cells results in a foul-smelling vaginal discharge, and a deodorizer is helpful. Nausea, vomiting, diarrhea, and malaise may develop as a systemic reaction to the radiation.

At the end of the prescribed period of radiation, the radioactive material and the catheter are removed. The patient is allowed off bed rest and is discharged from the hospital when stable. Late complications that may arise include fistulas (vesicovaginal, ureterovaginal), cystitis, phlebitis, hemorrhage, and fibrosis. If fibrosis occurs, the vaginal wall becomes smaller in diameter and shorter. Dilation of the vagina through intercourse or the use of sequentially sized dilators may be indicated. The patient is urged to report any unusual symptoms or com-

plaints to her physician. (Brachytherapy and related nursing care are discussed in Chapter 16.)

NURSING MANAGEMENT CANCERS OF FEMALE REPRODUCTIVE SYSTEM

NURSING ASSESSMENT

Malignant tumors of the female reproductive system can be found in the cervix, endometrium, ovaries, vagina, and vulva. A patient with any of these malignant tumors may experience a variety of clinical manifestations, including leukorrhea, irregular vaginal bleeding, vaginal discharge, abdominal pain and pressure, bowel and bladder dysfunction, and vulvar itching and burning. Assessment for these signs and symptoms is an important nursing responsibility.

NURSING DIAGNOSES

Nursing diagnoses for the female patient with cancer of the reproductive system include, but are not limited to, the following:

- Anxiety *related to* threat of a malignancy and lack of knowledge about the disease process and prognosis
- Acute pain *related to* pressure secondary to an enlarging tumor
- Disturbed body image *related to* loss of body part and loss of good health
- Ineffective sexuality pattern *related to* physiologic limitations and fatigue
- Grieving *related to* poor prognosis of advanced disease

PLANNING

The overall goals are that the patient with cancer of the female reproductive system will (1) actively participate in treatment decisions, (2) achieve satisfactory pain and symptom management, (3) recognize and report problems promptly, (4) maintain preferred lifestyle as long as possible, and (5) continue to practice cancer detection strategies.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Through your contact with women in a variety of settings, teach women the importance of routine screening for cancers of the reproductive system. Cancer can be prevented when screening reveals precancerous conditions of the vulva, cervix, endometrium, and, rarely, the ovaries. Also, routine screening increases the chance that a cancer will be found in an early stage. When cancer is identified early, treatment can be more conservative and the woman's prognosis improves. A yearly pelvic examination and Pap test (as indicated) allow the health care provider to detect lesions on the vulva or any uterine or ovarian irregularities and screen for cervical cancer. Encourage women to view routine cancer screening and vaccination against cervical cancer as important self-care activities.

Teaching women about risk factors for cancers of the reproductive system is also important. Limiting sexual activity during adolescence, using condoms, having fewer sexual partners, and not smoking reduce the risk of cervical cancer. When high-risk behaviors are identified, assist women in modifying their lifestyles to decrease risk.

ACUTE INTERVENTION RELATED TO SURGERY. All patients experience a degree of anxiety when contemplating surgery, but the prospect of major gynecologic surgery increases these concerns. Some women may experience guilt, anger, or embarrassment. Still others may focus on the effect the surgery will have on their reproductive and sexual functions. Some women view the whole process as annoying, whereas others are relieved by the thought of no longer having menstrual periods or becoming pregnant. Try to understand the patient's fears and concerns. Each patient needs to be assessed as an individual. Be willing to listen, since this can provide considerable psychologic support.

Preoperatively, prepare the patient physically for surgery with the standard perineal or abdominal preparation. A vaginal douche and enemas may be given (based on the surgeon's preference). The bladder should be emptied before the patient is sent to the operating room. An indwelling catheter is commonly inserted preoperatively. (See Chapter 18 for discussion of general preoperative patient care.)

Hysterectomy. Postoperatively, the patient who has had an abdominal hysterectomy will have an abdominal dressing. Observe the dressing frequently for any sign of bleeding during the first 8 hours after surgery. (See eNursing Care Plan 54-1 for care of the patient after a total abdominal hysterectomy.)

The patient who has had a vaginal hysterectomy will have a perineal pad. A moderate amount of serosanguineous drainage on the perineal pad is expected. The patient may experience urinary retention postoperatively because of temporary bladder atony resulting from edema or nerve trauma. At times an indwelling catheter is used for 1 to 2 days postoperatively to maintain constant drainage of the bladder and prevent strain on the suture line. If an indwelling catheter is not used, catheterization may be necessary if the patient has not urinated for 8 hours postoperatively. If residual urine is suspected after the removal of an indwelling catheter, catheterization is done to prevent bladder infection caused by pooling of urine. Accidental ligation of a ureter is a serious surgical complication. Report any complaint of backache or decreased urine output to the surgeon.

Abdominal distention may develop from the sudden release of pressure on the intestines when a large tumor is removed or from paralytic ileus secondary to anesthesia and pressure on the bowel. Food and fluids may be restricted if the patient is nauseated. Ambulation will help relieve abdominal flatus.

Take special care to prevent the development of deep vein thrombosis (DVT). Frequent changes of position, avoidance of the high Fowler's position, and avoidance of pressure under the knees minimize stasis and pooling of blood. Pay special attention to patients with varicosities. Encourage leg exercises to promote circulation.

The loss of the uterus may bring about grief response in some women, similar to any great personal loss. The ability to bear children may be associated with her perception of womanhood. Grief from this loss is normal. Elicit the woman's feelings and concerns about her surgery.

When surgery removes the ovaries as well, women experience surgical menopause. Estrogen is no longer available from the ovaries, so symptoms of estrogen deficiency arise. To counter this, HT may be initiated in the early postoperative period.

Teach the patient what to expect after surgery (e.g., she will not menstruate). Instructions should include specific activity restrictions. Intercourse should be avoided until the wound is healed (about 4 to 6 weeks). However, intercourse is not contraindicated once healing is complete. If a vaginal hysterectomy is performed, inform the patient that she may have a temporary loss of vaginal sensation. Reassure her that the sensation will return in several months.

Physical restrictions are limited for a short time. Heavy lifting should be avoided for 2 months. Teach her to avoid activities that may increase pelvic congestion, such as dancing and walking swiftly, for several months. However, activities such as swimming may be both physically and mentally helpful. Assure her that once healing is complete, all previous activity can be resumed.

Many women report a decrease in the quality of their sex lives after cancer treatment.[37] Provide information on what to expect related to their sexual functioning before the treatment and reinforce it afterward.

Salpingectomy and Oophorectomy. Postoperative care of the woman who has undergone removal of a fallopian tube (salpingectomy) or an ovary (oophorectomy) is similar to that for any patient having abdominal surgery. However, if a large ovarian cyst was removed, she may have abdominal distention caused by the sudden release of pressure in the intestines. An abdominal binder may provide relief until the distention subsides.

When both ovaries are removed (bilateral oophorectomy), surgical menopause results. The symptoms are similar to those of regular menopause but may be more severe because of the sudden withdrawal of hormones. Attempts may be made to leave at least a portion of an ovary.

Vulvectomy. Although cancer of the vulva is relatively uncommon, it is important to recognize the extent of the vulvectomy and the significant effect it is likely to have on the patient's life. Having an honest, open attitude with the patient and her partner preoperatively can be most helpful in the postoperative period.

After a vulvectomy (see Table 54-13), the patient has a wound in the perineal area extending to the groin. The wound may be covered or left exposed and frequently has drains attached to portable suction (e.g., Hemovac, Jackson-Pratt). A heavy pressure dressing is often in place for the first 24 to 48 hours. The wound is cleaned with normal saline solution or an antiseptic twice daily. Solutions can be applied with an aseptic bulb syringe or a Waterpik machine. Wound care must be meticulous to prevent infection, which results in delayed healing.

Special attention to bowel and bladder care is needed. A low-residue diet and stool softeners prevent straining and wound contamination. An indwelling catheter is used to provide urinary drainage. Be careful not to dislodge the catheter because extensive edema makes its reinsertion difficult. Heavy, taut sutures are often used to close the wounds, resulting in severe discomfort. In other instances, the wound may be allowed to heal by granulation. Analgesics may be required to control pain. Carefully position the patient using strategically placed pillows to provide comfort. Anticoagulant therapy to prevent DVTs is common.

Because the surgery causes mutilation of the perineal area and the healing process is slow, the patient is likely to become discouraged. Provide opportunities for the patient to express her feelings and concerns about the operation. Teach the patient specific instructions in self-care before discharge. Instruct her to report any unusual odor, fresh bleeding, breakdown of incision, or perineal pain. Home care nursing can benefit the patient during her adjustment period.

Sexual function is often retained. Whether clitoral sensation is retained may be critical to some women, particularly if it was a primary source of orgasmic satisfaction. Discussing alternative methods of achieving sexual satisfaction may be indicated.

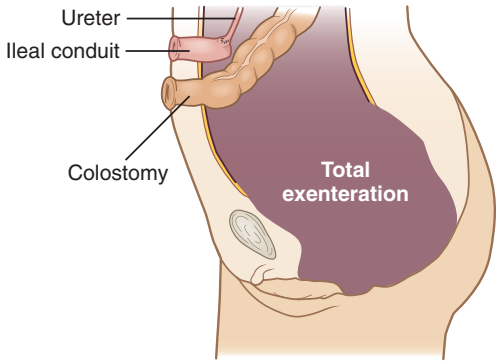

FIG. 54-11 Total exenteration is removal of all pelvic organs with creation of an ileal conduit and a colostomy.

Pelvic Exenteration. When other forms of therapy fail to control the spread of cancer and no metastases have been found outside of the pelvis, pelvic exenteration may be performed. This radical surgery usually involves removal of the uterus, ovaries, fallopian tubes, vagina, bladder, urethra, and pelvic lymph nodes (Fig. 54-11). In some situations, the descending colon, rectum, and anal canal may also be removed. Candidates for this procedure are selected on the basis of their likelihood of surviving the surgery and their ability to adjust to and accept the resulting limitations.

Postoperative care is similar to that of a patient who has had a radical hysterectomy, an abdominal perineal resection, and an ileostomy or a colostomy. The physical, emotional, and social adjustments to life required by the woman and her family are great. There are urinary or fecal diversions in the abdominal wall, a reconstructed vagina, and the onset of menopausal symptoms.

Assess the patient's physical and emotional adjustment to the changes in body image produced by the surgery and her ability to carry out any treatment measures. The patient's rehabilitative process should keep pace with her acceptance of the situation. Much understanding and support are needed from the nursing staff during a long recovery period. Gently encourage the patient to regain her independence. She needs to verbalize her feelings about her altered body structure. Including the family in the plan of care is important. Careful follow-up monitoring is needed so that early recurrence of the cancer can be identified and treated.

ACUTE INTERVENTION WITH RADIATION THERAPY. Instruct the patient who is to receive external radiation to urinate immediately before the treatment to minimize radiation exposure to the bladder. Advise her about radiation side effects, including enteritis and cystitis. These are natural reactions to radiation therapy and do not indicate an overdose. Fully inform the patient of the possible side effects and measures that can be used to reduce their impact.

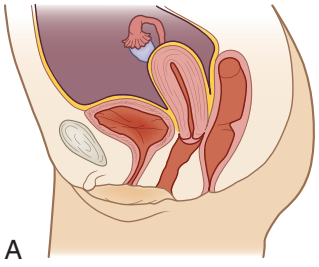
Nursing management of the patient receiving internal radiation therapy requires special considerations. Do not stay in the immediate area any longer than is necessary to give proper care and attention. No individual nurse should take care of the patient for more than 30 minutes per day. Stay at the foot of the bed or at the entrance to the room to minimize radiation exposure. Instruct visitors to stay 6 ft away from the bed and limit visits to less than 3 hr/day. Efficient organization of nursing care is essential so that you do not stay in the patient's immediate area any longer than is necessary. Fully explain the reasons for

these precautions to the patient and her visitors. (A more detailed discussion of nursing care of the patient receiving internal radiation therapy is presented in Chapter 16.)

EVALUATION

The expected outcomes are that the patient with cancer of the female reproductive system will

- Actively participate in treatment decisions
- Achieve satisfactory pain and symptom management
- Recognize and report problems promptly
- Maintain preferred lifestyle as long as possible
- Continue to practice cancer detection strategies



PROBLEMS WITH PELVIC SUPPORT

The most commonly occurring problems with pelvic support are uterine prolapse, cystocele, and rectocele. Although vaginal birth increases the risk for these problems, these conditions can occur in women who have never experienced childbirth. Obesity, chronic coughing, and straining during bowel movements can increase the likelihood of these problems. The decreased estrogen that normally accompanies perimenopause also reduces some connective tissue support.

UTERINE PROLAPSE

Uterine prolapse is the downward displacement of the uterus into the vaginal canal[38] (Fig. 54-12). Prolapse is rated by degrees. In first-degree prolapse the cervix rests in the lower part of the vagina. Second-degree prolapse means the cervix is at the vaginal opening. Third-degree prolapse means the uterus protrudes through the introitus.

Symptoms vary with the degree of prolapse. The patient may describe a feeling of "something coming down." She may have dyspareunia, a dragging or heavy feeling in the pelvis, backache, and bowel or bladder problems if cystocele or rectocele is also present. Stress incontinence is a common and troubling problem. When third-degree uterine prolapse occurs, the protruding cervix and vaginal walls are subjected to constant irritation, and tissue changes may occur.

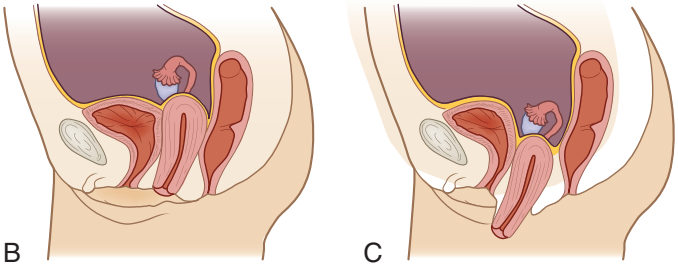


FIG. 54-12 Uterine prolapse. **A,** First-degree prolapse. **B,** Second-degree prolapse. **C,** Third-degree prolapse.

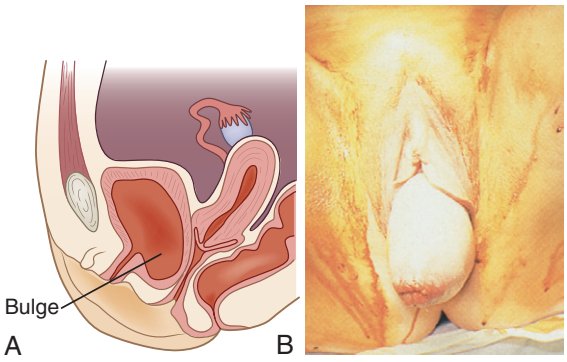

FIG. 54-13 **A,** Cystocele. **B,** Bladder has prolapsed into the vagina, causing a uterine prolapse.

Therapy depends on the degree of prolapse and how much the woman's daily activities have been affected. Pelvic muscle strengthening exercises (Kegel exercises) may be effective for some women (see Table 46-19). If not, a pessary may be used. A *pessary* is a device that is placed in the vagina to help support the uterus. A wide variety of shapes exist, including rings, arches, and balls. Most are made of plastic or wire coated with plastic. When a woman first receives a pessary, she needs instructions for its cleaning and follow-up. Pessaries that are left in place for long periods are associated with erosion, fistulas, and vaginal carcinoma.

If more conservative measures are not successful, surgery is indicated. Surgery generally involves a vaginal hysterectomy with anterior and posterior repair of the vagina and the underlying fascia.

CYSTOCELE AND RECTOCELE

Cystocele occurs when support between the vagina and bladder is weakened (Fig. 54-13). Similarly, a **rectocele** results from weakening between the vagina and rectum (Fig. 54-14). Cystocele and rectocele are common problems, and in many women they are asymptomatic. With large cystoceles, complete emptying of the bladder can be difficult, predisposing women to bladder infections. A woman with a large rectocele may not be able to completely empty her rectum when defecating unless she helps push the stool out by putting her fingers in her vagina.

As with uterine prolapse, Kegel exercises (see Table 46-19) may be used to strengthen the weakened perineal muscles if the cystocele or rectocele is not too problematic. A pessary may be helpful for cystoceles. Surgery designed to tighten the vaginal

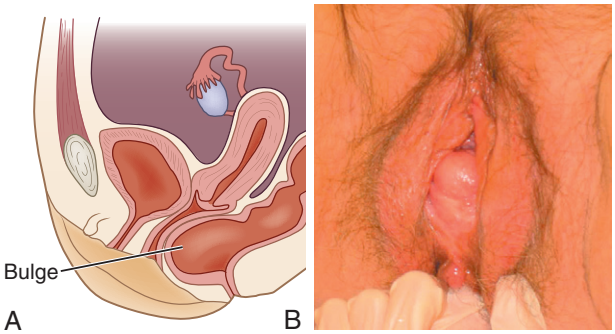

FIG. 54-14 **A,** Rectocele. **B,** Rectum has prolapsed into the vagina.

wall is generally the method of treatment. A cystocele is corrected with a procedure called an anterior colporrhaphy, whereas a posterior colporrhaphy is done for a rectocele. If further surgery is needed to relieve stress incontinence, procedures to support the urethra and restore the proper angle between the urethra and the posterior bladder wall are used.

NURSING MANAGEMENT
PROBLEMS WITH PELVIC SUPPORT

Assist women in avoiding or decreasing problems with pelvic support by teaching them how to do Kegel exercises. Women of all ages may benefit from these exercises. Instruct the patient to pull in or contract her muscles as if she were trying to stop the flow of urine. She should hold the contraction for several seconds and then relax. Sets of 5 to 10 contractions each should be done several times daily.

If vaginal surgery is necessary, the preoperative preparation usually includes a cleansing douche the morning of surgery. A cathartic and a cleansing enema are usually given when a rectocele repair is scheduled. A perineal shave may be done.

In the postoperative period the goals of care are to prevent wound infection and pressure on the vaginal suture line. This necessitates perineal care at least twice a day and after each urination or defecation. Apply an ice pack locally to help relieve the initial perineal discomfort and swelling. A disposable glove filled with ice and covered with a cloth works well. Later, sitz baths may be used.

After an anterior colporrhaphy, an indwelling catheter is usually left in the bladder for 4 days to allow the local edema to subside. The catheter keeps the bladder empty, preventing strain on the sutures. Twice-daily catheter care with an antiseptic is generally done. After posterior colporrhaphy, straining at stool is avoided by means of a low-residue diet and the prevention of constipation. A stool softener is usually given each night.

Review discharge instructions before the patient leaves the hospital. These include the use of douches or a mild laxative as needed; restrictions on heavy lifting and prolonged standing, walking, or sitting; and avoidance of intercourse until the physician gives permission. There may be a temporary loss of vaginal sensation, which can last for several months.

FISTULA

A *fistula* is an abnormal opening between internal organs or between an organ and the exterior of the body (Fig. 54-15).

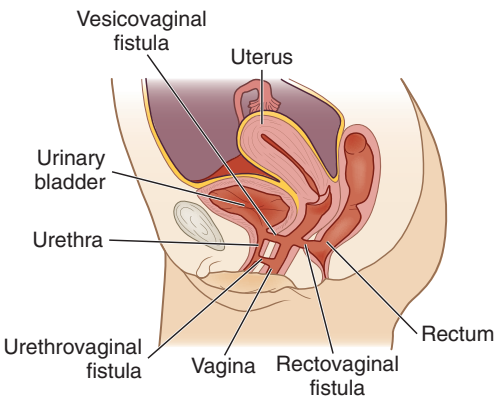

FIG. 54-15 Common fistulas involving the vagina.

Gynecologic procedures cause most urinary tract fistulas. Other causes include injury during childbirth and disease processes, such as cancer. Fistulas may develop between the vagina and the bladder, urethra, ureter, or rectum. When *vesicovaginal* fistulas (between the bladder and the vagina) develop, some urine leaks into the vagina, whereas with *rectovaginal* fistulas (between the rectum and the vagina), flatus and feces escape into the vagina. In both instances, excoriation and irritation of the vaginal and vulvar tissues occur and may lead to severe infections. In addition to wetness, offensive odors may develop, causing embarrassment and severely limiting socialization.

Because small fistulas may heal spontaneously within a matter of months, treatment may not be needed. If the fistula does not heal, surgical excision is required. Inflammation and tissue edema must be eliminated before surgery is attempted, which may involve a wait of up to 6 months. The fistulectomy may result in the patient's having an ileal conduit or temporary colostomy.

NURSING MANAGEMENT
FISTULAS

Perineal hygiene is of great importance both preoperatively and postoperatively. Cleanse the perineum every 4 hours. Warm sitz baths should be taken three times daily if possible. Change perineal pads frequently. Encourage the patient to maintain an adequate fluid intake. Encouragement and reassurance are needed to help the patient cope with her problems.

Postoperatively, emphasize the avoidance of stress on the repaired areas and prevention of infection. Take care so that the indwelling catheter, usually in place for 7 to 10 days, is draining at all times. Urge oral fluids to provide for internal catheter irrigation. Use minimal pressure and strict asepsis if catheter irrigation becomes necessary. The first stool after bowel surgery may be purposely delayed to prevent contamination of the wound. Later, give stool softeners or mild laxatives. (See Chapter 46 for care of a patient with an ileal conduit and Chapter 43 for care of a patient with a colostomy.) Surgical repair of fistulas is not always effective, even in the best conditions. Therefore supportive nursing care for the patient and her significant others is especially important.

SEXUAL ASSAULT

Sexual assault is the forcible perpetration of a sexual act on a person without his or her consent. It can include any of the following actions: sodomy (anal or oral copulation with a person of the same or opposite sex), forced vaginal intercourse, assault with a foreign object, and serial battery.

Sexual assault may be committed by a stranger or by an intimate partner. Intimate partner violence (IPV) is a major health problem in the United States.[39] Survivors can suffer physical trauma and mental health consequences. Pregnancy, STIs, and gynecologic problems can result from IPV. More than half of all female rape victims were raped by an intimate partner. Female victims of IPV frequently report chronic pain, sleep disturbances, poor physical health, and activity limitations.

Clinical Manifestations

Physical. Many women who seek help immediately after the assault will not have any evidence of physical trauma. Evidence of trauma may be limited because women do not resist for fear

TABLE 54-14 EMERGENCY MANAGEMENT

Sexual Assault

Etiology	Assessment Findings	Interventions
• Sexual molestation • Sodomy • Assault involving genitalia (male or female) without consent	• Emotional or physical manifestations of shock • Hysteria • Crying • Anger • Silence • Decreased level of consciousness • Hyperventilation • Oral, vaginal, and rectal injuries • Extragenital injuries • Pain in genital or extragenital area	**Initial** • Treat shock and other urgent medical problems (e.g., head injury, hemorrhage, wounds, fractures). • Assess emotional state. • Contact support person (i.e., social worker, rape advocate, sexual assault nurse examiner). • Do *not* clean the patient until all evidence is collected. Make sure the patient does not wash, douche, urinate, brush teeth, or gargle. • Place sheet on floor. Then have patient stand on sheet to remove clothing. Place sheet with clothing in paper bag. • Obtain forensic evidence per local protocol (e.g., body hair, nail scrapings, tissue, dried semen, vaginal washing, blood samples). • Maintain chain of evidence for all legal specimens. Clearly label evidence and keep in locked cabinet until given to law enforcement agency. • Obtain baseline HIV, syphilis, and other STI screening. • Determine method of contraception, date of last menstrual period, and date of last tetanus immunization. • Consider tetanus prophylaxis if lacerations contain soil or dirt. • Vaccinate against hepatitis B if not already done. **Ongoing Monitoring** • Monitor vital signs and emotional status. • Provide clothing as needed. • Counsel patient regarding confidential HIV and STI testing.

HIV, Human immunodeficiency virus; *STI,* sexually transmitted infection.

of physical danger and injury. When present, physical injuries may include bruising and lacerations to the perineum, hymen, vulva, vagina, cervix, and anus. Fractures, subdural hematomas, cerebral concussions, and intraabdominal injuries may result in the need for hospitalization. Sexual assault also places women at risk for STIs and pregnancy.

Psychologic. Immediately after the assault, women may show shock, numbness, denial, or withdrawal. Some women may seem unnaturally calm; others may cry or express anger. Feelings of humiliation, degradation, embarrassment, anger, self-blame, and fear of another assault are commonly expressed. These symptoms usually decrease after 2 weeks, and victims may appear to have adjusted. Yet any time from 2 to 3 weeks to months or years after the assault, symptoms may return and become more severe. *Rape trauma syndrome* is a classification of posttraumatic stress disorder. Flashbacks, intrusive recall, sleep disturbances, gastrointestinal symptoms, and numbing of feelings are common initial symptoms. Women feel embarrassment, self-blame, and powerlessness. Later symptoms include mood swings, irritability, and anger. Feelings of despair, shame, and hopelessness are often the cause of the anger. These feelings may be internalized and lead to depression. Suicidal ideations may also occur.

Collaborative Care

In the acute care of an assault survivor, ensuring the woman's emotional and physical safety has the highest priority. Table 54-14 outlines the emergency management of the patient who has been sexually assaulted. Most emergency departments (EDs) have identified personnel who have received special training to work with women who have been assaulted.

Many crime-fighting or victim advocate agencies within communities have implemented the position of the sexual assault nurse examiner (SANE).[40] The SANE is a registered nurse who is certified to provide care to victims of sexual assault, while ensuring evidence is safeguarded. Special procedures are followed in taking the history and conducting the examination to preserve all evidence in case of future prosecution.

When the survivor of an assault is admitted to the ED or clinic, a specific chain of events occurs (Table 54-15). A signed informed consent is obtained from the woman before any data are collected. All materials gathered are well documented, labeled, and given to the appropriate person, such as the pathologist or a police officer. The materials are handled by as few people as possible, and signatures of all responsible for keeping and handling the data are obtained. Many items can be used as evidence if the victim chooses to file a complaint. Consequently, the integrity of the material must be maintained. Your involvement in the medicolegal process depends on the policies of the individual institution and state law.

A gynecologic and sexual history and an account of the assault (who, what, when, and where), as well as a general physical and pelvic examination, add further information about the incident. Laboratory tests are done primarily to look for sperm in the vagina and to identify any existing STIs or pregnancy.

Follow-up physical and psychologic care is essential. Women should return weekly for the first month after the assault. This includes the time period when a woman's psychologic reactions may be the most severe. Provide the telephone numbers and names of contact persons for local resources for sexual assault survivors, including rape crisis centers, legal and law enforcement authorities, and human services.

NURSING MANAGEMENT SEXUAL ASSAULT

Assist all women in becoming aware of prevention tactics (Table 54-16). Also encourage women to learn some basic techniques

TABLE 54-15 EVALUATION OF ALLEGED SEXUAL ASSAULT

1. Medicolegal
- Valid written consent for examination, photographs, laboratory tests, release of information, and laboratory samples
- Appropriate "chain of evidence" documentation

2. History
- History of assault (who, what, when, where)
- Penetration, ejaculation, extragenital acts
- Activities since assault (e.g., changed clothes, bathed, douched)
- Inquire about safety
- Menstrual and contraceptive history
- Medical history
- Emotional status
- Current symptoms

3. General Physical Examination
- Vital signs and general appearance
- Extragenital trauma—mouth, breasts, neck
- Cuts, bruises, scratches (photographs taken)

4. Pelvic Examination
- Vulvar trauma, erythema; hymen, anal, and rectal status
- Matted hairs or free hairs
- Vaginal examination with unlubricated speculum for discharge, blood, lacerations
- Uterine size
- Adnexa, especially hematomas

5. Laboratory Samples
- Vaginal vault content sampling
- Vaginal smears—microscope evaluation for trichomonads and semen
- Oral or rectal swabs and smears, if indicated
- Blood samples—VDRL serology, pregnancy test; serologic testing for HIV and hepatitis B infection
- Freeze serum sample for later testing
- Cultures—cervix and other areas (if indicated) for gonorrhea and chlamydial infection
- Fingernail scrapings
- Pubic hair scrapings
- Clipping of matted pubic hairs

6. Treatment
- Care of injuries and emotional trauma
- Prophylaxis for STIs, tetanus, and hepatitis B (see appropriate chapters)
- If appropriate, consider levonorgestrel (Plan-B One-Step) emergency contraceptive pill up to 72 hr after assault; follow-up for pregnancy test in 2-3 wk
- Testing for HIV, syphilis, and hepatitis B may be done at 6-8 wk
- Protection of legal rights
- Recommendation of continued follow-up and services of rape crisis center

VDRL, Venereal Disease Research Laboratory.

TABLE 54-16 PATIENT TEACHING GUIDE

Sexual Assault Prevention

Include the following instructions when teaching measures to prevent sexual assault.

1. Be proactive and take a self-defense class.
2. Be aware of date-rape drugs (e.g., GHB, Rohypnol, Ketamine). Never leave your beverage unattended when socializing.
3. Place and maintain lights at all entrances to your home.
4. Keep your doors locked and do not open them to a stranger. Ask for identification if a service person comes to the door.
5. Do not advertise that you live alone. List only your initials with your last name in the telephone directory or on the mailbox. Never reveal to a caller that you are home alone.
6. Avoid walking alone in deserted areas. Walk to the parking lot with a friend; be sure you see each other leave.
7. Have your keys ready as you approach your car or home.
8. Keep all doors locked and the windows up when driving.
9. Never get on an elevator with a suspicious person. Pretend you have forgotten something and get off.
10. Say what you mean in social situations. Be sure your voice and body language reflect your response.
11. Proceed with caution in online correspondence.
12. Carry a loud whistle and use it when you think you are in danger.
13. Yell "Fire!" if you are attacked and run toward a lighted area.

of self-defense. Local high schools and the YWCA usually have self-defense classes for formal instruction. Practicing the various techniques with a friend strengthens a woman's confidence in her ability to fight back. Learning self-defense can make the woman less vulnerable and more self-reliant.

When a sexual assault survivor is brought to the clinic or ED, a quiet, private area should be used for the initial assessment and the examinations that follow. Do not leave the patient alone. Whenever possible, the same nurse should remain with her throughout her stay and provide needed emotional support. The patient's actions and words as she describes the incident may be inconsistent, confused, and inappropriate. Maintain a nonjudgmental attitude.

The patient usually has many feelings and thoughts about the assault and generally wants to talk about them to an interested listener. Talking may help the patient feel better and gain understanding of her reactions to the incident. When you listen carefully, the patient feels that she is not alone and is better able to gain control over the situation.

Assess the patient's stress level before preparing her for the various procedures that will follow. Let her know what to expect and what is expected of her, as well as why the particular procedure must be done. Because the pelvic examination may trigger a flashback of the attack, answer all related questions before the examination and be a supportive presence during the examination.

After the examination, consider the patient's physical comfort needs. She will need a change of clothing because her original garments may be torn or soiled, or kept as evidence. Most women who have been sexually assaulted feel dirty and need a place to wash and to use a mouthwash, especially if oral sex was involved. Food and drink may also provide comfort to the victim.

Discuss the possibility of pregnancy and offer the patient an emergency contraception pill. Taking a single tablet of levonorgestrel (Plan-B One-Step) within 72 hours after unprotected sexual intercourse reduces the risk of pregnancy. Levonorgestrel is generally effective and safe, and it will not affect an existing pregnancy. Mifepristone (RU-486) is approved for use in early abortions in the United States but not for emergency contraception.

Many sexual assault survivors are unaware of the availability of financial compensation (a law in most states) and appreciate information about the application process. This compensation is to assist them in paying for emergency services and for emotional injuries that may temporarily interfere with their ability to work.

When the patient is discharged, make certain the patient has transportation home. If friends or family members are not

CASE STUDY

Uterine Prolapse and Vaginal Hysterectomy

Jupiterimages/Photos.com/Thinkstock

Patient Profile

N.B. is a 65-yr-old white woman who has developed lower pelvic discomfort and stress incontinence. She has type 2 diabetes and hypertension. N.B. is the mother of three children. A second-degree uterine prolapse is diagnosed. N.B. was treated conservatively with a pessary, but her symptoms did not improve. She comes to the hospital for a vaginal hysterectomy and anteroposterior repair.

Subjective Data

- Was initially reluctant about surgery
- Concerned about her dyspareunia and her husband's reaction to the surgery
- Concerned she may have uterine cancer
- States she has stress incontinence and pelvic discomfort

Objective Data

Physical Examination

- Second-degree uterine prolapse on vaginal examination
- BP 150/100 mm Hg, pulse 110 beats/min, respirations 20 breaths/min

Laboratory Studies

- Hemoglobin 10 g/dL (0.10 g/L)
- Hemoglobin A1C 9%

Postoperative Status

- Returned to room with indwelling urinary catheter in place
- Vaginal packing in place
- Sequential compression devices on lower extremities
- Patient-controlled analgesia (PCA) pump for pain management

Discussion Questions

1. What are the common causes of uterine prolapse?
2. N.B. asks you about the effect of the surgery on her sexuality. How would you respond?
3. ***Priority Decision:*** What are priorities of care for N.B.?
4. What possible complications (including reasons for their development) can occur after a vaginal hysterectomy?
5. ***Delegation Decision:*** Which nursing personnel should be responsible for teaching N.B. related to her diabetes and hypertension: registered nurse, licensed practical/vocational nurse, unlicensed assistive personnel? What should she be taught?
6. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?

evolve Answers available at http://evolve.elsevier.com/Lewis/medsurg.

available, the hospital or clinic should make arrangements with an appropriate community resource. The patient should not be sent home alone. The victim's partner and family have tremendous potential as both a negative and positive influence. If the partner is the perpetrator of the assault, consultation with the risk management department and law enforcement is necessary to protect the woman.

Many communities today have crisis centers. These public service organizations have trained professional and nonprofessional volunteers who provide an emotional support system on request. Their programs provide advocacy to ensure dignified treatment throughout the medical and police procedures, short-term counseling for the woman and her family, and court assistance and public education on rape-related issues.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In telling a patient with infertility what she and her partner can expect, the nurse explains that
   - **a.** ovulatory studies can help determine tube patency.
   - **b.** a hysterosalpingogram is a common diagnostic study.
   - **c.** the cause will remain unexplained for 40% of couples.
   - **d.** if postcoital studies are normal, infection tests will be done.
2. An appropriate question to ask the patient with painful menstruation to differentiate primary from secondary dysmenorrhea is
   - **a.** "Does your pain become worse with activity or overexertion?"
   - **b.** "Have you had a recent personal crisis or change in your lifestyle?"
   - **c.** "Is your pain relieved by nonsteroidal antiinflammatory medications?"
   - **d.** "When in your menstrual history did the pain with your period begin?"
3. The nurse should advise the woman recovering from surgical treatment of an ectopic pregnancy that
   - **a.** she has an increased risk for salpingitis.
   - **b.** bed rest must be maintained for 12 hours to assist in healing.
   - **c.** having one ectopic pregnancy increases her risk for another.
   - **d.** intrauterine devices and infertility treatments should be avoided.
4. To prevent or decrease age-related changes that occur after menopause in a patient who chooses not to take hormone therapy, the most important self-care measure to teach is
   - **a.** maintaining usual sexual activity.
   - **b.** increasing the intake of dairy products.
   - **c.** performing regular aerobic, weight-bearing exercise.
   - **d.** taking vitamin E and B-complex vitamin supplements.
5. The patient's thick, white, and curdlike vaginal discharge and vulvar pruritus are most consistent with
   - **a.** trichomoniasis.
   - **b.** monilial vaginitis.
   - **c.** bacterial vaginosis.
   - **d.** chlamydial cervicitis.
6. In caring for a patient with pelvic inflammatory disease, the nurse should place her in semi-Fowler's position. The rationale for this measure is to
   - **a.** relieve severe pain.
   - **b.** promote drainage to prevent abscesses.
   - **c.** improve circulation and promote healing.
   - **d.** prevent complication of bowel obstruction.

7. Nursing responsibilities related to the patient receiving brachytherapy for endometrial cancer include
   a. maintaining absolute bed rest.
   b. keeping the patient in high Fowler's position.
   c. allowing visitors if they stay 3 ft (1 m) from the bed.
   d. limiting direct nurse-to-patient contact to 30 minutes per shift.
8. Postoperative goals in caring for the patient who has undergone an abdominal hysterectomy include *(select all that apply)*
   a. monitoring urine output.
   b. changing position frequently.
   c. restricting all food for 24 hours.
   d. observing perineal pad for bleeding.
   e. encouraging leg exercises to promote circulation.
9. Postoperative nursing care for the woman with a gynecologic fistula includes *(select all that apply)*
   a. ambulation.
   b. bladder training.
   c. warm sitz baths.
   d. perineal hygiene.
   e. use of stool softeners.
10. The first nursing intervention for the patient who has been sexually assaulted is to
    a. treat urgent medical problems.
    b. contact support person for the patient.
    c. provide supplies for the patient to cleanse self.
    d. document bruises and lacerations of the perineum and the cervix.

1. b, 2. d, 3. c, 4. c, 5. b, 6. b, 7. a, 8. a, b, e, 9. c, d, 10. a

LEARNING OUTCOMES

1. Describe the pathophysiology, clinical manifestations, and collaborative care of benign prostatic hyperplasia.
2. Describe the nursing management of benign prostatic hyperplasia.
3. Describe the pathophysiology, clinical manifestations, and collaborative care of prostate cancer.
4. Explain the nursing management of prostate cancer.
5. Specify the pathophysiology, clinical manifestations, and nursing and collaborative management of prostatitis and problems of the penis and scrotum.
6. Explain the clinical manifestations and collaborative care of testicular cancer.
7. Describe the pathophysiology, clinical manifestations, and nursing and collaborative management of problems related to male sexual function.
8. Summarize the psychologic and emotional implications related to male reproductive problems.

This chapter discusses problems of the male reproductive system. These involve a variety of structures, including the prostate, penis, urethra, ejaculatory duct, scrotum, testes, epididymis, ductus (vas) deferens, and rectum (Fig. 55-1).

PROBLEMS OF THE PROSTATE GLAND

BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH) is a benign enlargement of the prostate gland. It is the most common urologic problem in male adults. About 50% of all men in their lifetime will develop BPH. Of these men, almost half of them will have bothersome lower urinary tract symptoms.[1] Research is not clear about whether having BPH leads to an increased risk of developing prostate cancer.[2,3]

Etiology and Pathophysiology

Although the cause of BPH is not completely understood, it is thought that BPH results from hormonal changes associated with the aging process.[1] One possible cause is excessive accumulation of dihydroxytestosterone (DHT) (the principal intraprostatic androgen) in the prostate cells. This can stimulate cell growth and an overgrowth of prostate tissue. Older

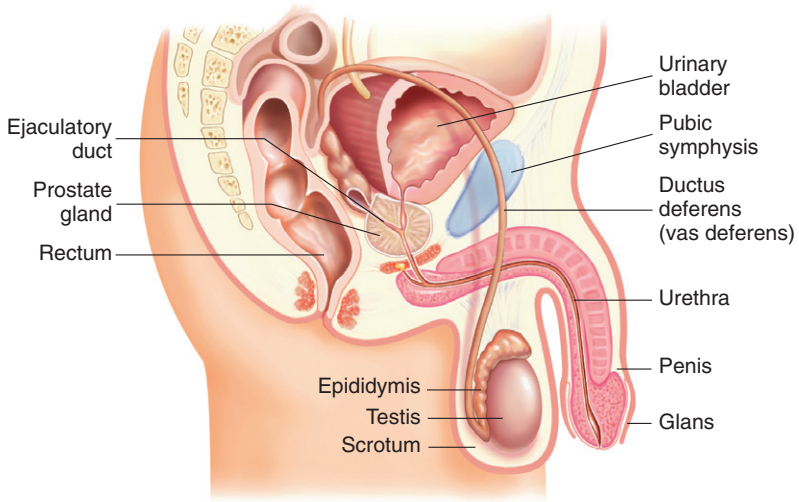

FIG. 55-1 Areas of the male reproductive system in which problems are likely to develop.

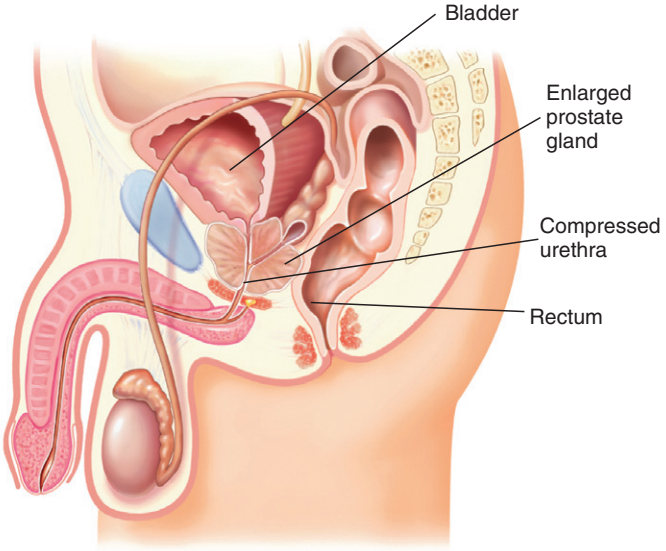

FIG. 55-2 Benign prostatic hyperplasia. The enlarged prostate compresses the urethra.

men have a decrease in the blood's testosterone level, but continue to produce and accumulate high levels of DHT in the prostate.

Another possible cause is an increased proportion of estrogen (as compared to testosterone) in the blood. Throughout their lives, men produce both testosterone and small amounts of estrogen. As men age, the amount of active testosterone in the blood decreases, leaving a higher proportion of estrogen. A higher amount of estrogen within the gland increases the activity of substances (e.g., DHT) that promote cell growth.

Typically BPH develops in the inner part of the prostate. (Prostate cancer is most likely to develop in the outer part.) This enlargement gradually compresses the urethra, eventually leading to partial or complete obstruction (Fig. 55-2). The compression of the urethra ultimately leads to the development of clinical symptoms. There is no direct relationship between the size of the prostate and the severity of symptoms or degree of obstruction. The location of the enlargement is most significant in the development of obstructive symptoms (Fig. 55-3). For example, it is possible for mild hyperplasia to cause severe

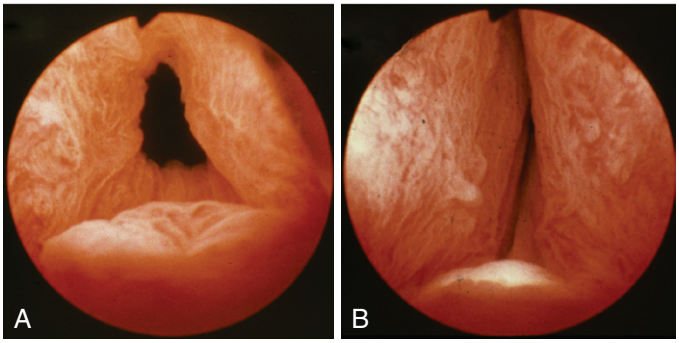

FIG. 55-3 Views of the prostate by cystoscopy. **A,** Normal appearance. **B,** Moderate benign prostatic hyperplasia with urethral obstruction.

obstruction, or for extreme hyperplasia to cause few obstructive symptoms.

Risk factors for BPH include aging, obesity (in particular increased waist circumference), lack of physical activity, alcohol consumption, erectile dysfunction, smoking, and diabetes.[4] A positive family history of BPH in first-degree relatives may also be a risk factor.

Clinical Manifestations

Manifestations of BPH are mainly associated with symptoms of the lower urinary tract.[5] The patient's symptoms are usually gradual in onset and may not be noticed until prostatic enlargement has been present for some time. Early symptoms are often minimal because the bladder can compensate for a small amount of resistance to urine flow. The symptoms gradually worsen as the degree of urethral obstruction increases.

Symptoms can be divided into two groups: irritative and obstructive. *Irritative symptoms,* which include nocturia, urinary frequency, urgency, dysuria, bladder pain, and incontinence, are associated with inflammation or infection. Nocturia is often the first symptom that the patient notices.[5]

Obstructive symptoms caused by prostate enlargement include a decrease in the caliber and force of the urinary stream, difficulty in initiating voiding, intermittency (stopping and starting stream several times while voiding), and dribbling at the end of urination. These symptoms are due to urinary retention.

TABLE 55-1 AUA SYMPTOM INDEX TO DETERMINE SEVERITY OF PROSTATIC PROBLEMS

Questions	AUA Symptom Score* (circle one number on each line)					
	Not At All	Less Than 1 Time in 5	Less Than Half the Time	About Half the Time	More Than Half the Time	Almost Always
Over the past month						
1. How often do you have the sensation that your bladder is not completely empty after you finish urinating?	0	1	2	3	4	5
2. How often do you have to urinate again, less than 2 hr after you finish urinating?	0	1	2	3	4	5
3. How often do you stop and start again several times when you urinate?	0	1	2	3	4	5
4. How often do you find it difficult to postpone urination?	0	1	2	3	4	5
5. How often do you have a weak urinary stream?	0	1	2	3	4	5
6. How often do you have to push or strain to begin urination?	0	1	2	3	4	5
7. How many times do you usually get up to urinate from the time you go to bed at night until the time you get up in the morning?	0 (None)	1 (1 time)	2 (2 times)	3 (3 times)	4 (4 times)	5 (5 times or more)
Sum of circled numbers (AUA Symptom Score): _____*

*Score is interpreted as follows: 0-7, mild; 8-19, moderate; 20-35, severe.
AUA, American Urological Association.

The American Urological Association (AUA) symptom index for BPH (Table 55-1) is a widely used tool to assess voiding symptoms associated with obstruction. Although this tool is not diagnostic, it helps determine the extent of symptoms.[6] Higher scores on this tool indicate greater symptom severity.

Complications

Complications of urinary obstruction are relatively uncommon in BPH. Acute urinary retention is a complication that is manifested by the sudden and painful inability to urinate. Treatment involves the insertion of a catheter to drain the bladder. Surgery may also be indicated.

Another complication is urinary tract infection (UTI) and potentially sepsis secondary to UTI. Incomplete bladder emptying (associated with partial obstruction) results in residual urine, which provides a favorable environment for bacterial growth. Calculi may develop in the bladder because of the alkalinization of the residual urine. Bladder stones are more common in men with BPH, although the risk of renal calculi is not significantly increased. Additional complications include renal failure caused by *hydronephrosis* (distention of pelvis and calyces of kidney by urine that cannot flow through the ureter to the bladder), pyelonephritis, and bladder damage if treatment for acute urinary retention is delayed.

Diagnostic Studies

The primary methods used to diagnose BPH include a history and physical examination. (Diagnostic studies are outlined in Table 55-2.) The prostate can be palpated by digital rectal examination (DRE) to estimate its size, symmetry, and consistency. In BPH, the prostate is symmetrically enlarged, firm, and smooth.

Additional diagnostic tests may be indicated, depending on the type and severity of symptoms and clinical findings. A urinalysis with culture is routinely done to identify any infection. Bacteria, white blood cells (WBCs), or microscopic hematuria indicate infection or inflammation.

A prostate-specific antigen (PSA) blood test may be done to rule out prostate cancer. However, PSA levels may be slightly elevated in patients with BPH. Serum creatinine levels may be ordered to rule out renal insufficiency. Because symptoms of BPH are similar to those of a neurogenic bladder, a neurologic examination may also be performed.

In patients with an abnormal DRE and elevated PSA, a transrectal ultrasound (TRUS) scan is typically indicated. This

Collaborative Therapy

Active Surveillance

Drug Therapy
- 5α-Reductase inhibitors (e.g., finasteride [Proscar], dutasteride [Avodart], dutasteride plus tamsulosin [Jalyn])
- α-Adrenergic receptor blockers (e.g., silodosin [Rapaflo], alfuzosin [Uroxatral], doxazosin [Cardura], prazosin [Minipress], terazosin [Hytrin], tamsulosin [Flomax])
- Erectogenic drugs (e.g., tadalafil [Cialis])

Minimally Invasive Therapy*
- Transurethral microwave thermotherapy (TUMT)
- Transurethral needle ablation (TUNA)
- Laser prostatectomy
- Transurethral electrovaporization of the prostate (TUVP)
- Intraprostatic urethral stents

Invasive (Surgery) Therapy*
- Transurethral resection of the prostate (TURP)
- Transurethral incision of the prostate (TUIP)
- Open prostatectomy

*See Table 55-3.

examination allows for accurate assessment of prostate size and is helpful in differentiating BPH from prostate cancer. Biopsies can be taken during the ultrasound procedure. Uroflowmetry, a study that measures the volume of urine expelled from the bladder per second, is helpful in determining the extent of urethral blockage and thus the type of treatment needed. Postvoid residual urine volume is often measured to determine the degree of urine flow obstruction. Cystoscopy, a procedure allowing internal visualization of the urethra and bladder, is performed if the diagnosis is uncertain and in patients scheduled for prostatectomy.

Collaborative Care

The goals of collaborative care are to (1) restore bladder drainage, (2) relieve the patient's symptoms, and (3) prevent or treat the complications of BPH. Treatment is generally based on the degree to which the symptoms bother the patient or the presence of complications, rather than the size of the prostate. Alternatives to surgical intervention for some patients now include drug therapy and minimally invasive procedures.

The most conservative treatment that may be recommended for some patients with BPH is referred to as *active surveillance,* or watchful waiting.[7] When the patient has no symptoms or only mild ones (AUA symptom scores of 0 to 7), a wait-and-see approach is taken. Because some patients have symptoms that disappear, a conservative approach has value. Making dietary changes (decreasing intake of caffeine, artificial sweeteners, and spicy or acidic foods), avoiding medications such as decongestants and anticholinergics, and restricting evening fluid intake may improve symptoms.

A timed voiding schedule may reduce or eliminate symptoms, thus negating the need for further intervention. If the patient begins to have signs or symptoms that indicate an increase in obstruction, further treatment is indicated.

Drug Therapy. Drugs that have been used to treat BPH with variable degrees of success include 5α-reductase inhibitors and α-adrenergic receptor blockers. Combination therapy using both types of these drugs has been shown to be more effective in reducing symptoms than using one drug alone.

5α-Reductase Inhibitors. These drugs work by reducing the size of the prostate gland. Finasteride (Proscar) blocks the enzyme 5α-reductase, which is necessary for the conversion of testosterone to DHT, the principal intraprostatic androgen. This drug results in regression of hyperplastic tissue through suppression of androgens. Finasteride is an appropriate treatment option for individuals who have a moderate to severe symptom score on the AUA symptom index (see Table 55-1). Although more than 50% of men who are treated with the drug show symptom improvement, it takes about 6 months to be effective. Furthermore, the drug must be taken on a continuous basis to maintain therapeutic results. Serum PSA levels are decreased by almost 50% when taking finasteride. Therefore PSA levels should be doubled when comparing the patient's current levels to premedication levels.

Dutasteride (Avodart) has the same effect on prostatic tissue as finasteride and is a dual inhibitor of 5α-reductase type 1 and 2 isoenzymes. (Finasteride inhibits only the type 2 isoenzyme.) The combination of a 5α-reductase inhibitor (dutasteride) and an α-adrenergic receptor blocker (tamsulosin) is now available in a single oral medication (Jalyn).

In addition to decreasing the symptoms of BPH, finasteride, dutasteride, and Jalyn (finasteride plus tamsulosin) may also lower the risk of prostate cancer.[8] However, the use of these drugs in prevention of prostate cancer has not been advised because of the increased risk of developing aggressive prostate cancer. Patients with an increased PSA level while taking these medications should be referred to their health care provider. The need for regular prostate cancer screening should also be discussed with the provider.

DRUG ALERT: Finasteride (Proscar)

- Patient should be aware of the increased risk of orthostatic hypotension with concomitant use of erectile dysfunction drugs.
- Women who may be or are pregnant should not handle tablets due to potential risk to male fetus (anomaly).

α-Adrenergic Receptor Blockers. α-Adrenergic receptor blockers are another drug treatment option for BPH. These agents selectively block α_1-adrenergic receptors, which are abundant in the prostate and are increased in hyperplastic prostate tissue. Although α-adrenergic blockers are more commonly used for treatment of hypertension, these drugs promote smooth muscle relaxation in the prostate, facilitating urinary flow through the urethra. These agents demonstrate a 50% to 60% efficacy in improvement of symptoms, which occurs within 2 to 3 weeks.

Several α-adrenergic blockers are currently in use, including silodosin (Rapaflo), alfuzosin (Uroxatral), doxazosin (Cardura), prazosin (Minipress), terazosin (Hytrin), and tamsulosin (Flomax). Note that although these drugs offer symptomatic relief of BPH, they do not treat hyperplasia.

Erectogenic Drugs. Tadalafil (Cialis) has been used in men who have symptoms of BPH alone or in combination with erectile dysfunction (ED). The drug has shown to be effective in reducing symptoms for both these conditions (see erectile dysfunction later in this chapter).[9]

Herbal Therapy. Herbal extracts have been used in the management of lower urinary symptoms associated with BPH. In particular, some patients take plant extracts such as saw palmetto *(Serenoa repens)*. However, research indicates that saw palmetto has no benefit over a placebo.[10,11] In a limited number of small trials, herbal preparations such as saxifrage, beta-sitosterol, *Pygeum africanum,* and Cernilton have shown some success in reducing the symptoms of BPH. Advise patients to tell their health care provider about all herbal supplements that they use.

Minimally Invasive Therapy. Minimally invasive therapies are becoming more common as an alternative to watchful waiting and invasive treatment (Table 55-3). They generally do not require hospitalization or catheterization and are associated with few adverse events. Many minimally invasive therapies have outcomes comparable to those of invasive techniques.[12]

Transurethral Microwave Thermotherapy. *Transurethral microwave thermotherapy* (TUMT) is an outpatient procedure that involves the delivery of microwaves directly to the prostate through a transurethral probe to raise the temperature of the prostate tissue to about 113°F (45°C). The heat causes death of tissue, thus relieving the obstruction. A rectal temperature probe is used during the procedure to ensure that the temperature is kept below 110°F (43.5°C) to prevent rectal tissue damage. The procedure takes about 90 minutes.

Postoperative urinary retention is a common complication. Thus the patient is generally sent home with an indwelling catheter for 2 to 7 days to maintain urinary flow and to facilitate the passing of small clots or necrotic tissue. Antibiotics, pain medication, and bladder antispasmodic medications are used to

TABLE 55-3 TREATMENT FOR BENIGN PROSTATIC HYPERPLASIA

Description	Advantages	Disadvantages
Minimally Invasive		
Transurethral Microwave Thermotherapy (TUMT)		
Use of microwave radiating heat to produce coagulative necrosis of the prostate.	Outpatient procedure Erectile dysfunction, urinary incontinence, and retrograde ejaculation are rare	Potential for damage to surrounding tissue Urinary catheter needed after procedure
Transurethral Needle Ablation (TUNA)		
Low-wave radiofrequency used to heat the prostate, causing necrosis.	Outpatient procedure Erectile dysfunction, urinary incontinence, and retrograde ejaculation are rare Precise delivery of heat to desired area Very little pain experienced	Urinary retention common Irritative voiding symptoms Hematuria
Laser Prostatectomy		
Procedure uses a laser beam to cut or destroy part of the prostate. Different techniques are available: • Visual laser ablation of prostate (VLAP) • Contact laser • Photovaporization of prostate (PVP) • Interstitial laser coagulation (ILC)	Short procedure Comparable results to TURP Minimal bleeding Fast recovery time Rapid symptom improvement Very effective	Catheter (up to 7 days) needed after procedure due to edema and urinary retention Delayed sloughing of tissue Takes several weeks to reach optimal effect Retrograde ejaculation
Transurethral Electrovaporization of Prostate (TUVP)		
Electrosurgical vaporization and desiccation are used together to destroy prostatic tissue.	Minimal risks Minimal bleeding and sloughing	Retrograde ejaculation Intermittent hematuria
Intraprostatic Urethral Stents		
Insertion of self-expandable metallic stent into the urethra where enlarged area of prostate occurs.	Safe and effective Low risk	Stent may move Long-term effect is unknown
Invasive (Surgery)		
Transurethral Resection of Prostate (TURP)		
Use of excision and cauterization to remove prostate tissue cystoscopically. Remains the standard for treatment of BPH.	Erectile dysfunction unlikely	Bleeding Retrograde ejaculation
Transurethral Incision of Prostate (TUIP)		
Involves transurethral incisions into prostatic tissue to relieve obstruction. Effective for men with small to moderate prostates.	Outpatient procedure Minimal complications Low occurrence of erectile dysfunction or retrograde ejaculation	Urinary catheter needed after procedure
Open Prostatectomy		
Surgery of choice for men with large prostates, bladder damage, or other complicating factors. Involves external incision with two possible approaches (see Fig. 55-6).	Complete visualization of prostate and surrounding tissue	Erectile dysfunction Bleeding Postoperative pain Risk of infection

treat and prevent postprocedure problems. The procedure is not appropriate for men with rectal problems. Anticoagulant therapy should be stopped 10 days before treatment. Mild side effects include occasional problems of bladder spasm, hematuria, dysuria, and retention.

Transurethral Needle Ablation. *Transurethral needle ablation* (TUNA) is another procedure that increases the temperature of prostate tissue, thus causing localized necrosis. TUNA differs from TUMT in that low-wave radiofrequency is used to heat the prostate. Only prostate tissue in direct contact with the needle is affected, thus allowing greater precision in removal of the target tissue. The extent of tissue removed by this process is determined by the amount of tissue contact (needle length), amount of energy delivered, and duration of treatment. The majority of the patients undergoing TUNA have an improvement in symptoms.

This procedure is performed in an outpatient unit or physician's office using local anesthesia and IV or oral sedation. The TUNA procedure lasts approximately 30 minutes. The patient typically experiences little pain with an early return to regular activities. Complications include urinary retention, UTI, and irritative voiding symptoms (e.g., frequency, urgency, dysuria). Some patients require a urinary catheter for a short time. Patients often have hematuria for up to a week.

Laser Prostatectomy. The use of laser therapy through visual or ultrasound guidance is an effective alternative to transurethral resection of the prostate (TURP) in treating BPH. The laser beam is delivered transurethrally through a fiber instrument and is used for cutting, coagulation, and vaporization of prostatic tissue. There are a variety of laser procedures using different sources, wavelengths, and delivery systems. Retreatment rates are comparable to those of a TURP.[13]

One common procedure is *visual laser ablation of the prostate* (VLAP), which uses the laser beam to produce deep coagulation necrosis. The affected prostate tissue gradually sloughs in the urinary stream. It takes several weeks before the patient reaches optimal results after this type of laser therapy. At the completion of VLAP, a urinary catheter is inserted to allow for drainage.

Contact laser techniques involve the direct contact of the laser with the prostate tissue, producing an immediate vaporization of the tissue. Blood vessels near the laser tip are immediately cauterized. Thus bleeding during the procedure is rare. A three-way catheter with slow-drip irrigation is placed immediately after the procedure for a short time. Typically the catheter is removed within 6 to 8 hours after the procedure. Advantages of this procedure over TURP include minimal bleeding both during and after the procedure, faster recovery time, and ability to perform the surgery on patients taking anticoagulants.

Photovaporization of the prostate (PVP) uses a high-power green laser light to vaporize prostate tissue. Improvements in urine flow and symptoms are almost immediate after the procedure. Bleeding is minimal, and a catheter is usually inserted for 24 to 48 hours afterward. PVP works well for larger prostate glands.

Another approach to laser prostatectomy is *interstitial laser coagulation* (ILC). The prostate is viewed through a cystoscope. A laser is used to quickly treat precise areas of the enlarged prostate by placement of interstitial light guides directly into the prostate tissue.

Intraprostatic Urethral Stents. Symptoms from obstruction in patients who are poor surgical candidates can be relieved with intraprostatic urethral stents. The stents are placed directly into the prostatic tissue. Complications include chronic pain, infection, and encrustation. The long-term effects are not known.

Invasive Therapy (Surgery). Invasive treatment of symptomatic BPH involves surgery. The choice of the treatment approach depends on the size and location of the prostatic enlargement and patient factors such as age and surgical risk. Invasive treatments are summarized in Table 55-3.

Invasive therapy is indicated when the decrease in urine flow is sufficient to cause discomfort, persistent residual urine, acute urinary retention because of obstruction with no reversible precipitating cause, or hydronephrosis. Intermittent catheterization or insertion of an indwelling catheter can temporarily reduce symptoms and bypass the obstruction. However, avoid long-term catheter use because of the increased risk of infection.

Transurethral Resection of the Prostate. **Transurethral resection of the prostate (TURP)** is a surgical procedure involving the removal of prostate tissue using a resectoscope inserted through the urethra. TURP has long been considered the gold standard for surgical treatments of obstructing BPH. Although this procedure remains the most common operation performed, the number of TURP procedures done in recent years has declined due to the development of less invasive technologies.[12]

TURP is performed under a spinal or general anesthetic and requires a 1- to 2-day hospital stay. No external surgical incision is made. A resectoscope is inserted through the urethra to excise and cauterize obstructing prostatic tissue (Fig. 55-4). A large three-way indwelling catheter with a 30-mL balloon is inserted into the bladder after the procedure to provide hemostasis and to facilitate urinary drainage. The bladder is irrigated, either continuously or intermittently, usually for the first 24 hours to prevent obstruction from mucus and blood clots.

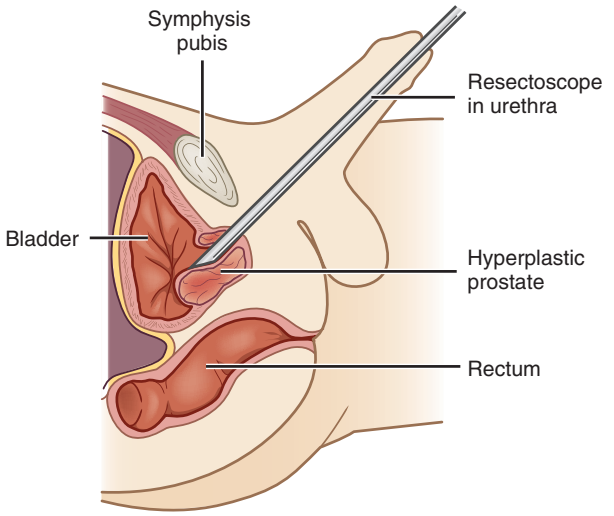

FIG. 55-4 Transurethral resection of the prostate.

The outcome for 80% to 90% of patients is excellent, with marked improvements in symptoms and urinary flow rates. Quality of life is also improved. TURP is a surgical procedure with a relatively low risk. Postoperative complications include bleeding, clot retention, and dilutional hyponatremia associated with irrigation. Because bleeding is a common complication, patients taking aspirin, warfarin (Coumadin), or other anticoagulants must discontinue these medications several days before surgery.

Transurethral Incision of the Prostate. Transurethral incision of the prostate (TUIP) is a surgical procedure done under local anesthesia for men with moderate to severe symptoms. Several small incisions are made into the prostate gland to expand the urethra, which relieves pressure on the urethra and improves urine flow. TUIP is an option for patients with a small or moderately enlarged prostate gland. TUIP has similar patient outcomes to TURP in relieving symptoms.

NURSING MANAGEMENT BENIGN PROSTATIC HYPERPLASIA

Because you will be most directly involved in care of patients with BPH having invasive therapies, the focus of nursing management in this section is on preoperative and postoperative care.

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a patient with BPH are presented in Table 55-4.

NURSING DIAGNOSES

Nursing diagnoses for the patient with BPH preoperatively may include, but are not limited to, the following:

- Acute pain *related to* bladder distention secondary to enlarged prostate
- Risk for infection *related to* an indwelling catheter, urinary stasis, or environmental pathogens

Nursing diagnoses for the patient with BPH who has invasive therapy (surgery) are presented in eNursing Care Plan 55-1 (available on the website for this chapter).

TABLE 55-4 NURSING ASSESSMENT

Benign Prostatic Hyperplasia

Subjective Data

Important Health Information

Medications: Estrogen or testosterone supplementation
Surgery or other treatments: Previous treatment for BPH

Functional Health Patterns

Health perception–health management: Knowledge of the condition
Nutritional-metabolic: Voluntary fluid restriction
Elimination: Urinary urgency, diminution in caliber and force of urinary stream; hesitancy in initiating voiding; postvoid dribbling; urinary retention; incontinence
Sleep: Nocturia
Cognitive-perceptual: Dysuria, sensation of incomplete voiding; bladder discomfort
Sexuality-reproductive: Anxiety about sexual dysfunction

Objective Data

General

Older adult male

Urinary

Distended bladder on palpation; smooth, firm, elastic enlargement of prostate on rectal examination

Possible Diagnostic Findings

Enlarged prostate on ultrasonography; vesicle neck obstruction on cystoscopy; residual urine with postvoiding catheterization; white blood cells, bacteria, or microscopic hematuria with infection; ↑ serum creatinine levels with renal involvement

PLANNING

The overall preoperative goals for the patient having invasive procedures are to have (1) restoration of urinary drainage; (2) treatment of any UTI; and (3) understanding of the upcoming procedure, implications for sexual function, and urinary control. The overall postoperative goals are to have (1) no complications, (2) restoration of urinary control, (3) complete bladder emptying, and (4) satisfying sexual expression.

NURSING IMPLEMENTATION

HEALTH PROMOTION. The cause of BPH is largely attributed to the aging process.[14] Health promotion focuses on early detection and treatment. The American Cancer Society, along with the AUA, recommends a yearly medical history and DRE for men over 50 years of age in an effort to detect prostate problems early. When symptoms of prostatic hyperplasia are present, further diagnostic screening may be necessary (see Table 55-2).

Some men find that the ingestion of alcohol and caffeine tends to increase prostatic symptoms because the diuretic effect increases bladder distention. Compounds found in common cough and cold remedies such as pseudoephedrine (in Sudafed) and phenylephrine (in Allerest PE and Coricidin D) often worsen the symptoms of BPH. These drugs are α-adrenergic agonists that cause smooth muscle contraction. If this happens, the patient should avoid these drugs.

Advise patients with obstructive symptoms to urinate every 2 to 3 hours and when they first feeling the urge. This will minimize urinary stasis and acute urinary retention. Fluid intake should be maintained at a normal level to avoid dehydration or fluid overload. The patient may believe that if he restricts his fluid intake, symptoms will be less severe, but this only increases the chances of an infection. However, if the patient increases his intake too rapidly, bladder distention can develop because of the prostatic obstruction.

ACUTE INTERVENTION. The following discussion focuses on preoperative and postoperative care for the patient undergoing a TURP.

Preoperative Care. Urinary drainage must be restored before surgery. Prostatic obstruction may result in acute retention or inability to void. A urethral catheter such as a coudé (curved-tip) catheter may be needed to restore drainage. In many health care settings, 10 mL of sterile 2% lidocaine gel is injected into the urethra before insertion of the catheter. The lidocaine gel not only acts as a lubricant, but also provides local anesthesia and helps open the urethral lumen. If a sizable obstruction of the urethra exists, the urologist may insert a filiform catheter with sufficient rigidity to pass the obstruction. Aseptic technique is important at all times to avoid introducing bacteria into the bladder. (Urinary catheters are discussed in Chapter 46.)

Antibiotics are usually administered before any invasive procedure. Any infection of the urinary tract must be treated before surgery. Restoring urinary drainage and encouraging a high fluid intake (2 to 3 L/day unless contraindicated) are also helpful in managing the infection.

Patients are often concerned about the impact of the impending surgery on sexual function. Provide an opportunity for the patient and the partner to express their concerns. Inform the patient that surgery may affect sexual function. The ejaculate may be decreased in amount or be totally absent. Most types of prostatic surgery result in some degree of retrograde ejaculation. This may decrease orgasmic sensations felt during ejaculation. Retrograde ejaculation is not harmful because the semen is eliminated during the next urination.

Postoperative Care. The main complications after surgery are hemorrhage, bladder spasms, urinary incontinence, and infection. The plan of care should be adjusted to the type of surgery, the reasons for surgery, and the patient's response to surgery.

After surgery the patient will have a standard catheter or a triple-lumen catheter. Bladder irrigation is typically done to remove clotted blood from the bladder and ensure drainage of urine. The bladder is irrigated either manually on an intermittent basis or more commonly as continuous bladder irrigation (CBI) with sterile normal saline solution or another prescribed solution. If the bladder is manually irrigated (if ordered), instill 50 mL of irrigating solution and then withdraw with a syringe to remove clots that may be in the bladder and catheter. Painful bladder spasms often occur as a result of manual irrigation.

With CBI, irrigating solution is continuously infused and drained from the bladder. The rate of infusion is based on the color of drainage. Ideally the urine drainage should be light pink without clots. Continuously monitor the inflow and outflow of the irrigant. If outflow is less than inflow, assess the catheter patency for kinks or clots. If the outflow is blocked and patency cannot be reestablished by manual irrigation, stop the CBI and notify the physician.

Use careful aseptic technique when irrigating the bladder because bacteria can easily be introduced into the urinary tract. To prevent urethral irritation and minimize the risk of bladder infection, secure the catheter to the leg with tape or a catheter strap. The catheter should be connected to a closed-drainage system. Do not disconnect unless it is being removed, changed, or irrigated. Proper care of the catheter is important. On a daily basis, cleanse the secretions that accumulate around the meatus with soap and water.

Blood clots are expected after prostate surgery for the first 24 to 36 hours. However, large amounts of bright red blood in the urine can indicate hemorrhage. Postoperative hemorrhage may occur from displacement of the catheter, dislodgment of a large clot, or increases in abdominal pressure.

Release or displacement of the catheter dislodges the balloon that provides counterpressure on the operative site. Traction on the catheter may be applied to provide counterpressure (tamponade) on the bleeding site in the prostate, thereby decreasing bleeding. Such traction can result in local necrosis if pressure is applied for too long. Therefore pressure should be relieved on a scheduled basis by qualified personnel. Activities that increase abdominal pressure, such as sitting or walking for prolonged periods and straining to have a bowel movement (Valsalva maneuver), should be avoided in the postoperative recovery period.

Bladder spasms are a distressing complication for the patient after transurethral procedures. They occur as a result of irritation of the bladder mucosa from the insertion of the resectoscope, presence of a catheter, or clots leading to obstruction of the catheter. Instruct the patient not to urinate around the catheter because this increases the likelihood of spasm. If bladder spasms develop, check the catheter for clots. If present, remove the clots by irrigation so that urine can flow freely. Belladonna and opium suppositories or other antispasmodics (e.g., oxybutynin [Ditropan]), along with relaxation techniques, are used to relieve the pain and decrease spasm.

The catheter is often removed 2 to 4 days after surgery. The patient should urinate within 6 hours after catheter removal. If he cannot, reinsert a catheter for a day or two. If the problem continues, instruct the patient to perform clean intermittent self-catheterization (see Chapter 46).

Sphincter tone may be poor immediately after catheter removal, resulting in urinary incontinence or dribbling. This is a common but distressing situation for the patient. Sphincter tone can be strengthened by having the patient practice Kegel exercises (pelvic floor muscle technique) 10 to 20 times per hour while awake. (Kegel exercises are discussed in Table 46-19.) Encourage the patient to practice starting and stopping the stream several times during urination. This facilitates learning the pelvic floor exercises.

It usually takes several weeks to achieve urinary continence. In some instances, control of urine may never be fully regained. Continence can improve for up to 12 months. If continence has not been achieved by that time, refer the patient to a continence clinic. A variety of methods, including biofeedback, have been used to achieve positive results.

You can also instruct the patient to use a penile clamp, a condom catheter, or incontinence pads or briefs to avoid embarrassment from dribbling. In severe cases, an occlusive cuff that serves as an artificial sphincter can be surgically implanted to restore continence. Assist the patient in finding ways to manage the problem that allow him to continue socializing and interacting with others.

Observe the patient for signs of postoperative infection. If an external wound is present (from an open prostatectomy), assess the area for redness, heat, swelling, and purulent drainage. Special care must be taken if a perineal incision is present because of the proximity of the anus. Avoid rectal procedures, such as taking rectal temperatures and administering enemas. The insertion of well-lubricated belladonna and opium suppositories is acceptable.

Dietary intervention and stool softeners are important in the postoperative period to prevent the patient from straining while having bowel movements. Straining increases the intraabdominal pressure, which can lead to bleeding at the operative site. A diet high in fiber facilitates the passage of stool.

AMBULATORY AND HOME CARE. Discharge planning and home care issues are important aspects of care after prostate surgery. Instructions include (1) caring for an indwelling catheter (if one is left in place); (2) managing urinary incontinence; (3) maintaining adequate oral fluid intake; (4) observing for signs and symptoms of urinary tract and wound infection; (5) preventing constipation; (6) avoiding heavy lifting (more than 10 lb [4.5 kg]); and (7) refraining from driving or intercourse after surgery as directed by the physician.

The patient may experience a change in sexual function after surgery. Many men experience *retrograde ejaculation* because of trauma to the internal urethral sphincter. Semen is discharged into the bladder at orgasm and may produce cloudy urine when the patient urinates after orgasm. ED may occur if the nerves are cut or damaged during surgery. The patient may experience anxiety over the change because of a perceived loss of his sex role, self-esteem, or quality of sexual interaction with his partner.

Discuss these changes with the patient and his partner and allow them to ask questions and express their concerns. Sexual counseling and treatment options may be necessary if ED becomes a chronic or permanent problem. (ED is discussed later in this chapter.)

Point out that although some patients experience concerns regarding change in sexual function, this is not a universal concern. Recovery depends on the type of surgery performed and the interval of time between when symptoms first appeared and the date of surgery. It may take up to 1 year for complete sexual function to return.

The bladder may take up to 2 months to return to its normal capacity. Instruct the patient to drink at least 2 to 3 L of fluid per day and urinate every 2 to 3 hours to flush the urinary tract. Teach the patient to avoid or limit the amounts of bladder irritants such as caffeine products, citrus juices, and alcohol. Because the patient may experience incontinence or dribbling, he may incorrectly believe that decreasing fluid intake will relieve this problem.

Urethral strictures may result from instrumentation or catheterization. Treatment may include teaching the patient intermittent clean self-catheterization or having a urethral dilation.

Advise the patient to continue having a yearly DRE if he has had any procedure other than complete removal of the prostate. Hyperplasia or cancer can occur in the remaining prostatic tissue.

EVALUATION

The expected outcomes are that the patient with BPH who has surgery will

- Report satisfactory pain control
- Report improved urinary function with no pain or incontinence

Additional information on expected outcomes for the patient with BPH is presented in eNursing Care Plan 55-1.

PROSTATE CANCER

Prostate cancer is a malignant tumor of the prostate gland. It is estimated that 241,740 new cases of prostate cancer are diag-

nosed and 28,170 men die annually from the disease in the United States.[15] One of every six men will develop prostate cancer at some point during his life. Prostate cancer is the most common cancer among men, excluding skin cancer. It is the second leading cause of cancer death in men (exceeded only by lung cancer). The majority (more than 60%) of cases occur in men over age 65. However, many cases occur in younger men who sometimes have a more aggressive type of cancer. Almost 2.8 million men in the United States are survivors of prostate cancer.[16]

Etiology and Pathophysiology

Prostate cancer is an androgen-dependent adenocarcinoma that is usually slow growing. It can spread by three routes: direct extension, through the lymph system, or through the bloodstream. Spread by direct extension involves the seminal vesicles, urethral mucosa, bladder wall, and external sphincter. The cancer later spreads through the lymphatic system to the regional lymph nodes. The bloodstream seems to be the mode of spread to pelvic bones, head of the femur, lower lumbar spine, liver, and lungs.

Age, ethnicity, and family history are known risk factors for prostate cancer. (Additional information on ethnicity is presented in the Cultural & Ethnic Health Disparities box on this page.) The incidence of prostate cancer rises markedly after age 50 with a median age at diagnosis of 67 years old.[16] The incidence of prostate cancer worldwide is higher in African Americans than in any other ethnic group (except Jamaican men of African descent).[15] The reasons for the higher rate are unknown. In addition, African American men are likely to have more aggressive tumors at diagnosis and have higher mortality rates from prostate cancer. Differences in survival may be due to body composition, dietary factors, and endogenous hormones.

It is not clear if smoking is a risk factor for prostate cancer. As mentioned earlier, neither is it clear if having BPH increases the risk of developing prostate cancer.[2,3]

Dietary factors and obesity may be associated with prostate cancer. A diet high in red and processed meat and high-fat dairy products along with a low intake of vegetables and fruits may increase the risk of prostate cancer. The role of dietary carotenoids (e.g., lycopene) and antioxidants (e.g., vitamins D and E and selenium) in the risk for prostate cancer is not clear. A large research study found that men who took vitamin E had an increased incidence of prostate cancer, with selenium supplements showing no benefit.[17]

Genetic Link

Currently no known single gene causes prostate cancer. Some genes or gene mutations are more common in men with prostate cancer. From a genetics viewpoint, prostate cancer can be classified into three categories.

Most prostate cancers (about 75%) are considered *sporadic,* which means that damage to the genes occurs by chance after a person is born. Prostate cancer that runs in a family, called *familial prostate cancer,* is less common (about 20%). It occurs because of a combination of shared genes and shared environment or lifestyle factors. Familial prostate cancer is when two or more first-degree relatives (father, brother, son) are diagnosed with prostate cancer.

Hereditary (inherited) prostate cancer is rare (5% to 10%) and occurs when gene mutations are passed down in a family from one generation to the next. In hereditary prostate cancer a family has any of the following characteristics: (1) three or more first-degree relatives with prostate cancer, (2) prostate cancer in three generations on the same side of the family, and (3) two or more close relatives (father, brother, son, grandfather, uncle, nephew) on the same side of the family diagnosed with prostate cancer before age 55.

Only genetic testing can determine whether a man has a genetic mutation. However, no genetic tests are available to determine if a man is predisposed to developing prostate cancer.

Having a family history does not mean that a man will develop prostate cancer; it indicates that he has an increased risk. Men with a family history of prostate cancer should talk with their health care provider about their concerns. It is important for the health care provider to obtain a detailed family history, including a family pedigree (see Figs. 13-4 and 13-5). Depending on the findings of the family history, a referral to a genetic counselor may be appropriate.

Hereditary breast and ovarian cancer (HBOC) syndrome is associated with mutations in the *BRCA1* and/or *BRCA2* genes (BRCA stands for BReast CAncer). HBOC is most commonly associated with an increased risk of breast and ovarian cancer in women. However, men with HBOC also have an increased risk of breast cancer and prostate cancer. Mutations in *BRCA1* and *BRCA2* cause only a small percentage of familial prostate cancers. Genetic testing may be appropriate for families with prostate cancer that also have HBOC.

Clinical Manifestations and Complications

Prostate cancer is usually asymptomatic in the early stages. Eventually the patient may have symptoms similar to those of BPH, including dysuria, hesitancy, dribbling, frequency, urgency, hematuria, nocturia, retention, interruption of urinary stream, and inability to urinate. Pain in the lumbosacral area that radiates down to the hips or the legs, when combined with urinary symptoms, may indicate metastasis.

The tumor can spread to pelvic lymph nodes, bones, bladder, lungs, and liver. Once the tumor has spread to distant sites, the major problem becomes the management of pain. As the cancer spreads to the bones (a common site of metastasis), pain can become severe, especially in the back and the legs because of compression of the spinal cord and destruction of bone (Fig. 55-5).

CULTURAL & ETHNIC HEALTH DISPARITIES

Cancers of the Male Reproductive System

Prostate Cancer

- African American men have the highest rate of prostate cancer in the world (except Jamaican men of African descent).
- African American men tend to be diagnosed with prostate cancer at an earlier age, have more advanced disease at the time of diagnosis, and have a higher mortality rate than do white men.
- Although the mortality rate for prostate cancer among African American men is higher than that among whites, the mortality rate is declining.
- Asian American men have a lower incidence and lower mortality rates from prostate cancer than white men.

Testicular Cancer

- Testicular cancer occurs more frequently among whites than in other ethnic groups.

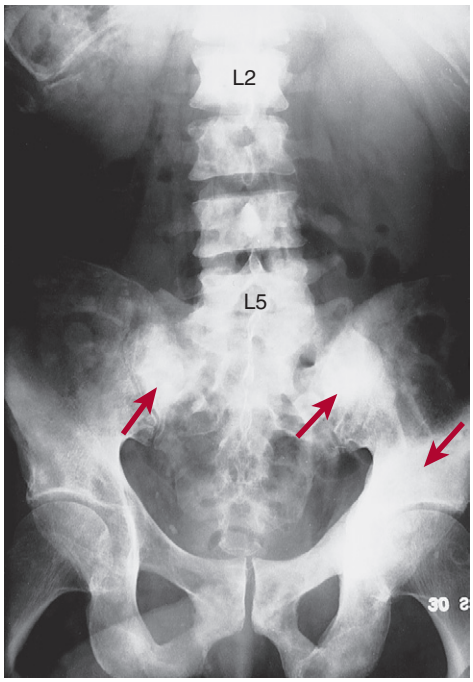

FIG. 55-5 Metastasis of prostate cancer to the pelvis and lumbar spine indicated by arrows.

Diagnostic Studies

Most men in the United States with prostate cancer are diagnosed by PSA screening. Health care providers' recommendations for screening vary. Some encourage yearly screening for men over age 50, and some advise men who are at a higher risk for prostate cancer to begin screening at age 40 or 45. Others caution against routine screening.[18] Although specific recommendations regarding PSA screening vary, there is general agreement that men should be informed about the potential risks (e.g., subsequent evaluation and treatment that may be unnecessary) and benefits (early detection of prostate cancer) of PSA screening before being tested.

At the core of the controversy over routine screening is that many men live and die *with* prostate cancer but not *from* it. As screening has become more widespread, smaller cancers are being found in older men. Slow-growing cancers, in most cases, probably do not need to be treated. However, early detection of aggressive cancers by PSA testing has saved lives.

Patients need to discuss the use of PSA screening in their particular situation with their health care provider. This discussion should start earlier for men ages 40 to 45 who are at high risk of developing prostate cancer (e.g., African American, positive family history). After this discussion, men who want to be screened may have an annual DRE and PSA test. On DRE, an abnormal prostate may feel hard, nodular, and asymmetric.

Elevated levels of PSA (normal level, 0 to 4 ng/mL [0 to 4 mcg/L]), a glycoprotein produced by the prostate, does not necessarily indicate prostate cancer. Mild elevations in PSA may occur with aging, BPH, recent ejaculation, or acute or chronic prostatitis or after long bike rides. In addition, cystoscopy, indwelling urethral catheters, and prostate biopsies may also produce elevated PSA levels. Decreases in the PSA level can occur with drugs such as finasteride and dutasteride.

PSA is used not only to detect prostate cancer, but also to monitor the success of treatment. When treatment has been successful in removing prostate cancer, PSA levels should fall to undetectable levels. The regular measurement of PSA levels after treatment is important to evaluate the effectiveness of treatment and possible recurrence of prostate cancer.

An elevated level of prostatic isoenzyme of serum acid phosphatase (prostatic acid phosphatase [PAP]) is another indicator of prostate cancer, especially if there is extracapsular spread. With advanced prostate cancer, serum alkaline phosphatase is increased as a result of bone metastasis. Investigations to locate a serum biomarker for prostate cancer are ongoing.

Neither PSA nor DRE is a definitive diagnostic test for prostate cancer. If PSA levels are continually elevated or if the DRE is abnormal, a biopsy of the prostate tissue is usually indicated. Biopsy of prostate tissue is necessary to confirm the diagnosis of prostate cancer. The biopsy is typically done by a transrectal resection of the prostate (TRUS) because it allows the physician to visualize the prostate and pinpoint abnormalities. When a suspicious area is located, a biopsy needle is inserted into the prostate to obtain a tissue sample. A pathologic examination of the specimen is done to assess for malignant changes. Other tests used to determine the location and extent of the spread of the cancer may include bone scan, computed tomography (CT), and magnetic resonance imaging (MRI) using an endorectal probe.

Collaborative Care

Chemoprevention of prostate cancer is an active area of research. As discussed earlier in this chapter, finasteride and other drugs used to treat BPH may reduce the chance of getting prostate cancer by up to 25%.[8] Which men may benefit from these drugs is unknown given the increased risk of developing aggressive (high-grade) prostate cancer from these drugs. Men who are concerned about prostate cancer should discuss with their health care provider the potential risks and benefits of taking finasteride.

Early recognition and treatment are important to control tumor growth, prevent metastasis, and preserve quality of life. Most patients (90%) with prostate cancer are initially diagnosed when the cancer is in either a local or a regional stage. The 5-year survival rate with an initial diagnosis at this stage is 100%.

The most common classification system for determining the extent of the prostate cancer is the tumor, node, and metastasis (TNM) system (Table 55-5). The tumor is graded on the basis of tumor histology using the Gleason scale.[19] The scale grades the tumor from 1 to 5 based on the degree of glandular differentiation. Grade 1 represents the most well-differentiated or lowest grade (most like the original cells), and grade 5 represents the most poorly differentiated (unlike the original cells) or highest grade. The two most commonly occurring patterns of cells are graded, and then the two scores are added together to create a Gleason score, which ranges from 2 to 10. The PSA level at diagnosis and the patient's Gleason score are used with the TNM system to determine the stage grouping of the tumor.

The collaborative care of the patient with prostate cancer depends on the stage of the cancer and the patient's overall health. At all stages, there is more than one possible treatment option (Table 55-6). The decision of which treatment course to pursue should be made jointly by patients, their partners, and the health care team.[20]

Active Surveillance. Prostate cancer is relatively slow growing. Therefore a conservative approach to management of

TABLE 55-5 STAGE GROUPING OF PROSTATE CANCER

Stage	Tumor Size	Lymph Node Involvement	Metastasis	PSA Level	Gleason Score
I	Not felt on DRE. Not seen by visual imaging.	No	No	<10	≤6
II	Felt on DRE. Seen by imaging. Tumor confined to prostate.	No	No	10-20	6-7

TABLE 55-6 COLLABORATIVE CARE

Prostate Cancer

Diagnostic and Staging Workup
- History and physical examination
- Digital rectal examination (DRE)
- Prostate-specific antigen (PSA)
- Prostatic acid phosphatase (PAP)
- Transrectal ultrasound (TRUS)
- Biopsy of prostate and lymph nodes
- Computed tomography (CT)
- Magnetic resonance imaging (MRI)
- Bone scan (to evaluate for metastatic disease)

Collaborative Therapy

Active Surveillance
- Annual PSA and DRE

Surgery
- Radical prostatectomy
- Cryotherapy
- Orchiectomy (for metastatic disease)

Radiation Therapy
- External beam for primary, adjuvant, and recurrent disease
- Brachytherapy

Drug Therapy
- Androgen deprivation therapy (see Table 55-7)
- Chemotherapy for metastatic disease

EVIDENCE-BASED PRACTICE

Applying the Evidence

You are working as an occupational health nurse at a large manufacturing company. G.N. is a 56-yr-old African American who has come to you for his regular blood pressure check. His father and uncle have a history of prostate cancer. He tells you that he has heard that screening for prostate cancer is "all over the news." He has been getting a blood test for prostate-specific antigen (PSA) yearly and asks you if he needs to continue.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
PSA screening saves lives when performed appropriately in men at high risk of developing prostate cancer.	You know that G.N. is in a high-risk category for prostate cancer. He is African American, is more than 50 yr old, and has first-degree relatives with prostate cancer. Based on these risk factors, you encourage him to continue to get yearly PSA screening.	G.N. wants the best preventive measures to screen for prostate cancer. He was involved in the care of both his father and uncle when they were sick, and does not want that to happen to him.

Your Decision and Action

You encourage G.N. to discuss his concerns about annual PSA testing with his primary health care provider. You also discuss the potential influence of risk factors and diet on developing prostate cancer and teach him about food to avoid or limit (e.g., red meat, high-fat dietary products) and those to increase (e.g., vegetables, fruits).

Reference for Evidence

prostate cancer is active surveillance, or "watchful waiting." This strategy is appropriate when the patient has (1) a life expectancy of less than 10 years (low risk of dying of the disease); (2) a low-grade, low-stage tumor; and (3) serious coexisting medical conditions. With active surveillance, patients are typically followed with frequent PSA measurements, along with DRE, to monitor the progress of the disease. Significant changes in the PSA level or the DRE, or the development of symptoms, warrant a reevaluation of treatment options.

Surgical Therapy

Radical Prostatectomy. With **radical prostatectomy,** the entire prostate gland, seminal vesicles, and part of the bladder neck (ampulla) are removed. The entire prostate is removed because the cancer tends to be in many different locations within the gland. In addition, a retroperitoneal lymph node dissection is usually done as a separate procedure. Surgery is usually not considered an option for advanced stage disease (except to relieve symptoms associated with obstruction) because metastasis has already occurred.

Traditional surgical approaches for a radical prostatectomy include retropubic and perineal resection (Fig. 55-6). With the *retropubic* approach, a low midline abdominal incision is made to access the prostate gland, and the pelvic lymph nodes can be dissected. With the *perineal* resection, an incision is made between the scrotum and anus.

A *laparoscopic* approach to prostatectomy is being used in some settings. In this method four small incisions are made into the abdomen. It results in less bleeding, less pain, and a faster recovery compared with other approaches.

A *robotic-assisted* (e.g., da Vinci system) prostatectomy is a type of laparoscopy in which the surgeon sits at a computer console while controlling high-resolution cameras and microsurgical instruments. Robotics is being used more, since it allows for increased precision, visualization, and dexterity by the surgeon when removing the prostate gland. Compared with traditional approaches, a robotic-assisted radical prostatectomy

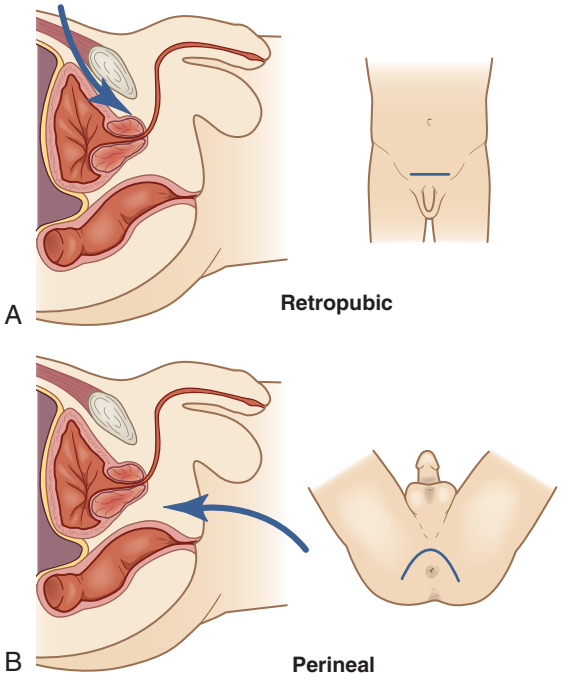

FIG. 55-6 Common approaches used to perform a prostatectomy. **A,** Retropubic approach involves a midline abdominal incision. **B,** Perineal approach involves an incision between the scrotum and the anus.

has resulted in similar surgical outcomes with improved recovery time.[21]

After surgery, the patient has a large indwelling catheter with a 30-mL balloon placed in the bladder via the urethra. A drain is left in the surgical site to aid in the removal of drainage from the area. This drain is typically removed after a couple of days. Because the perineal approach has a higher risk of postoperative infection (because of the location of the incision related to the anus), careful dressing changes and perineal care after each bowel movement are important for comfort and to prevent infection. Depending on the type of surgery, the length of hospital stay postoperatively ranges from 1 to 3 days.

Two major adverse outcomes after a radical prostatectomy are ED and urinary incontinence.[22] The incidence of ED depends on the patient's age, preoperative sexual function, whether nerve-sparing surgery was performed, and the surgeon's expertise. Sexual function after surgery tends to return gradually over at least 24 months or more. Medications such as sildenafil (Viagra) may help improve sexual function.

Problems with urinary control may occur for the first few months after surgery because the bladder must be reattached to the urethra after the prostate is removed. Over time, the bladder adjusts and most men regain control.[23] Kegel exercises strengthen the urinary sphincter and may help improve continence. (Kegel exercises are presented in Table 46-19.) Other complications associated with surgery include hemorrhage, urinary retention, infection, wound dehiscence, deep vein thrombosis, and pulmonary emboli.

Nerve-Sparing Procedure. Near the prostate gland are neurovascular bundles that maintain erectile functioning. The preservation of these bundles during a prostatectomy is possible while still removing all of the cancer. Nerve-sparing prostatectomy is not indicated for patients with cancer outside of the prostate gland. Although the risk of ED is significantly reduced with this procedure, there is no guarantee that potency will be maintained. However, most men younger than 50 years of age with good preoperative erectile function and low-stage prostate cancer can expect a return of potency after nerve-sparing prostatectomy.

Cryotherapy. *Cryotherapy* (cryoablation) is a surgical technique for prostate cancer that destroys cancer cells by freezing the tissue.[24] It has been used both as an initial treatment and as a second-line treatment after radiation therapy failed. A TRUS probe is inserted to visualize the prostate gland. Probes containing liquid nitrogen are then inserted into the prostate. Liquid nitrogen delivers freezing temperatures, thus destroying the tissue. The treatment takes about 2 hours under general or spinal anesthesia and does not involve an abdominal incision.

Possible complications include damage to the urethra and, in rare cases, a urethrorectal fistula (an opening between the urethra and the rectum) or a urethrocutaneous fistula (an opening between the urethra and the skin). Tissue sloughing, ED, urinary incontinence, prostatitis, and hemorrhage can also occur.

Radiation Therapy. Radiation therapy is another common treatment option for prostate cancer. Radiation therapy may be the only treatment, or it may be used in combination with surgery or with hormone therapy. Salvage radiation therapy given for prostate cancer recurrence after a radical prostatectomy may improve survival in some men.

External Beam Radiation. External beam is the most widely used method of delivering radiation treatments for those with prostate cancer. This therapy can be used to treat patients with prostate cancer confined to the prostate and/or surrounding tissue. Patients are usually treated on an outpatient basis 5 days a week for 4 to 8 weeks. Each treatment lasts only a few minutes.

Side effects from radiation can be acute (occurring during treatment or within 90 days that follow) or delayed (occurring months or years after treatment). The most common side effects involve changes to the skin (dryness, redness, irritation, pain), gastrointestinal tract (diarrhea, abdominal cramping, bleeding), urinary tract (dysuria, frequency, hesitancy, urgency, nocturia), and sexual function (ED).[25] Fatigue may also occur. These problems may lessen 2 to 3 weeks after the completion of radiation therapy. In patients with localized prostate cancer, cure rates with external beam radiation are comparable to those with radical prostatectomy.[15]

Brachytherapy. *Brachytherapy* involves placing radioactive seed implants into the prostate gland, allowing higher radiation doses directly in the tissue while sparing the surrounding tissue (rectum and bladder). The radioactive seeds are placed in the prostate gland with a needle through a grid template guided by TRUS (Fig. 55-7). The grid template and the ultrasound ensure accurate placement of the seeds.

Because brachytherapy is a one-time outpatient procedure, many patients find this more convenient than external beam radiation treatment. Brachytherapy is best suited for patients with early stage disease. The most common side effect is the development of urinary irritative or obstructive problems. Some men may also experience ED. The AUA Symptom Index (see Table 55-1) can be used to measure urinary function for patients undergoing brachytherapy and can be incorporated into postoperative nursing management. For those with more advanced tumors, brachytherapy may be offered in combination

with external beam radiation treatment.[26] (Brachytherapy is discussed further in Chapter 16.)

Drug Therapy. The forms of drug therapy available for the treatment of prostate cancer are androgen deprivation (hormone) therapy, chemotherapy, or a combination of both.

Androgen Deprivation Therapy. Prostate cancer growth is largely dependent on the presence of androgens. *Androgen deprivation therapy* (ADT) reduces the levels of circulating androgens to reduce the tumor growth. Androgen deprivation can be produced by inhibiting androgen production or blocking androgen receptors (Table 55-7).

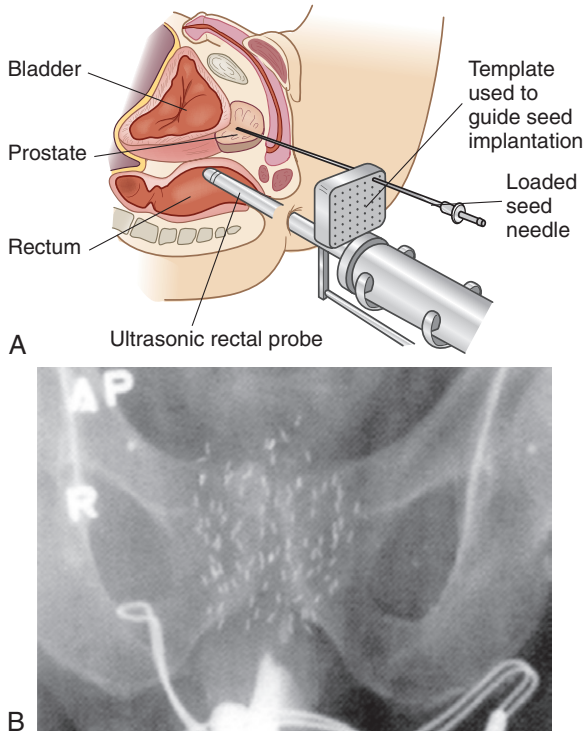

FIG. 55-7 **A,** Prostate brachytherapy. Implantation of radioactive seeds with a needle guided by ultrasound and a template grid. **B,** Radioactive seeds.

One of the biggest challenges with ADT is that almost all tumors treated become resistant to this therapy *(hormone refractory)* within a few years. An elevated PSA level is often the first sign that this therapy is no longer effective. Patients taking ADT have an increased risk of cardiovascular side effects, including elevated serum cholesterol and triglyceride levels and coronary artery disease.[27] Research is also examining whether ADT may increase the risk of developing metabolic syndrome.

Osteoporosis and fractures may occur in prostate cancer patients receiving ADT. Drugs recommended to reduce bone mineral loss in these patients include zoledronic acid (Reclast) and raloxifene (Evista).[28] Denosumab (Prolia), a drug that slows the breakdown of bone, may also be used to increase bone mass in men with nonmetastatic prostate cancer.

Androgen Synthesis Inhibitors. The hypothalamus produces luteinizing hormone–releasing hormone (LH-RH), which stimulates the anterior pituitary to produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH stimulates the testicular Leydig cells to produce testosterone. *LH-RH agonists* superstimulate the pituitary. This ultimately results in downregulation of the LH-RH receptors, leading to a refractory condition in which the anterior pituitary is unresponsive to LH-RH. These drugs cause an initial transient increase in LH and testosterone called a *flare.* Symptoms may worsen during this time. However, with continued administration, LH and testosterone levels are decreased.

LH-RH agonists include leuprolide (Lupron, Lupron Depot, Eligard, Viadur,) goserelin (Zoladex), triptorelin (Trelstar), and buserelin (Suprefact) (see Table 55-7). These drugs essentially produce a chemical castration similar to the effects of an orchiectomy. These drugs are given by subcutaneous or intramuscu-

TABLE 55-7 DRUG THERAPY

leuprolide (Lupron, Lupron Depot, Eligard, Viadur) goserelin (Zoladex) triptorelin (Trelstar) buserelin (Suprefact)	Reduce secretion of LH and FSH Decrease testosterone production	Hot flashes, gynecomastia, decreased libido, erectile dysfunction Depression and mood changes
LH-RH Antagonist		
degarelix	Blocks LH receptors Immediate testosterone suppression	Pain, redness, and swelling at injection site Elevated liver enzymes
CYP17 Enzyme Inhibitor		
abiraterone (Zytiga)	Inhibits CYP17, an enzyme needed for production of testosterone Inhibits testosterone synthesis from testes, adrenal glands, and prostate cancer cells	Joint swelling, fluid retention, muscle discomfort, hot flashes, diarrhea
Androgen Receptor Blockers		
bicalutamide (Casodex) flutamide (Eulexin) nilutamide (Nilandron) enzalutamide (Xtandi)	Block action of testosterone by competing with receptor sites	Loss of libido, erectile dysfunction, and hot flashes Breast pain and gynecomastia may also occur

FSH, Follicle-stimulating hormone; *LH,* luteinizing hormone; *LH–RH,* luteinizing hormone–releasing hormone.

lar injections on a regular basis. Viadur is an implant that is placed subcutaneously and delivers leuprolide continuously for 1 year.

Degarelix is an *LH-RH antagonist* that lowers testosterone levels. Unlike the LH-RH agonists, degarelix does not cause a testosterone flare because it acts directly to block LH and FSH receptors. It is given as a subcutaneous injection.

Abiraterone (Zytiga) works by inhibiting an enzyme, CYP17, which is needed for the production of testosterone. This drug is given orally.

Androgen Receptor Blockers. Another classification of antiandrogens is drugs that compete with circulating androgens at the receptor sites. Flutamide (Eulexin), nilutamide (Nilandron), bicalutamide (Casodex), and enzalutamide (Xtandi) are androgen receptor blockers. They are taken daily as an oral medication and can be used in combination with an LH-RH agonist (e.g., goserelin, leuprolide). Combining an androgen receptor blocker with an LH-RH agonist is an often-used treatment, which results in combined androgen blockade.

Chemotherapy. The use of chemotherapy has primarily been limited to treatment for those with hormone-refractory prostate cancer (HRPC) in late-stage disease. In HRPC the cancer is progressing despite treatment. This occurs in patients who have taken an antiandrogen for a certain period. The goal of chemotherapy is mainly palliative.

Some commonly used chemotherapy drugs include docetaxel (Taxotere), cabazitaxel (Jevtana), paclitaxel (Abraxane), mitoxantrone (Novantrone), vinblastine (Velban), cyclophosphamide (Cytoxan), and estramustine (Emcyt).

Men with advanced prostate cancer who have HRPC may receive a vaccine (sipuleucel-T [Provenge]). The vaccine stimulates the patient's system against the cancer and may prolong survival.

Radiotherapy. Radium-223 dichloride (Xofigo) can be used in the treatment of patients with castration-resistant prostate cancer, symptomatic bone metastases, and no known visceral metastatic disease. It is an alpha particle–emitting radiotherapy drug that mimics calcium and forms complexes with hydroxyapatite at areas of increased bone turnover, such as bone metastases.

Orchiectomy. Testosterone, produced by the testes, stimulates growth of the prostate cancer. A bilateral orchiectomy is the surgical removal of the testes that may be done alone or in combination with prostatectomy. For advanced stages of prostate cancer, an orchiectomy is one treatment option for cancer control. Another possible benefit of this procedure is the rapid relief of bone pain associated with advanced tumors. Orchiectomy may also shrink the prostate, thus relieving urinary obstruction in the later stages of disease when surgery is not an option.

After an orchiectomy, the weight gain and loss of muscle mass can alter a man's physical appearance. These physical changes can affect self-esteem, leading to grief and depression. Because this procedure is permanent, many men prefer drug therapy over an orchiectomy.

CULTURALLY COMPETENT CARE

PROSTATE CANCER

You need to be aware of ethnic and cultural considerations when providing information about the risk for prostate cancer and screening recommendations. Consider not only the ethnic differences in the incidence of prostate cancer, but also differences in health promotion practices.

African American men have higher mortality rates from prostate cancer than white men. In part this is because their prostate cancer often is more advanced at the time of diagnosis. Despite the availability of early screening measures (PSA and DRE), African American men and those in lower socioeconomic groups frequently do not use them. This is partially related to knowledge levels about prostate cancer. In comparison to white men, African American men with prostate cancer reported more problems with financial access to transportation and health care costs, and they indicated using more religious coping strategies. White men were also perceived as receiving more favorable treatment from their physicians than African Americans.[29]

Although exposure to electronic and print media is successful in informing some men about prostate cancer, the effectiveness differs significantly based on demographic variables such as ethnicity, age, education level, and socioeconomic level. Ideally, all men should be aware of the risks associated with prostate cancer and the screening methods available. Consider the best method to communicate this information to men of all cultures and ethnicities that will result in the greatest degree of understanding and participation in prostate cancer screening.

DELEGATION DECISIONS

Caring for the Patient Receiving Bladder Irrigation

Intermittent or continuous bladder irrigation (CBI) is usually required after invasive prostate surgery to prevent bladder obstruction by clots or mucus.

Role of Registered Nurse (RN)

- Assess for bleeding and clots.
- Assess catheter patency by measuring intake and output and presence of bladder spasms.
- Manually irrigate catheter if bladder spasms or decreased outflow occurs.
- Discontinue CBI and notify physician if obstruction occurs.
- Teach patient Kegel exercises after catheter removal.
- Provide care instructions for patient discharged with indwelling catheter.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- Monitor catheter drainage for increased blood or clots.
- Increase flow of irrigating solution to maintain light pink color in outflow.
- Administer antispasmodics and analgesics as needed.

Role of Unlicensed Assistive Personnel (UAP)

- Clean around catheter daily.
- Record intake and output.
- Notify RN if large amount of bright red blood in urine.
- Report complaints of pain or bladder spasms to RN.

NURSING MANAGEMENT
PROSTATE CANCER

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a patient with prostate cancer are presented in Table 55-8.

NURSING DIAGNOSES

Nursing diagnoses for the patient with prostate cancer depend on the stage of the cancer. General nursing diagnoses may include, but are not limited to, the following.

TABLE 55-8 NURSING ASSESSMENT

Prostate Cancer

Subjective Data

Important Health Information

Medications: Testosterone supplements; use of any medications affecting urinary tract such as morphine, anticholinergics, monoamine oxidase inhibitors, and tricyclic antidepressants

Functional Health Patterns

Health perception–health management: Positive family history; increasing fatigue and malaise

Nutritional-metabolic: High-fat diet; anorexia, weight loss (possible indicators of metastasis)

Elimination: Hesitancy or straining to start stream, urinary urgency, frequency, retention with dribbling, weak stream, hematuria

Sleep: Nocturia

Cognitive-perceptual: Dysuria; low back pain radiating to legs or pelvis, bone pain (possible indicators of metastasis)

Self-perception–self-concept: Anxiety regarding self-concept

Objective Data

General

Older adult male; pelvic lymphadenopathy (late sign)

Urinary

Distended bladder on palpation; unilaterally hard, enlarged, fixed prostate on rectal examination

Musculoskeletal

Pathologic fractures (metastasis)

Possible Diagnostic Findings

Serum PSA; ↑ serum PAP (metastasis); nodular and irregular prostate on ultrasonography, positive biopsy results; anemia

PAP, Prostatic acid phosphatase; *PSA,* prostate-specific antigen.

- Decisional conflict *related to* numerous alternative treatment options
- Acute pain *related to* surgery, prostatic enlargement, bone metastasis, and bladder spasms
- Urinary retention and impaired urinary elimination *related to* obstruction of the urethra by the prostate and loss of bladder tone
- Sexual dysfunction *related to* effects of treatment
- Anxiety *related to* uncertain outcome of disease process on life and lifestyle and effect of treatment on sexual function

PLANNING

The overall goals are that the patient with prostate cancer will (1) be an active participant in the treatment plan, (2) have satisfactory pain control, (3) follow the therapeutic plan, (4) understand the effect of the therapeutic plan on sexual function, and (5) find a satisfactory way to manage the impact on bladder and bowel function.

NURSING IMPLEMENTATION

HEALTH PROMOTION. One of your most important roles in relation to prostate cancer is to encourage patients, in consultation with their health care providers, to have annual prostate screening (PSA and DRE) starting at age 50 (or younger if risk factors are present). Because of their increased risk of prostate cancer, African American men and other men with a family history of prostate cancer should have an annual PSA and DRE beginning at ages 40 to 45.

ACUTE INTERVENTION. Preoperative and postoperative phases of radical prostatectomy are similar to surgical procedures for BPH (see pp. 1310-1312). Nursing interventions for the patient who undergoes radiation therapy and chemotherapy are discussed in Chapter 16. An additional consideration is the patient's psychologic response to a diagnosis of cancer. Provide sensitive, caring support for the patient and his family to help them cope with the diagnosis. Prostate cancer support groups are available for men and their families to encourage them to be active, informed participants in their own care.

AMBULATORY AND HOME CARE. Teach appropriate catheter care if the patient is discharged with an indwelling catheter in place. Instruct the patient to clean the urethral meatus with soap and water once a day; maintain a high fluid intake; keep the collecting bag lower than the bladder at all times; keep the catheter securely anchored to the inner thigh or abdomen; and report any signs of bladder infection, such as bladder spasms, fever, or hematuria.

If urinary incontinence is a problem, encourage the patient to practice pelvic floor muscle exercises (Kegel exercises) at every urination and throughout the day. Continuous practice during the 4- to 6-week healing process improves the success rate. Products used for incontinence specifically designed for men are available through home care product catalogs and retail stores.

Palliative and end-of-life care is often appropriate and beneficial to the patient with advanced disease and his family (see Chapter 10). Common problems experienced by the patient with advanced prostate cancer include fatigue, bladder outlet obstruction and ureteral obstruction (caused by compression of the urethra and/or ureters from tumor mass or lymph node metastasis), severe bone pain and fractures (caused by bone metastasis), spinal cord compression (from spinal metastasis), and leg edema (caused by lymphedema, deep vein thrombosis, and other medical conditions). Nursing interventions must focus on all of these problems. However, pain management is one of the most important aspects of your care for these patients. Pain control involves ongoing pain assessment, administration of prescribed medications (both opioid and nonopioid agents), and nonpharmacologic methods of pain relief (e.g., relaxation breathing). (Pain management is discussed further in Chapter 9.)

EVALUATION

The outcomes are that the patient with prostate cancer will

- Be an active participant in the treatment plan
- Have satisfactory pain control
- Follow the therapeutic plan
- Understand the effect of the treatment on sexual function
- Find a satisfactory way to manage the impact on bladder or bowel function

PROSTATITIS

Etiology and Pathophysiology

Prostatitis is a broad term that describes a group of inflammatory and noninflammatory conditions affecting the prostate gland. Prostatitis is one of the most common urologic disorders. It is estimated that 12% of all men experience prostatitis in their lifetime.[30] Almost 2 million men are treated for prostatitis every

year. The four categories of prostatitis syndromes are (1) acute bacterial prostatitis, (2) chronic bacterial prostatitis, (3) chronic prostatitis/chronic pelvic pain syndrome, and (4) asymptomatic inflammatory prostatitis.

Both acute and chronic bacterial prostatitis generally results from organisms reaching the prostate gland by one of the following routes: ascending from the urethra, descending from the bladder, and invading via the bloodstream or the lymphatic channels. Common causative organisms are *Escherichia coli; Klebsiella, Pseudomonas, Enterobacter,* or *Proteus; Chlamydia trachomatis; Neisseria gonorrhoeae;* and group D streptococci. Chronic bacterial prostatitis differs from acute prostatitis in that it involves recurrent episodes of infection.

Chronic prostatitis/chronic pelvic pain syndrome describes a syndrome of prostate and urinary pain in the absence of an obvious infectious process. The etiology of this syndrome is not known. It may occur after a viral illness, or it may be associated with sexually transmitted infections (STIs), particularly in younger adults. A culture reveals no causative organisms. However, leukocytes may be found in prostatic secretions.

Asymptomatic inflammatory prostatitis is usually diagnosed in individuals who have no symptoms, but are found to have an inflammatory process in the prostate. These patients are usually diagnosed during the evaluation of other genitourinary tract problems. Leukocytes are present in the seminal fluid from the prostate, but the cause of this process is unclear.

Clinical Manifestations and Complications

In acute bacterial prostatitis, common manifestations include fever, chills, back pain, and perineal pain, along with acute urinary symptoms such as dysuria, urinary frequency, urgency, and cloudy urine. The patient may also have acute urinary retention caused by prostatic swelling. With DRE, the prostate is extremely swollen, very tender, and firm. The complications of prostatitis are epididymitis and cystitis. Sexual function may be affected as manifested by postejaculation pain, libido problems, and ED. Prostatic abscess is also a potential, but uncommon, complication.

In chronic bacterial prostatitis and chronic prostatitis/chronic pelvic pain syndrome, manifestations are similar but generally milder than those of acute bacterial prostatitis. These include irritative voiding symptoms (frequency, urgency, dysuria), backache, perineal and pelvic pain, and ejaculatory pain. Obstructive symptoms are uncommon unless there is coexisting BPH. With DRE, the prostate feels enlarged and firm (often described as boggy) and is slightly tender with palpation. Chronic prostatitis can predispose the patient to recurrent UTIs.

The clinical features of prostatitis can mimic those of a UTI. However, it is important to remember that acute cystitis is not common in men.

Diagnostic Studies

Because patients with prostatitis have urinary symptoms, a urinalysis (UA) and urine culture are indicated. Often WBCs and bacteria are present. If the patient has a fever, WBC count and blood cultures are also indicated. The PSA test may be done to rule out prostate cancer. However, PSA levels are often elevated with prostatic inflammation. Thus it is not considered diagnostic in itself.

Microscopic evaluation and culture of expressed prostate secretion are considered useful in the diagnosis of prostatitis. Expressed prostate secretion is obtained using a premassage and postmassage test.[31] The patient is asked to void into a specimen cup just before and just after a vigorous prostate massage. Prostatic massage (for expressed prostate secretion) should be avoided if acute bacterial prostatitis is suspected, since compression is extremely painful and can increase the risk of bacterial spread. TRUS has not been useful in the diagnosis of prostatitis. However, transabdominal ultrasound or MRI may be done to rule out an abscess on the prostate.

NURSING AND COLLABORATIVE MANAGEMENT PROSTATITIS

Antibiotics commonly used for acute and chronic bacterial prostatitis include trimethoprim/sulfamethoxazole (Bactrim), ciprofloxacin (Cipro), ofloxacin (Floxin), carbachol (Miostat), carbenicillin (Geocillin), cephalexin (Keflex), and doxycycline (Vibramycin) or tetracycline. These antibiotics may be prescribed for those patients with multiple sex partners. Antibiotics are usually given orally for up to 4 weeks for acute bacterial prostatitis. However, if the patient has high fever or other signs of impending sepsis, hospitalization and IV antibiotics are prescribed. Patients with chronic bacterial prostatitis may be given oral antibiotic therapy for 4 to 12 weeks. Antibiotics may be given for a lifetime if the patient is immunocompromised. A short course of oral antibiotics is usually prescribed for those with chronic prostatitis/chronic pelvic pain syndrome. However, antibiotic therapy often is ineffective for patients whose prostatitis is not due to bacteria.

Although patients with acute and chronic bacterial prostatitis tend to experience a great amount of discomfort, the pain resolves as the infection is treated. Pain management for patients with chronic prostatitis/chronic pelvic pain syndrome is more difficult because the pain persists for weeks to months. No single approach has been shown to provide relief for everyone with this condition. Antiinflammatory agents (e.g., ibuprofen, indomethacin) may be used for pain control in prostatitis, but these drugs provide only moderate pain relief. Warm sitz baths may also help. Relaxation of muscle tissue in the prostate using α-adrenergic blockers (e.g., tamsulosin, alfuzosin) has been shown to be effective in reducing discomfort for some men.

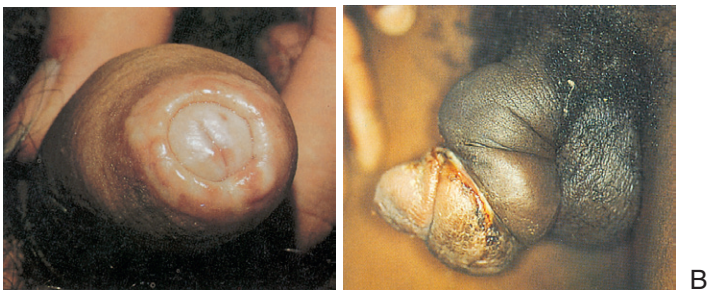
Acute urinary retention can develop in acute prostatitis, requiring insertion of a urinary catheter. However, passage of a catheter through an inflamed urethra is contraindicated in acute prostatitis. The placement of a suprapubic catheter may then be indicated. Repetitive prostatic massage may be recommended as adjunct therapy for prostatitis for men.[31] This measure relieves congestion within the prostate by squeezing out excess prostatic secretions, thus providing pain relief. Prostatic massage is performed using the index finger of a gloved hand and pressing down on the prostate, covering the entire gland's surface in longitudinal strokes. Similar to massage, measures to stimulate ejaculation (masturbation and intercourse) may help to drain the prostate and provide some relief.

Because the prostate can serve as a source of bacteria, fluid intake should be kept at a high level for all patients experiencing prostatitis. Encourage the patient to drink plenty of fluids. This is especially important for those with acute bacterial prostatitis because of the increased fluid needs associated with fever and infection. Management of fever is also an important nursing intervention.

PROBLEMS OF THE PENIS

Health problems of the penis are rare if STIs are excluded (see Chapter 53). Problems of the penis may be classified as congenital, problems of the prepuce, problems with the erectile mechanism, and cancer.

CONGENITAL PROBLEMS



Hypospadias is a urologic abnormality in which the urethral meatus is located on the ventral surface of the penis anywhere from the corona to the perineum. Possible causes are hormonal influences in utero, environmental factors, and genetic factors. Surgical repair of hypospadias may be necessary if it is associated with *chordee* (a painful downward curvature of the penis during erection) or if it prevents intercourse or normal urination. Surgery may also be done for cosmetic reasons or emotional well-being.

PROBLEMS OF PREPUCE

Problems of the prepuce in the United States are not common because circumcision has been a routine procedure for many male infants. Circumcision, the surgical removal of the foreskin of the penis, is a procedure done to male infants for religious or cultural reasons.

Phimosis is a tightness or constriction of the foreskin around the head of the penis, making retraction difficult (Fig. 55-8, *A*). It is caused by edema or inflammation of the foreskin, usually associated with poor hygiene techniques that allow bacterial and yeast organisms to become trapped under the foreskin. The goal of treatment is to return the foreskin to its natural position over the glans penis through manual reduction. One strategy involves pushing the glans back through the prepuce by applying constant thumb pressure while the index fingers pull the prepuce over the glans. Ice and/or hand compression on the foreskin, glans, and penis may be done before this technique to reduce edema. Topical corticosteroid cream applied two or three times daily to the exterior and interior of the tip of the foreskin may also be effective.

Paraphimosis is tightness of the foreskin resulting in the inability to pull it forward from a retracted position and preventing normal return over the glans. An ulcer can develop if the foreskin remains contracted (Fig. 55-8, *B*). Paraphimosis can occur when the foreskin is pulled back during bathing, use of urinary catheters, or intercourse and is not placed back in the forward position. Replacement of the foreskin after careful cleaning helps to prevent this condition. Treatment may include antibiotics; warm soaks; and, in some situations, circumcision or dorsal slit of the prepuce.

A B

FIG. 55-8 A, Phimosis: inability to retract the foreskin due to secondary lesions on the prepuce. **B,** Paraphimosis: ulcer with edema from foreskin remaining contracted over the prepuce.

PROBLEMS OF ERECTILE MECHANISM

Priapism is a painful erection lasting longer than 6 hours that may constitute a medical emergency. Priapism is caused by complex vascular and neurologic factors that result in an obstruction of venous outflow in the penis. Conditions that may be associated with priapism include sickle cell disease, diabetes mellitus, trauma to the spinal cord, degenerative lesions of the spine, and medications (e.g., cocaine, trazodone). Vasoactive medications (e.g., sildenafil) injected into the corpora cavernosa for ED can also cause priapism.

Complications include penile tissue necrosis caused by lack of blood flow or hydronephrosis from bladder distention. With immediate medical treatment, the risk of permanent ED is low.

Treatment varies depending on the cause. In patients with sickle cell disease, a blood exchange transfusion may be done, whereas other patients may be treated with sedatives, an injection of a smooth muscle relaxant directly into the penis, or aspiration and irrigation of the corpora cavernosa with a large-bore needle.

Peyronie's disease, sometimes referred to as curved or crooked penis, is caused by plaque formation in one of the corpora cavernosa of the penis. The palpable, nontender, hard plaque formation is usually found on the posterior surface. It may occur spontaneously or result from trauma to the penile shaft. The plaque prevents adequate blood flow into the spongy tissue, which results in a curvature during erection. The condition is not dangerous but can result in painful erections, ED, or embarrassment. Patients may improve over time, stabilize, or need surgery.

CANCER OF PENIS

Cancer of the penis is rare, with about 1500 cases diagnosed annually. It occurs more commonly in men who have cancers associated with human papillomavirus (HPV) and in men who were not circumcised as infants.[32] The tumor may appear as a superficial ulceration or a pimple-like nodule. The nontender warty lesion may be mistaken for a venereal wart. The majority of malignancies (95%) are well-differentiated squamous cell carcinomas.

Treatment in the early stages is laser removal of the growth. A radical resection of the penis may be done if the cancer has spread. Surgery, radiation, or chemotherapy may be tried depending on the extent of the disease, lymph node involvement, or metastasis.

PROBLEMS OF SCROTUM AND TESTES

INFLAMMATORY AND INFECTIOUS PROBLEMS

Skin Problems

The skin of the scrotum is susceptible to a number of common skin diseases. The most common are fungal infections, dermatitis (neurodermatitis, contact dermatitis, seborrheic dermatitis), and parasitic infections (scabies, lice). These conditions involve discomfort for the patient but are associated with few severe complications (see Chapter 24).

Epididymitis

Epididymitis is an acute, painful inflammatory process of the epididymis (Fig. 55-9), which is often due to an infectious process, trauma, or urinary reflux down the ductus (vas) deferens. It is usually unilateral. Swelling may progress to the point that the epididymis and testis are indistinguishable. In men younger than 40 years of age, the most common cause is gonorrhea or chlamydial infection. UTI and prostatitis are common causes in older men.

The use of antibiotics is important for both partners if the transmission is through sexual contact. Encourage patients to refrain from sexual intercourse during the acute phase. If they do engage in intercourse, a condom should be used. Conservative treatment consists of bed rest with elevation of the scrotum, ice packs, and analgesics. Ambulation places the scrotum in a dependent position and increases pain. Most tenderness subsides within 1 week, although swelling may last for weeks or months.

Orchitis

Orchitis refers to an acute inflammation of the testis. In orchitis, the testis is painful, tender, and swollen. It generally occurs after an episode of bacterial or viral infection such as mumps, pneumonia, tuberculosis, or syphilis. It can also be a side effect of epididymitis, prostatectomy, trauma, infectious mononucleosis, influenza, catheterization, or complicated UTI. Mumps orchitis is a condition contributing to infertility that could be avoided by childhood vaccination against mumps. Treatment involves the use of antibiotics (if the organism is known), pain medications, or bed rest with the scrotum elevated on an ice pack.

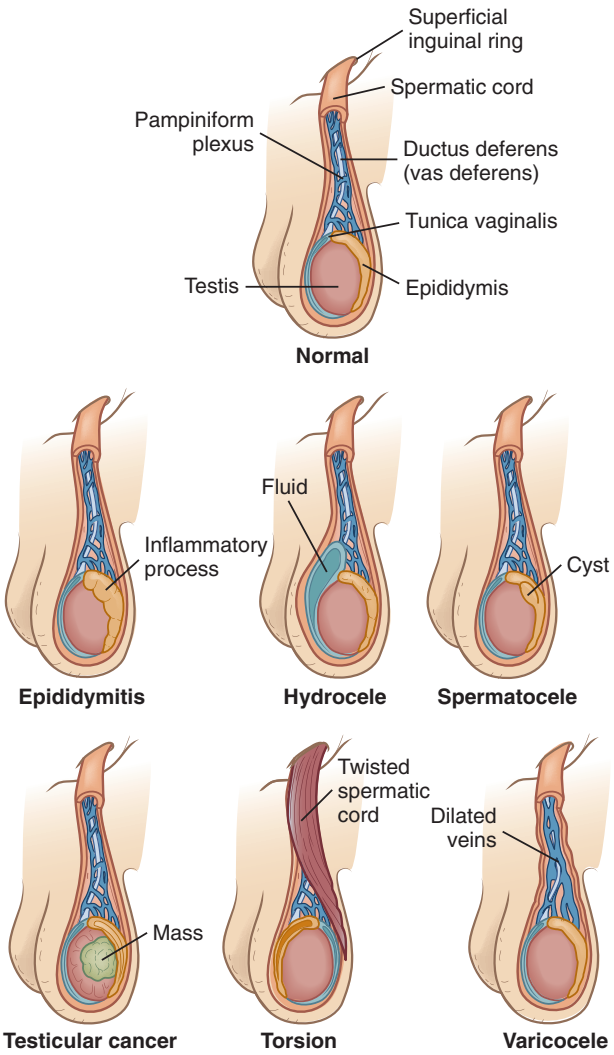


FIG. 55-9 Scrotal masses.

CONGENITAL PROBLEMS

Cryptorchidism (undescended testes) is failure of the testes to descend into the scrotal sac before birth. It is the most common congenital testicular condition. It may occur bilaterally or unilaterally and may be the cause of infertility if corrective surgery is not done by 2 years of age. The incidence of testicular cancer is also higher if the condition is not corrected before puberty. Surgery is performed to locate and suture the testis or testes to the scrotum.

ACQUIRED PROBLEMS

Hydrocele

A *hydrocele* is a nontender, fluid-filled mass that results from interference with lymphatic drainage of the scrotum and swelling of the tunica vaginalis that surrounds the testis (Fig. 55-10; also see Fig. 55-9). Diagnosis is fairly simple because the mass can be seen by shining a flashlight through the scrotum (transillumination). No treatment is indicated unless the swelling becomes large and uncomfortable, in which case aspiration or surgical drainage of the mass is performed.

Spermatocele

A *spermatocele* is a firm, sperm-containing, painless cyst of the epididymis that may be visible with transillumination (see Fig. 55-9). The cause is unknown, and surgical removal is the treatment. It is important for the patient to see his health care provider if he feels any scrotal lumps. He would be unable to distinguish this cyst from cancer when performing self-examination.

Varicocele

A *varicocele* is a dilation of the veins that drain the testes (see Fig. 55-9). The scrotum feels wormlike when palpated. The cause of the problem is unknown. The varicocele is usually located on the left side of the scrotum as a consequence of ret-

FIG. 55-10 Hydrocele.

rograde blood flow from the left renal vein. Surgery is indicated if the patient is infertile, since persistent varicoceles are associated with 40% to 50% of cases of infertility. Sperm is thought to be damaged by varicoceles. Repair of the varicocele may be through injection of a sclerosing agent or by surgical ligation of the spermatic vein.

Testicular Torsion

Testicular torsion involves a twisting of the spermatic cord that supplies blood to the testes and epididymis (see Fig. 55-9). It is most commonly seen in males younger than age 20. It can occur spontaneously, as a result of trauma, or as a result of an anatomic abnormality. The patient experiences severe scrotal pain, tenderness, swelling, nausea, and vomiting. Urinary symptoms, fever, and WBCs or bacteria in the urine are absent. The pain does not usually subside with rest or elevation of the scrotum.

The *cremasteric reflex* is elicited by lightly stroking (with a reflex hammer or tongue blade) the inner aspect of the thigh in a downward direction. The normal response is a contraction of the cremaster muscle that pulls up the scrotum and testis on the side stroked. In testicular torsion, this reflex is absent on the side of the swelling.

Nuclear scan of the testes or Doppler ultrasound is typically performed to assess blood flow within the testicle. Decreased or absent blood flow confirms the diagnosis. Torsion constitutes a surgical emergency because, if the blood supply to the affected testicle is not restored within 4 to 6 hours, ischemia to the testis will occur, leading to necrosis and the possible need for removal. Unless the torsion resolves spontaneously, surgery to untwist the cord and restore the blood supply must be performed immediately.

TESTICULAR CANCER

Etiology and Pathophysiology

Testicular cancer is rare and accounts for less than 1% of all cancers found in males. However, testicular cancer is the most common type of cancer in young men between 15 and 35 years of age.[33] In the United States about 8600 new cases occur annually with a median age at diagnosis of 33 years old.[16] It is one of the most curable types of cancer. Testicular tumors are more common in males who have had undescended testes (cryptorchidism) or a family history of testicular cancer or anomalies. Other predisposing factors include orchitis, human immunodeficiency virus (HIV) infection, maternal exposure to exogenous estrogen, and testicular cancer in the contralateral testis.

Most testicular cancers develop from two types of embryonic germ cells: seminomas and nonseminomas. Although seminoma germ cell cancers are the most common, they are the least aggressive. Nonseminoma testicular germ cell tumors are rare, but very aggressive. Non–germ cell tumors arise from other testicular tissue and include Leydig cell and Sertoli cell tumors. These account for less than 10% of testicular cancers.

Clinical Manifestations and Complications

Testicular cancer may have a slow or rapid onset depending on the type of tumor (see Fig. 55-9). The patient may notice a painless lump in his scrotum, scrotal swelling, and a feeling of heaviness. The scrotal mass usually is nontender and firm. Some patients complain of a dull ache or heavy sensation in the lower abdomen, the perianal area, or the scrotum. Acute pain is the initial symptom in about 10% of patients. Manifestations associated with advanced disease are varied and include lower back or chest pain, cough, and dyspnea.

Diagnostic Studies

Palpation of the scrotal contents is the first step in diagnosing testicular cancer. A cancerous mass is firm and does not transilluminate. Ultrasound of the testes is indicated whenever testicular cancer is suspected (e.g., palpable mass) or when persistent or painful testicular swelling is present. If a testicular neoplasm is suspected, blood is obtained to determine the serum levels of α-fetoprotein (AFP), lactate dehydrogenase (LDH), and human chorionic gonadotropin (hCG).[34] (These tumor markers are discussed in Chapter 16.) A chest x-ray and CT scan of the abdomen and the pelvis are done to detect metastasis. Anemia may be present, and liver function levels may be elevated in metastatic disease.

NURSING AND COLLABORATIVE MANAGEMENT TESTICULAR CANCER

TESTICULAR SELF-EXAMINATION

The scrotum is easily examined, and beginning tumors are usually palpable. Instruct and encourage every male starting at puberty to perform a monthly testicular self-examination for the purpose of detecting testicular tumors or other scrotal abnormalities such as varicoceles. Teach male patients, especially those with a history of an undescended testis or a previous testicular tumor, how to perform self-examination.

The procedure for self-examination is not difficult. The man may indicate some reluctance to examine his own genitalia, but with your encouragement he can learn this simple procedure. Guidelines for self-examination of the scrotum are presented in Table 55-9 and Fig. 55-11 on the following page. Encourage him to perform self-examinations frequently until he is comfortable with the procedure. The scrotum should then be examined once a month. Use teaching aids such as videotapes and illustrations on shower hangers, and introduce students to them during high school or college physical education classes.

COLLABORATIVE CARE

Collaborative care of testicular cancer generally involves a radical orchiectomy (surgical removal of the affected testis, spermatic cord, and regional lymph nodes). Some patients with early stage disease do not need further treatment after an orchiectomy. Retroperitoneal lymph node dissection and removal may also be done in early stage disease. These nodes are the primary route for metastasis.

Postorchiectomy treatment may also involve surveillance, radiation therapy, or chemotherapy, depending on the stage of the cancer. Radiation therapy is mainly used for patients with a seminoma, which is very sensitive to radiation. Radiation does not seem to work well for nonseminomas.

Chemotherapy protocols use a combination of agents, including bleomycin (Blenoxane), etoposide (VePesid), ifosfamide (Ifex), and cisplatin (Platinol). (Testicular germ cell tumors are more sensitive to systemic chemotherapy than any other adult solid tumor.) Retroperitoneal lymph node dissection may be done after chemotherapy as adjunct therapy in patients with advanced testicular cancer.[34]

The prognosis for patients with testicular cancer in recent years has greatly improved, and 95% of the patients obtain

TABLE 55-9 PATIENT TEACHING GUIDE

Testicular Self-Examination

Include the following instructions when teaching a patient testicular self-examination.

1. During a shower or bath is the easiest time to examine the testes. Warm temperatures make the testes hang lower in the scrotum (see Fig. 55-11).
2. Use both hands to feel each testis. Roll the testis between the thumb and first three fingers until the entire surface has been covered. Palpate each one separately.
3. Identify the structures. The testis should feel round and smooth, like a hard-boiled egg. Differentiate the testis from the epididymis. The epididymis is not as smooth as the egg-shaped testis. One testis may be larger than the other. Size is not as important as texture. Check for lumps, irregularities, pain in the testes, or a dragging sensation. Locate the spermatic cord, which is usually firm and smooth and goes up toward the groin.
4. Choose a consistent day of the month (one that is easy to remember, such as a birth date) on which to examine the testes. The examination can be performed more frequently if desired.
5. Notify the health care provider at once if any abnormalities are found.

FIG. 55-11 Testicular self-examination.

complete remission if the disease is detected in the early stages. As a result of treatment successes, a majority of men with testicular cancer are long-term survivors.

However, some of the drugs used to treat testicular cancer can cause serious long-term side effects. These include pulmonary toxicity, kidney damage, nerve damage (which can cause numbness and tingling), and hearing loss (from nerve damage). Secondary malignancies can occur as a result of chemotherapy (see Chapter 16).

All patients with testicular cancer, regardless of pathology or stage, require surveillance and regular physical examinations, chest x-rays, CT scans, and assessment of hCG and AFP. The goal is to detect relapse when the tumor burden is minimal.

Prior infertility or impaired fertility is often present at diagnosis. In treatment of testicular cancer, chemotherapy with cisplatin and/or pelvic irradiation often damages the testicular germ cells.[35] However, spermatogenesis can return in some patients. Because of the high risk for infertility, the cryopreservation of sperm in a sperm bank before treatment begins should be sensitively discussed and recommended for the man with testicular cancer. Ejaculatory dysfunction may result from retroperitoneal lymph node dissection. These issues may be hard to discuss with the newly diagnosed patient. Men may think that the disease is a threat to their maleness and self-worth.

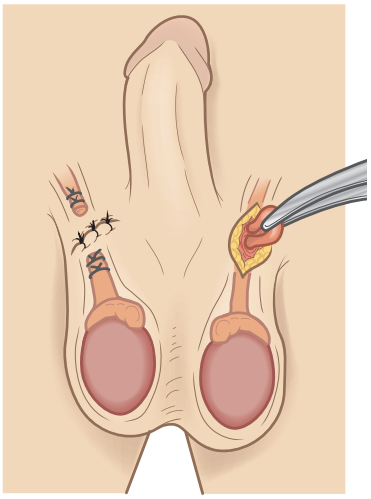

FIG. 55-12 Vasectomy procedure. The ductus deferens is ligated or resected for the purpose of sterilization.

SEXUAL FUNCTION

VASECTOMY

Vasectomy is the bilateral surgical ligation or resection of the ductus deferens performed for the purpose of sterilization (Fig. 55-12). The procedure requires only 15 to 30 minutes and is usually performed with the patient under local anesthesia on an outpatient basis. Although vasectomy is considered a permanent form of sterilization, successful reversals *(vasovasotomy)* have been done.

After vasectomy, the patient should not notice any difference in the look or feel of the ejaculate because its major component is seminal and prostatic fluid. The patient needs to use an alternative form of contraception until semen examination reveals no sperm. This usually requires at least 10 ejaculations or 6 weeks to evacuate sperm distal to the surgical site. Sperm cells continue to be produced by the testes but are absorbed by the body rather than being passed through the ductus deferens. Occasionally postoperative hematoma and swelling of the scrotum occur.

Vasectomy does not affect the production of hormones, ability to ejaculate, or physiologic mechanisms related to erection or orgasm. Psychologic adjustment may be a problem after surgery. It may be difficult for the patient to separate vasectomy from castration at a subconscious level. Some men may develop ED or may feel the need to become more sexually active than they were in the past to prove their masculinity. Careful discussion of the procedure and its outcome before the surgery can help detect patients who may have problems with psychologic adjustment. Surgery should be delayed for these patients.

ERECTILE DYSFUNCTION

Erectile dysfunction (ED) is the inability to attain or maintain an erect penis that allows satisfactory sexual performance. Although sexual function is a topic that many individuals are uncomfortable discussing, health care providers must be able and willing to address ED.[36]

ED is a condition that is significant because of its prevalence, with more than 10 million men in the United States estimated to have ED. It can occur at any age, although the incidence

ETHICAL/LEGAL DILEMMAS

Sterilization

Situation

C.R., a 43-year-old male patient requesting a vasectomy, informs you that he does not wish to discuss this with his wife. The physician's policy is to have the spouse or partner sign a form acknowledging the patient's desire to be sterilized. C.R. explains that although his wife wants to have more children, the one that they already have is all he wants.

Ethical/Legal Points for Consideration

- Legally, for the competent adult, the only person with the right to consent to or refuse health care treatment including sterilization is that competent adult. It is considered a violation of the right to privacy and the Fourteenth Amendment to limit an adult's right to consent or approve by requiring the consent of another.
- Between consenting and competent adults where there is a legally valid marriage contract, there has been some interest in requiring spousal notification of sterilization and abortion.
- Spousal consent or consent of the husband for sterilization of the wife is certainly a common practice in other countries. However, it has never been successfully required in the United States.
- Prior to sterilization procedures, health care providers can require documentation from the other spouse (not having the procedure) that substantiates the informed consent or refusal, including some document showing that the other spouse has been informed of the procedure and the consequences for childbearing.
- The requesting spouse certainly has the right to select another health care provider for the procedure if that spouse wants to avoid creating that documentation.
- In some religions where the ability to terminate a marriage contract by divorce is very limited, the intentional act by one spouse to permanently limit childbearing by sterilization does provide acceptable grounds to break the marriage contract.

Discussion Questions

1. How would you approach this situation?
2. Are there ever circumstances in which deception of a patient or family would be justified?

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Do Lifestyle Changes and Cardiovascular Medication Improve Erectile Dysfunction?

Clinical Question

For patients with erectile dysfunction (P), what is the effect of lifestyle modifications and drugs for cardiovascular risk factors (I) on severity of dysfunction (O)?

Best Available Evidence

Systematic review and meta-analysis of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Six RCTs (n = 740, mean age of 55 yr old) that examined the effect of lifestyle interventions and drugs targeting cardiovascular (CV) risk factors on erectile dysfunction (ED).
- Interventions lasting at least 6 wk included diet, exercise, maintaining an active lifestyle, and drugs to reduce CV risk factors (i.e., statins to lower cholesterol).
- Changes in lifestyle with improved lipid values were related to a decrease in the severity of ED.

Conclusion

- Sexual function was significantly improved in men with ED through lifestyle modification and drugs for CV risk factors.

Implications for Nursing Practice

- Emphasize the importance of a healthy diet and regular physical activity with men experiencing ED.
- Counsel men that declining sexual health should be brought to the attention of the health care provider for early identification of CV risk factors.

Reference for Evidence

Gupta BP, Murad MH, Clifton MM, et al: The effect of lifestyle modification and cardiovascular risk factor reduction on erectile dysfunction: a systematic review and meta-analysis, *Arch Intern Med* 171:1797, 2011.

P, Patient population of interest; *I*, intervention or area of interest; *O*, outcomes of interest (see p. 12).

increases with age. In fact, it is estimated that about 50% of all men between ages 40 and 70 have at least some degree of ED. ED is increasing in all sexually active males regardless of age. In younger men, the increase is attributed to substance abuse (e.g., recreational drugs, alcohol). Middle-aged men are affected by medical conditions (e.g., diabetes, hypertension) or treatment for these conditions (e.g., antihypertensive drugs) that may cause ED.

Etiology and Pathophysiology

ED can result from a large number of etiologic factors (Table 55-10). Common causes include diabetes, vascular disease, side effects from medications, result of surgery (such as prostatectomy), trauma, chronic illness, stress, difficulty in a relationship, or depression. Although studies suggest a link between cardiovascular disease (CVD) and ED, whether ED is a risk factor for CVD is controversial.[37] A reduction in blood flow is a major factor in ED and CVD, and both of these disorders share many of the same risk factors. Physical inactivity may also be linked to ED (see Evidence-Based Practice box).

Normal physiologic age-related changes are associated with changes in erectile function and may be an underlying cause of ED for some men. Table 51-3 lists age-related changes in sexual function. Explain these age-related changes (if necessary) to reassure an anxious older man regarding normal changes in his sexual abilities. (The male sexual response is discussed in Chapter 51.)

Clinical Manifestations and Complications

The typical symptom of ED is a patient's self-report of problems associated with sexual performance. He usually describes an inability to attain or maintain an erection. The symptoms may occur only occasionally, may be continual with a gradual onset, or may occur with a sudden onset. A gradual onset of symptoms is usually associated with physiologic factors, whereas a sudden or rapid onset of symptoms may be associated with psychologic issues.

A man's inability to perform sexually can cause great distress in his interpersonal relationships and may interfere with his concept of himself as a man. It can also affect the relationship between the man and his partner. Problems with ED can lead to a number of personal issues, including anger, anxiety, and depression.

Diagnostic Studies

The first step in diagnosis and management of ED begins with a thorough sexual, health, and psychosocial history. Self-administered assessment and treatment-related questionnaires

- Intraurethral medication pellet
- Intracavernosal self-injection
- Penile implants
- Sexual counseling

have been developed and may prove useful as primary screening tools. For example, the International Index of Erectile Function (IIEF) identifies a man's response to five key areas of male sexual function: erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction.[38]

Second, a physical examination should be performed that focuses on secondary sexual characteristics, including size and appearance of the penis and scrotum. A DRE should be done to assess prostate size, consistency, and presence of nodules. Assessment of blood pressure with palpation and auscultation of the femoral arteries and peripheral pulses should also be included.

Further examination or diagnostic testing is typically based on findings from the history and physical examination. A serum glucose and lipid profile is recommended to rule out diabetes mellitus. Hormonal levels for testosterone, prolactin, LH, and thyroid hormones may help identify endocrine-related problems. Blood chemistries (e.g., PSA level) and a complete blood count may help identify systemic diseases.

Other diagnostic tests may be done to diagnose ED. Nocturnal penile tumescence and rigidity testing is a noninvasive method that involves the continuous measurement of penile circumference and axial rigidity during sleep. Such measurements are used to differentiate between physiologic or psychogenic causes of ED and to evaluate the effectiveness of drug therapy. Vascular studies, including penile arteriography, penile blood flow study, and duplex Doppler ultrasound studies, are used to assess penile blood inflow and outflow. Such studies help assess vascular problems interfering with erection.

Collaborative Care

The goal of ED therapy is for the patient and his partner to achieve a satisfactory sexual relationship. The treatment for ED is based on the underlying cause.

A variety of treatment options are available (Table 55-11). Advise patients that none of the options will restore ejaculation or tactile sensations if they were absent before treatment. The results of these interventions are usually most satisfactory when both partners are involved in the decision-making process and have realistic expectations of the treatment.

It is important to determine if ED is reversible before treatment is started. For example, if ED appears to be a side effect of prescribed drugs, alternative treatments should be explored. With an established diagnosis of testicular failure (hypogonadism), androgen replacement therapy may sometimes be effective. For individuals who have ED that is psychologic in nature, counseling for the patient (and possibly his partner) is recommended. This counseling should be carried out by a qualified therapist.

Erectogenic Drugs. Sildenafil, tadalafil, vardenafil (Levitra, Staxyn), and avanafil (Stendra) are erectogenic drugs.[39] These drugs are phosphodiesterase type 5 (PDE5) inhibitors that cause smooth muscle relaxation and increased blood flow into the corpus cavernosum, thus promoting penile erection. They are taken orally about 30 to 60 minutes before sexual activity, but not more than once a day. These drugs have been found to be generally safe and effective for the treatment of most types of ED.

Side effects include headaches, dyspepsia, flushing, and nasal congestion. Additional rare side effects are blurred or blue-green visual disturbances, sudden hearing loss, and an erection lasting more than 4 hours that will not go away (priapism). Instruct the patient to seek immediate medical attention if any of these rare reactions occur. Because these drugs may potentiate the hypotensive effect of nitrates, they are contraindicated for individuals taking nitrates (e.g., nitroglycerin).

DRUG ALERT: Sildenafil (Viagra)
- Should not be used with nitrates (nitroglycerin) in any form.
- Can potentiate hypotensive effects of nitrates.

Vacuum Constriction Devices. Vacuum constriction devices (VCDs) are suction devices that can be applied to the flaccid penis to produce an erection by pulling blood up into the corporeal bodies. A penile ring or constrictive band is placed around the base of the penis to retain venous blood, thereby preventing the erection from subsiding. (A VCD is shown in eFig. 55-1, available on the website for this chapter.)

Intraurethral Devices. Intraurethral devices include the use of vasoactive drugs administered as a topical gel, an injection into the penis (intracavernosal self-injection), or a medication pellet inserted into the urethra (intraurethral) using a medicated urethral system for erection (MUSE) device. These

vasoactive drugs enhance blood flow into the penile arteries. Current vasoactive drugs include papaverine (topical gel or injection), alprostadil (Caverject) (topical gel, transurethral pellet, or injection), and phentolamine (Vasomax). (These devices are shown in eFig. 55-2, available on the website for this chapter.)

Penile Implants. Surgical implants of semirigid or inflatable penile prostheses are shown in eFig. 55-3, available on the website for this chapter. These surgical procedures are highly invasive and associated with potential complications. Thus they are usually indicated for men with severe ED for which other interventions are ineffective.

The devices are implanted into the corporeal bodies to provide an erection firm enough for penetration. The inflatable implant consists of cylinders in the penis, a small pump in the scrotum, and a reservoir in the lower abdomen. The main problems associated with penile prostheses are mechanical failure, infection, and erosions.

Sexual Counseling. Sexual counseling is often recommended before and after treatment. The ability to please both partners enhances satisfaction levels. Counseling should address psychologic or interpersonal factors that may enhance sexual expression, as well as other factors that are of concern. Counseling can be effective for the individual patient, but it is typically best to include his partner, particularly if he is involved in a long-term relationship.[40] Counseling should begin before the start of medical treatment for ED.

NURSING MANAGEMENT ERECTILE DYSFUNCTION

The man experiencing ED requires a great deal of emotional support for both himself and his partner. Men often do not feel comfortable discussing their problems with others because of society's expectations of a man's sexual abilities. Reassure the patient that confidentiality will be maintained. The majority of men delay seeking medical assistance. They are often highly motivated and expect immediate solutions to their problems. The health care team should provide a support system and accurate information as soon as possible.

Conducting routine health assessments on men seeking any form of medical treatment places you in a unique position. It provides an opportunity to ask the patient questions pertaining to general health, as well as sexual health and function. Given the opportunity, men will be less hesitant to answer these questions when they know that someone cares and can provide them with answers.

ANDROPAUSE

Andropause is a gradual decline in androgen secretion that occurs in most men as they age. The primary male androgen that is reduced is testosterone (Fig. 55-13). Andropause, also called late onset hypogonadism and male menopause, can begin as early as age 40. Factors that determine the rate of decline are not clearly known. Signs and symptoms associated with a lowered level of testosterone include loss of libido, fatigue, ED, depression and mood swings, and sleep disturbances. Symptoms are often attributed to normal aging and frequently are not reported by the patient. The long-term effects, including a loss of muscle mass and strength, may contribute to an increased risk of falls and fractures.[41]

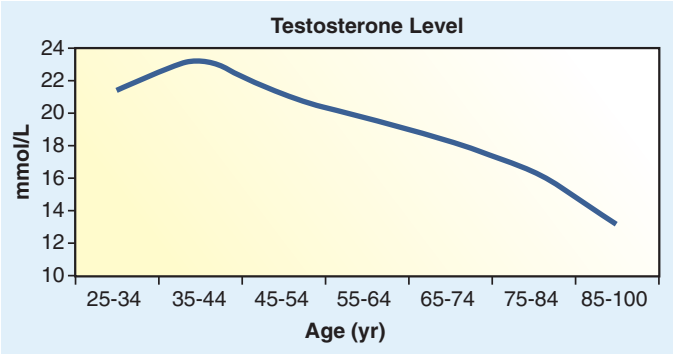

FIG. 55-13 Changes in testosterone plasma level in men as they age.

A diagnosis of andropause is made after a complete physical examination and serum total testosterone levels have been obtained. Normal testosterone levels can range from 280 to 1000 ng/dL. Replacement therapy is generally considered once levels drop below 200 ng/dL.[42] Therapy may be started earlier depending on severity of symptoms. Testosterone replacement therapy (TRT) should not be started until the patient, in consultation with his health care provider, considers the risks and benefits of therapy. Symptoms may improve with TRT, but potential risks include lowered levels of high-density lipoprotein (HDL) cholesterol, increased hematocrit, and worsening sleep apnea. The effect of testosterone on prostatic tissue makes this therapy contraindicated in patients with BPH or prostate cancer. Before treatment is initiated, a DRE and PSA test should be performed. Once TRT begins, patients should be closely monitored by their health care provider.

Replacement therapy is available in different forms. Oral TRT (e.g., methyltestosterone, fluoxymesterone) is not recommended because it is less effective and liver damage can occur with high doses.[43] Intramuscular injections such as cypionate (Depo-Testosterone) and enanthate (Delatestryl) are available in varying doses. These drugs create a cyclic rise and fall in serum testosterone levels with the highest levels 2 or 3 days after the injection. Then the testosterone levels slowly decrease until the next injection. Mood swings can occur with these fluctuations.

Transdermal preparations, including patches and gels (e.g., Androderm, Testim), are more convenient. They are generally applied to the skin daily at various sites, including the back, the arm, and the abdomen. Skin irritation is the most common side effect. Triamcinolone creams (diacetate [Amcort], acetonide [Kenalog]) rubbed into the skin before application of the patch may decrease and prevent irritation. Testosterone may also be given as a buccal tablet (Striant) or as an underarm application (Axiron).

Women of childbearing age and children should avoid direct contact with these products, since they may cause early signs of puberty in young children and changes (virilization) in the external genitalia of a female fetus. Emphasize to the patient the importance of hand washing with soap and water after applying testosterone preparations to the skin. Covering the area with clothing until the preparation has dried is also recommended.

INFERTILITY

Infertility in a couple is defined as the inability to conceive after 1 year of frequent unprotected intercourse. Infertility is a disor-

der of a couple, not of one individual. For this reason, both partners must be involved in determining the cause of infertility. In about 33% of cases, infertility is primarily caused by factors involving the man. Male infertility can be caused by disorders of the hypothalamic-pituitary system, disorders of the testes, and abnormalities of the ejaculatory system.

The physical causes are generally divided into three categories: pretesticular, testicular, and posttesticular. The *pretesticular* or endocrine causes occur only in about 3% of the cases and can generally be treated with medication or surgery. *Testicular problems* make up 50% of the cases. The most common cause of male infertility is a varicocele. Other factors that influence the testes include infection (e.g., mumps virus, STIs, bacterial infections), congenital anomalies, medications, radiation, substance abuse (alcohol, nicotine, drugs), and environmental hazards. *Posttesticular* causes account for approximately 5% to 7% of the cases, with obstruction, infection, and the result of a surgical procedure being the primary causes. The remaining 40% are classified as *idiopathic,* or of unknown causes.

A careful health history and examination may reveal the cause of a patient's infertility. Thus the history is a starting point for determining cause and treatment. The history should include age; occupation; past injury, surgery, or infections to the genital tract; lifestyle issues such as hot tubs, weight training, or wearing tight undergarments; sexual practices; frequency of intercourse; and emotional factors such as stress levels and the desire for children. Document the use of drugs, such as chemotherapeutic agents, anabolic steroids (testosterone), sulfasalazine (Azulfidine), cimetidine (Tagamet), and recreational drugs, since these drugs can reduce the sperm count. A physical examination can disclose a varicocele, Peyronie's disease, or other physical abnormalities.

The first test in an infertility study is a semen analysis. The test determines the sperm concentration, motility, and morphology. Additional tests that may be helpful in determining the etiology include plasma testosterone and serum LH and FSH measurements. A test for sperm penetration abilities may also be done. The specific cause of infertility is often not determined.

Be concerned and tactful in dealing with the male patient undergoing infertility studies. Many men equate fertility and masculinity.

Treatment options for the man include medications, conservative lifestyle changes (e.g., avoidance of scrotal heat, substance abuse, and high stress), in vitro fertilization techniques, and corrective surgery. Infertility can seriously strain a relationship, and the couple may require counseling and discussion of alternatives if conception is not achieved. (Female infertility is discussed in Chapter 54.)

CASE STUDY

Benign Prostatic Hyperplasia With Acute Urinary Retention

iStockphoto/Thinkstock

Patient Profile

B.G., a 60-yr-old married African American man, comes to the primary health outpatient clinic because of an inability to void for the past 13 hr and pain in the lower abdomen.

Subjective Data

- Complains of the urge to void
- Is restless, anxious, and agitated

Objective Data

- Has prostate enlargement on digital rectal examination
- Has hematuria, bacteria, and WBCs in urine
- Has a tender and palpable bladder above the umbilicus
- PSA test: 8 ng/mL

Collaborative Care

- Indwelling catheter inserted by a urology resident
- Admitted to the hospital

Discussion Questions

1. What risk factors for prostate problems are present in B.G.?
2. Explain the etiology of the objective symptoms B.G. exhibited.
3. Offer possible reasons for B.G.'s elevated PSA level.
4. Discuss the drug and surgical options available to B.G.
5. B.G. asks you about the effect of the various surgical options on his ability to have sex. How would you respond?
6. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
7. ***Priority Decision:*** What is the priority nursing intervention for B.G.?
8. On further assessment, you note that B.G. has a nursing diagnosis of decisional conflict. How would you help him resolve this conflict related to treatment options?
9. ***Evidence-Based Practice:*** What information would you offer to B.G. when he asks if he should start taking saw palmetto to prevent future UTIs?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg.*

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. An older male patient is experiencing difficulty in initiating voiding and a feeling of incomplete bladder emptying. These symptoms of BPH are primarily caused by
   - **a.** obstruction of the urethra.
   - **b.** untreated chronic prostatitis.
   - **c.** decreased bladder compliance.
   - **d.** excessive secretion of testosterone.
2. Postoperatively, a patient who has had a laser prostatectomy has continuous bladder irrigation with a three-way urinary catheter with a 30-mL balloon. When he complains of bladder spasms with the catheter in place, the nurse should
   - **a.** deflate the catheter balloon to 10 mL to decrease bulk in the bladder.
   - **b.** deflate the catheter balloon and then reinflate to ensure that it is patent.
   - **c.** encourage the patient to try to have a bowel movement to relieve colon pressure.
   - **d.** explain that this feeling is normal and that he should not try to urinate around the catheter.

3. Which factors would place a patient at higher risk for prostate cancer *(select all that apply)?*
   a. Older than 65 years
   b. Asian or Native American
   c. Long-term use of an indwelling urethral catheter
   d. Father diagnosed and treated for early stage prostate cancer
   e. Previous history of undescended testicle and testicular cancer
4. A patient scheduled for a prostatectomy for prostate cancer expresses the fear that he will have erectile dysfunction. In responding to this patient, the nurse should keep in mind that
   a. erectile dysfunction can occur even with a nerve-sparing procedure.
   b. retrograde ejaculation affects sexual function more frequently than erectile dysfunction.
   c. the most common complication of this surgery is postoperative bowel incontinence.
   d. preoperative sexual function is the most important factor in determining postoperative erectile dysfunction.
5. The nurse explains to the patient with chronic bacterial prostatitis who is undergoing antibiotic therapy that *(select all that apply)*
   a. all patients require hospitalization.
   b. pain will lessen once treatment has ended.
   c. course of treatment is generally 2 to 4 weeks.
   d. long-term therapy may be indicated in immunocompromised patient.
   e. if the condition is unresolved and untreated, he is at risk for prostate cancer.
6. In assessing a patient for testicular cancer, the nurse understands that the manifestations of this disease often include
   a. acute back spasms and testicular pain.
   b. rapid onset of scrotal swelling and fever.
   c. fertility problems and bilateral scrotal tenderness.
   d. painless mass and heaviness sensation in the scrotal area.
7. The nurse should explain to the patient who has had a vasectomy that
   a. the procedure blocks the production of sperm.
   b. erectile dysfunction is temporary and will return with sexual activity.
   c. the ejaculate will be about half the volume it was before the procedure.
   d. an alternative form of contraception will be necessary for 6 to 8 weeks.
8. To decrease the patient's discomfort over care related to his reproductive organs, the nurse should
   a. relate his sexual concerns to his sexual partner.
   b. arrange to have male nurses care for the patient.
   c. maintain a nonjudgmental attitude toward his sexual practices.
   d. use technical terminology when discussing reproductive function.

1. a, 2. d, 3. a, d, 4. a, 5. b, d, 6. d, 7. d, 8. c

CASE STUDY

Managing Multiple Patients

Introduction

You are working on the medical-surgical unit and have been assigned to care for the following six patients. You have one LPN and one UAP on your team to help you.

Patients

iStockphoto/Thinkstock

L.M. is a 35-yr-old Hispanic woman who went to the clinic 3 days ago complaining of "just not feeling well." She was admitted to the hospital for treatment of hypertension caused by newly diagnosed Cushing syndrome. She has been very depressed and crying because of her physical appearance. Her most recent blood pressure was 150/84 mm Hg.

iStockphoto/Thinkstock

N.B. is a 34-yr-old Native American man admitted to the ICU 2 days ago with a diagnosis of diabetic ketoacidosis. He was transferred to the nursing unit yesterday evening. His fasting blood glucose this morning is 296 mg/dL.

iStockphoto/Thinkstock

A.K. is a 68-yr-old Asian American woman recently diagnosed with adenocarcinoma of her right breast. She had a lumpectomy and axillary node dissection yesterday. She has a Jackson-Pratt drain in her right chest. Her last pain medication was administered 1 hour ago, at which time she rated her pain as a 7 on a scale of 0-10.

iStockphoto/Thinkstock

B.G. is a 60-yr-old African American man who was admitted to the hospital because of an inability to void for 13 hours and pain in the lower abdomen. He has a urinary tract infection and prostatic enlargement. An indwelling catheter was inserted by a urology resident. B.G. is scheduled to undergo a transurethral resection of his prostate (TURP) this morning.

Jupiterimages/Photos.com/Thinkstock

R.D. is a 47-yr-old white woman who was diagnosed with Graves' disease 2 months ago. She was treated with antithyroid medication for 2 months and underwent a subtotal thyroidectomy yesterday. She has been complaining of slight numbness and tingling in her fingers.

Jupiterimages/Photos.com/Thinkstock

N.B. is a 65-yr-old white woman who underwent a vaginal hysterectomy and anterior/posterior repair 1 day ago. She has vaginal packing and a urinary catheter in place. Her vital signs are stable and she is not complaining of pain.

Management Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Second? Provide a rationale.
2. ***Delegation Decision:*** Which tasks could you delegate to UAP *(select all that apply)?*
   a. Assist N.B. to sit out of bed in a chair.
   b. Teach B.G. what to expect postoperatively.
   c. Take R.D.'s vital signs and report the results to you.
   d. Assess A.K.'s mastectomy incision for manifestations of infection.
   e. Listen to L.M. talk about her feelings while helping her with AM care.
3. ***Priority and Delegation Decision:*** As you are assessing R.D., the LPN informs you that A.K.'s chest dressing is totally saturated with bloody drainage. Which initial action would be most appropriate?
   a. Ask the LPN to call the lab for a stat Hgb and Hct on A.K.
   b. Have the LPN reinforce the dressing with sterile 4 × 4 gauze pads.
   c. Have the LPN stay with R.D. while you assess the patency of A.K.'s Jackson-Pratt drain.
   d. Ask the LPN to stay with A.K. and the UAP to monitor R.D. while you call A.K.'s surgeon.

Case Study Progression

A.K.'s Jackson-Pratt drain was not functioning properly. You get it working and change the chest dressing. The incision is well approximated without signs of infection. When you leave the room, the Jackson-Pratt has a small amount of serosanguineous drainage in it. As you enter R.D.'s room you notice that the patient is having a carpopedal spasm on the same arm that the LPN is taking her blood pressure on. You recognize this as a manifestation of hypocalcemia and notify the health care provider.

4. Which interventions would you expect the health care provider to order for R.D. *(select all that apply)?*
   a. IV calcium gluconate
   b. IV sodium bicarbonate
   c. Have patient hold breath
   d. Rebreathing into paper bag
   e. Parathyroid hormone replacement therapy
5. Which intervention would be most appropriate in caring for L.M.?
   a. Assess her for signs and symptoms of hypoglycemia.
   b. Teach her the need for a high-carbohydrate, low-protein diet.
   c. Administer IV methylprednisolone (Solu-Medrol) over 2 min.
   d. Reassure her that her physical appearance will improve with treatment.
6. B.G. asks you what to expect when he returns from surgery. You explain that he will have a(n)
   a. dressing in his groin as well as a urinary catheter.
   b. 3-way urinary catheter connected to an irrigation system.
   c. patient-controlled analgesia (PCA) pump for pain control.
   d. abdominal and a perineal drain that will be recharged q4h.
7. ***Priority and Management Decision:*** The LPN is assigned to administer medications to N.B., including his sliding scale Novolog insulin with breakfast. The UAP, who is also a senior nursing student, tells you that the LPN administered N.B.'s insulin at least 30 min after the patient ate his breakfast. What is your best initial action?
   a. Report the incident to the charge nurse for follow-up.
   b. Talk to the LPN about the importance of timely medication administration.
   c. Ask the LPN what time the insulin was given and when the patient ate breakfast.
   d. Ask the UAP to first discuss the concern with the LPN so as to follow proper channels of communication.

LEARNING OUTCOMES

1. Differentiate between the functions of neurons and glial cells.
2. Explain the anatomic location and functions of the cerebrum, brainstem, cerebellum, spinal cord, peripheral nerves, and cerebrospinal fluid.
3. Identify the major arteries supplying the brain.
4. Describe the functions of the 12 cranial nerves.
5. Compare the functions of the two divisions of the autonomic nervous system.
6. Link the age-related changes in the neurologic system to the differences in assessment findings.
7. Select significant subjective and objective data related to the nervous system that should be obtained from a patient.
8. Select appropriate techniques to use in the physical assessment of the nervous system.
9. Differentiate normal from abnormal findings of a physical assessment of the nervous system.
10. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the nervous system.

STRUCTURES AND FUNCTIONS OF NERVOUS SYSTEM

The human nervous system is responsible for the control and integration of the body's many activities. The nervous system can be divided into the central nervous system and the peripheral nervous system. The **central nervous system (CNS)** consists of the brain, spinal cord, and cranial nerves I and II. The **peripheral nervous system (PNS)** consists of cranial nerves III to XII, spinal nerves, and the peripheral components of the autonomic nervous system (ANS).

Cells of Nervous System

The nervous system is made up of two types of cells: neurons and glial cells.

Neurons. **Neurons** are the primary functional unit of the nervous system, Although neurons come in many shapes and sizes, they share three characteristics: (1) *excitability,* or the ability to generate a nerve impulse; (2) *conductivity,* or the ability to transmit an impulse; and (3) *influence,* or the ability to influence other neurons, muscle cells, or glandular cells by transmitting nerve impulses to them.

A typical *neuron* consists of a cell body, multiple dendrites, and an axon (Fig. 56-1). The cell body containing the nucleus and cytoplasm is the metabolic center of the neuron. *Dendrites* are short processes extending from the cell body that receive impulses from the axons of other neurons and conduct impulses toward the cell body. The *axon* projects varying distances from the cell body, ranging from several micrometers to more than a meter. The axon carries nerve impulses to other neurons or to end organs. The end organs are smooth and striated muscles and glands.

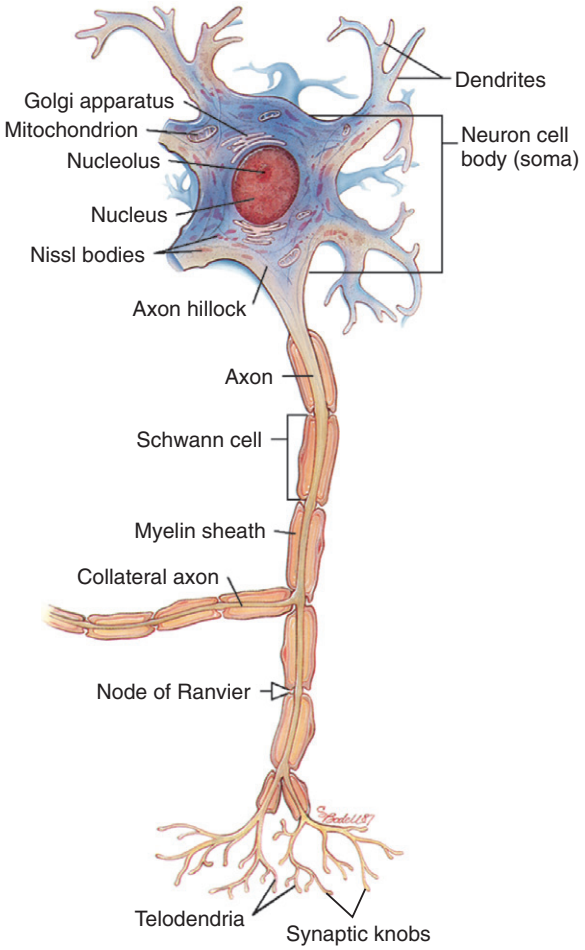

FIG. 56-1 Structural features of neurons: dendrites, cell body, and axons.

Many axons in the CNS and PNS are covered by a *myelin sheath,* a white, lipid substance that acts as an insulator for the conduction of impulses. Axons may be myelinated or unmyelinated. Generally, the smaller fibers are unmyelinated.

Neurons have long been thought to be nonmitotic. That is, after being damaged neurons could not be replaced. The discovery of neuronal stem cells now demonstrates that neurogenesis occurs in adult brains after cerebral injury.[1]

Glial Cells. **Glial cells** (glia or neuroglia) provide support, nourishment, and protection to neurons. Glial cells constitute almost half of the brain and spinal cord mass and are 5 to 10 times more numerous than neurons.

Glial cells are divided into microglia and macroglia. *Microglia,* specialized macrophages capable of phagocytosis, protect the neurons. These cells are mobile within the brain and multiply when the brain is damaged.

Different types of *macroglial cells* include the astrocytes (most abundant), oligodendrocytes, and ependymal cells.[2] *Astrocytes* are found primarily in gray matter and provide structural support to neurons. Their delicate processes form the blood-brain barrier with the endothelium of the blood vessels. They also play a role in synaptic transmission (conduction of impulses between neurons). When the brain is injured, astrocytes act as phagocytes for neuronal debris. They help restore the neurochemical milieu and provide support for repair. Proliferation of astrocytes contributes to the formation of scar tissue *(gliosis)* in the CNS.

Oligodendrocytes are specialized cells that produce the myelin sheath of nerve fibers in the CNS and are primarily found in the white matter of the CNS. (*Schwann cells* myelinate the nerve fibers in the periphery.) *Ependymal cells* line the brain ventricles and aid in the secretion of cerebrospinal fluid (CSF).

Neuroglia are mitotic and can replicate. In general, when neurons are destroyed, the tissue is replaced by the proliferation of neuroglial cells. Most primary CNS tumors involve glial cells. Primary malignancies involving neurons are rare.

Nerve Regeneration

If the axon of the nerve cell is damaged, the cell attempts to repair itself. Damaged nerve cells attempt to grow back to their original destinations by sprouting many branches from the damaged ends of their axons. Axons in the CNS are generally less successful than peripheral axons in regeneration.[3]

Injured nerve fibers in the PNS can regenerate by growing within the protective myelin sheath of the supporting Schwann cells if the cell body is intact. The final result of nerve regeneration depends on the number of axon sprouts that join with the appropriate Schwann cell columns and reinnervate appropriate end organs.

Nerve Impulse

The purpose of a neuron is to initiate, receive, and process messages about events both within and outside the body. The initiation of a neuronal message *(nerve impulse)* involves the generation of an action potential. Once an action potential is initiated, a series of action potentials travels along the axon. When the impulse reaches the end of the nerve fiber, it is trans-

mitted across the junction between nerve cells *(synapse)* by a chemical interaction involving neurotransmitters. This chemical interaction generates another set of action potentials in the next neuron. These events are repeated until the nerve impulse reaches its destination.

Because of its insulating capacity, myelination of nerve axons facilitates the conduction of an action potential. Many peripheral nerve axons have *nodes of Ranvier* (gaps in the myelin sheath) that allow an action potential to travel much faster by jumping from node to node without traversing the insulated membrane segment. This is called *saltatory* (hopping) conduction. In an unmyelinated fiber, the wave of depolarization travels the entire length of the axon, with each portion of the membrane becoming depolarized in turn.

Synapse. A **synapse** is the structural and functional junction between two neurons. It is the point at which the nerve impulse is transmitted from one neuron to another. The nerve impulse can also be transmitted from neurons to glands or muscles. The essential structures of synaptic transmission are a presynaptic terminal, a synaptic cleft, and a receptor site on the postsynaptic cell.

Neurotransmitters. **Neurotransmitters** are chemicals that affect the transmission of impulses across the synaptic cleft. (Examples of neurotransmitters are presented in Table 56-1.) Excitatory neurotransmitters activate postsynaptic receptors that increase the likelihood that an action potential will be generated. Inhibitory neurotransmitters activate postsynaptic receptors that inhibit the likelihood that an action potential will be generated.

Each of the hundreds to thousands of synaptic connections of a single neuron has an influence on that neuron. In general, the net effect (excitatory or inhibitory) depends on the number of presynaptic neurons that are releasing neurotransmitters on the postsynaptic cell. A presynaptic cell that releases an excitatory neurotransmitter does not always cause the postsynaptic cell to depolarize enough to generate an action potential.

Neurotransmitters can be affected by drugs and toxins, which can modify their function or block their attachment to receptor sites on the postsynaptic membrane. When many presynaptic cells release excitatory neurotransmitters on a single neuron, the sum of their input is enough to generate an action potential. Neurotransmitters continue to combine with the receptor sites at the postsynaptic membrane until they are inactivated by enzymes, are taken up by the presynaptic endings, or diffuse away from the synaptic region. With the use of cerebral microdialysis (minimally invasive sampling technique), neurotransmitter levels can now be measured in the cerebral cortex.[4]

TABLE 56-1 NEUROTRANSMITTERS*

Neurotransmitter	Clinical Relevance
Acetylcholine	A decrease in acetylcholine-secreting neurons is seen in Alzheimer's disease. Myasthenia gravis results from a reduction in acetylcholine receptors.
Amines	
Epinephrine (adrenalin)	Is both a hormone and neurotransmitter. Produced in neurons of CNS and neurosecretory cells of adrenal medulla. Critical component of the fight-or-flight response of SNS.
Norepinephrine	Is both a hormone and neurotransmitter. Has important role as neurotransmitter released from SNS affecting the heart. Along with epinephrine, has important role in fight-or-flight response, increasing heart rate, triggering the release of glucose from energy stores, and increasing blood flow to skeletal muscle.
Serotonin	Primarily found in GI tract, platelets, and CNS. Involved in moods, emotions, and sleep.
Dopamine	Produced in several areas of brain. Involved in emotions and moods and regulating motor control. Parkinson's disease results from destruction of dopamine-secreting neurons.
Amino Acids	
γ-Aminobutyric acid (GABA)	Chief inhibitory neurotransmitter in CNS. Has a role in regulating neuronal excitability throughout the nervous system. Drugs that increase GABA function have been used to treat seizure disorders.
Glutamate and aspartate	Plays key role in learning and memory. Sustained release of glutamate and prolonged excitation is toxic to nerve cells. Glutamate is a destructive factor in amyotrophic lateral sclerosis.
Neuropeptides	
Endorphins and enkephalins	Endogenous opioids that function as neurotransmitters. Produced in pituitary gland and hypothalamus. Produce analgesia and a feeling of well-being. The opioids morphine and heroin bind to endorphin and enkephalin receptors and produce the same effect as the endogenous opioids.
Substance P	Neurotransmitter in pain transmission pathways. Morphine blocks its release.

*These are examples only. Most of the neurotransmitters are also found in other locations and may have additional functions.
CNS, Central nervous system; *SNS,* sympathetic nervous system.

Central Nervous System

The components of the CNS include the cerebrum (cerebral hemispheres), brainstem, cerebellum, and spinal cord.

Spinal Cord. The spinal cord is continuous with the brainstem and exits from the cranial cavity through the foramen magnum. A cross section of the spinal cord reveals gray matter that is centrally located in an H shape and is surrounded by white matter. The gray matter contains the cell bodies of voluntary motor neurons, preganglionic autonomic motor neurons, and association neurons (interneurons). The white matter contains the axons of the ascending sensory and the descending (suprasegmental) motor fibers. The myelin surrounding these fibers gives them their white appearance. The spinal pathways or tracts are named for the point of origin and the point of destination (e.g., spinocerebellar tract [ascending], corticospinal tract [descending]).

Ascending Tracts. In general, the ascending tracts carry specific sensory information to higher levels of the CNS. This information comes from special sensory receptors in the skin, muscles and joints, viscera, and blood vessels and enters the spinal cord by way of the dorsal roots of the spinal nerves. The fasciculus gracilis and the fasciculus cuneatus (commonly called the dorsal or posterior columns) carry information and transmit impulses concerned with touch, deep pressure, vibration, position sense, and kinesthesia (appreciation of movement,

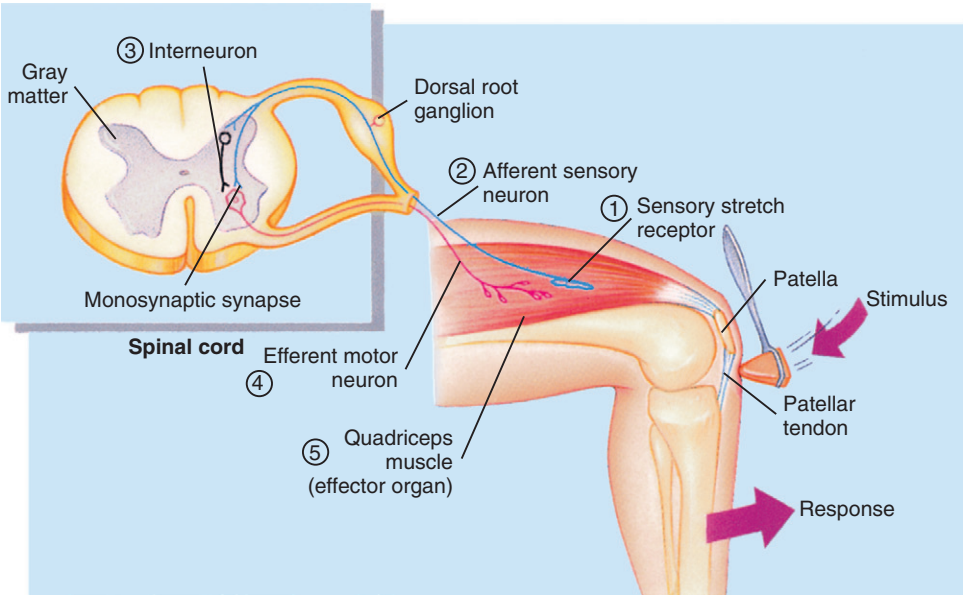

FIG. 56-2 Basic diagram of the patellar "knee jerk" reflex arc, including the *(1)* sensory stretch receptor, *(2)* afferent sensory neuron, *(3)* interneuron, *(4)* efferent motor neuron, and *(5)* quadriceps muscle (effector organ).

weight, and body parts). The *spinocerebellar tracts* carry information about muscle tension and body position to the cerebellum for coordination of movement. The *spinothalamic tracts* carry pain and temperature sensations. Therefore the ascending tracts are organized by sensory modality, as well as by anatomy.

Although the functions of these pathways are generally accepted, other ascending tracts may also carry sensory modalities. The symptoms of various neurologic diseases suggest that additional pathways for touch, position sense, and vibration exist.

Descending Tracts. Descending tracts carry impulses that are responsible for muscle movement. Among the most important descending tracts are the corticobulbar and corticospinal tracts, collectively termed the *pyramidal tract.* These tracts carry volitional (voluntary) impulses from the cerebral cortex to the cranial and peripheral nerves. Another group of descending motor tracts carries impulses from the extrapyramidal system (all motor systems except the pyramidal) concerned with voluntary movement. It includes pathways originating in the brainstem, basal ganglia, and cerebellum. The motor output exits the spinal cord by way of the ventral roots of the spinal nerves.

Lower and Upper Motor Neurons. **Lower motor neurons (LMNs)** are the final common pathway through which descending motor tracts influence skeletal muscle. The cell bodies of LMNs, which send axons to innervate the skeletal muscles of the arms, trunk, and legs, are located in the anterior horn of the corresponding segments of the spinal cord (e.g., cervical segments contain LMNs for the arms). LMNs for skeletal muscles of the eyes, face, mouth, and throat are located in the corresponding segments of the brainstem. These cell bodies and their axons make up the somatic motor components of the cranial nerves. LMN lesions generally cause weakness or paralysis, denervation atrophy, hyporeflexia or areflexia, and decreased muscle tone (flaccidity).

Upper motor neurons (UMNs) originate in the cerebral cortex and project downward. The corticobulbar tract ends in the brainstem, and the corticospinal tract descends into the spinal cord. These neurons influence skeletal muscle movement.

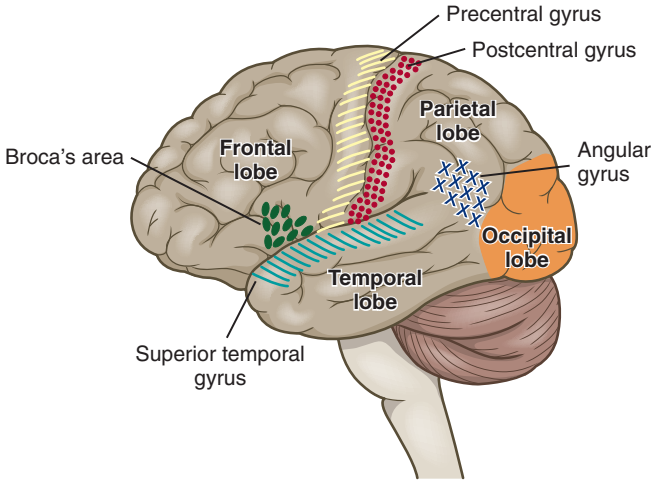

FIG. 56-3 Left hemisphere of cerebrum, lateral surface, showing major lobes and areas of the brain.

UMN lesions generally cause weakness or paralysis, disuse atrophy, hyperreflexia, and increased muscle tone (spasticity).

Reflex Arc. A **reflex** is an involuntary response to stimuli. In the spinal cord, reflex arcs play an important role in maintaining muscle tone, which is essential for body posture. The components of a monosynaptic reflex arc (Fig. 56-2) are a receptor organ, an afferent neuron, an effector neuron, and an effector organ (e.g., skeletal muscle). The afferent neuron synapses with the efferent neuron in the gray matter of the spinal cord. More complex reflex arcs have other neurons (interneurons) in addition to the afferent neuron influencing the effector neuron.

Brain. The term *brain* usually refers to the three major intracranial components: cerebrum, brainstem, and cerebellum.

Cerebrum. The *cerebrum* is composed of the right and left cerebral hemispheres and divided into four lobes: frontal, temporal, parietal, and occipital (Fig. 56-3). The functions of the cerebrum are multiple and complex (Table 56-2). The *frontal lobe* controls higher cognitive function, memory retention, vol-

TABLE 56-2 FUNCTION OF CEREBRUM

Part	Location	Function
Cortical Areas		
Motor		
Primary	Precentral gyrus	Motor control and movement on opposite side of body
Supplemental	Anterior to precentral gyrus	Facilitates proximal muscle activity, including activity for stance and gait, and spontaneous movement and coordination
Sensory		
Somatic	Postcentral gyrus	Sensory response from opposite side of body
Visual	Occipital lobe	Registers visual images
Auditory	Superior temporal gyrus	Registers auditory input
Association areas	Parietal lobe	Integrates somatic and sensory input
	Posterior temporal lobe	Integrates visual and auditory input for language comprehension
	Anterior temporal lobe	Integrates past experiences
	Anterior frontal lobe	Controls higher-order processes (e.g., judgment, reasoning)
Language		
Comprehension	Wernicke's area	Integrates auditory language (understanding of spoken words)
Expression	Broca's area	Regulates verbal expression
Basal Ganglia	Near lateral ventricles of both cerebral hemispheres	Control and facilitate learned and automatic movements
Thalamus	Below basal ganglia	Relays sensory and motor input to and from the cerebrum
Hypothalamus	Below thalamus	Regulates endocrine and autonomic functions
Limbic System	Lateral to hypothalamus	Influences emotional behavior and basic drives such as feeding and sexual behavior

untary eye movements, voluntary motor movement, and speech in Broca's area. The *temporal lobe* integrates somatic, visual, and auditory data and contains Wernicke's speech area. The *parietal lobe* interprets spatial information and contains the sensory cortex. Processing of sight takes place in the *occipital lobe*.

The division of the cerebrum into lobes is useful to delineate portions of the neocortex (gray matter), which makes up the outer layer of the cerebral hemispheres. Neurons in specific parts of the neocortex are essential for various highly complex and sophisticated aspects of mental function, such as language, memory, and appreciation of visual-spatial relationships.

The basal ganglia, thalamus, hypothalamus, and limbic system are also located in the cerebrum. The *basal ganglia* are a group of structures located centrally in the cerebrum and

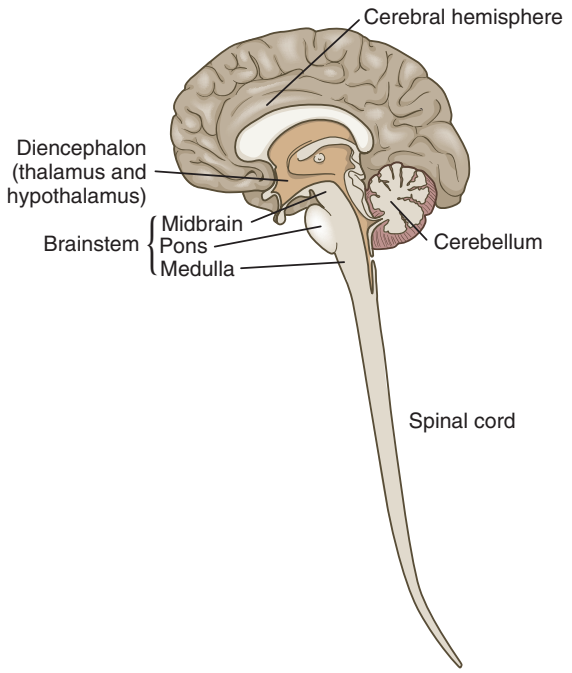

FIG. 56-4 Major divisions of the central nervous system (CNS).

midbrain. Most of them are on both sides of the thalamus. The function of the basal ganglia includes the initiation, execution, and completion of voluntary movements, learning, emotional response, and automatic movements associated with skeletal muscle activity (e.g., swinging the arms while walking, swallowing saliva, and blinking).

The *thalamus* (part of the diencephalon) lies directly above the brainstem (Fig. 56-4) and is the major relay center for afferent inputs to the cerebral cortex. The *hypothalamus* is located just inferior to the thalamus and slightly in front of the midbrain. It regulates the ANS and the endocrine system. The *limbic system* is located near the inner surfaces of the cerebral hemispheres and is concerned with emotion, aggression, feeding behavior, and sexual response.

Brainstem. The *brainstem* includes the midbrain, pons, and medulla (see Fig. 56-4). Ascending and descending fibers to and from the cerebrum and cerebellum pass through the brainstem. The nuclei of cranial nerves III through XII are in the brainstem. The vital centers concerned with respiratory, vasomotor, and cardiac function are located in the medulla.

Also located in the brainstem is the *reticular formation,* a diffusely arranged group of neurons and their axons that extends from the medulla to the thalamus and hypothalamus. The functions of the reticular formation include relaying sensory information, influencing excitatory and inhibitory control of spinal motor neurons, and controlling vasomotor and respiratory activity. The *reticular activating system* (RAS) is a complex system that requires communication among the brainstem, reticular formation, and cerebral cortex. The RAS is responsible for regulating arousal and sleep-wake transitions. The brainstem also contains the centers for sneezing, coughing, hiccupping, vomiting, sucking, and swallowing.

Cerebellum. The *cerebellum* is located in the posterior part of the cranial fossa inferior to the occipital lobe. The cerebellum coordinates voluntary movement and maintains trunk stability and equilibrium. The cerebellum receives information from the

cerebral cortex, muscles, joints, and inner ear. It influences motor activity through axonal connections to the motor cortex, the brainstem nuclei, and their descending pathways.

Ventricles and Cerebrospinal Fluid. The ventricles are four interconnected fluid-filled cavities. The lower portion of the fourth ventricle becomes the central canal in the lower part of the brainstem. The spinal canal extends centrally through the full length of the spinal cord.

Cerebrospinal fluid (CSF) circulates within the subarachnoid space that surrounds the brain, brainstem, and spinal cord. This fluid provides cushioning for the brain and the spinal cord, allows fluid shifts from the cranial cavity to the spinal cavity, and carries nutrients. The formation of CSF in the choroid plexus in the ventricles involves both passive diffusion and active transport of substances. CSF resembles an ultrafiltrate of blood. Although CSF is produced at an average rate of about 500 mL/day, many factors influence CSF production and absorption. The ventricles and central canal are normally filled with an average of 135 mL of CSF. Changes in the rate of production or absorption will result in a change in the volume of CSF that remains in the ventricles and central canal. Excessive buildup of CSF results in a condition known as *hydrocephalus*.

The CSF circulates throughout the ventricles and seeps into the subarachnoid space surrounding the brain and spinal cord. It is absorbed primarily through the *arachnoid villi* (tiny projections into the subarachnoid space), into the intradural venous sinuses, and eventually into the venous system.

The analysis of CSF composition provides useful diagnostic information related to certain nervous system diseases. CSF pressure is often measured in patients with actual or suspected intracranial injury. Increased intracranial pressure, indicated by increased CSF pressure, can force downward (central) herniation of the brain and brainstem. The signs marking this event are part of the herniation syndrome (see Chapter 57).

Peripheral Nervous System

The PNS includes all the neuronal structures that lie outside the CNS. It consists of the spinal and cranial nerves, their associated ganglia (groupings of cell bodies), and portions of the ANS.

Spinal Nerves. The spinal cord can be seen as a series of spinal segments, one on top of another. In addition to the cell bodies, each segment contains a pair of dorsal (afferent) sensory nerve fibers or roots and ventral (efferent) motor fibers or roots, which innervate a specific region of the body. This combined motor-sensory nerve is called a *spinal nerve* (Fig. 56-5). The cell bodies of the voluntary motor system are located in the anterior horn of the spinal cord gray matter. The cell bodies of the autonomic (involuntary) motor system are located in the anterolateral portion of the spinal cord gray matter. The cell bodies of sensory fibers are located in the dorsal root ganglia just outside the spinal cord. On exiting the spinal column, each spinal nerve divides into ventral and dorsal rami, a collection of motor and sensory fibers that eventually goes to peripheral structures (e.g., skin, muscles, viscera).

A **dermatome** is the area of skin innervated by the sensory fibers of a single dorsal root of a spinal nerve (Fig. 56-6). The dermatomes give a general picture of somatic sensory innervation by spinal segments. A *myotome* is a muscle group innervated by the primary motor neurons of a single ventral root. The dermatomes and myotomes of a given spinal segment

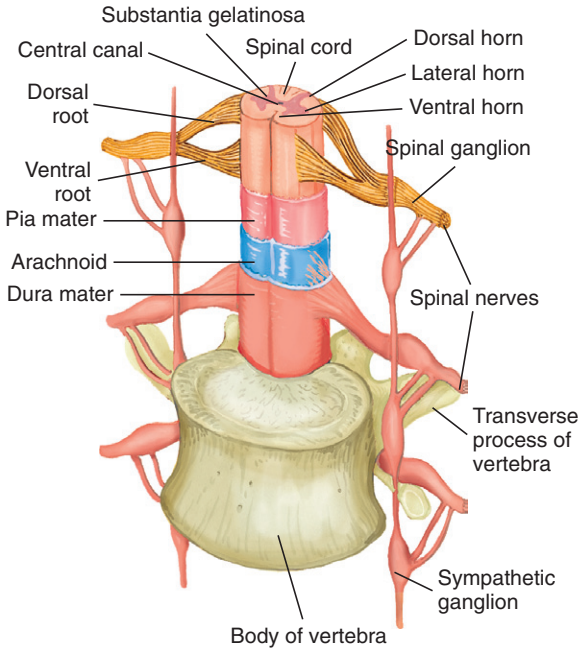

FIG. 56-5 Cross section of spinal cord showing attachments of spinal nerves and coverings of the spinal cord.

overlap with those of adjacent segments because of the development of ascending and descending collateral branches of nerve fibers.

Cranial Nerves. The **cranial nerves (CNs)** are the 12 paired nerves composed of cell bodies with fibers that exit from the cranial cavity. Unlike the spinal nerves, which always have both afferent sensory and efferent motor fibers, some CNs are only sensory, some only motor, and some both.

Table 56-3 summarizes the motor and sensory components of the CNs. Fig. 56-7 shows the position of the CNs in relation to the brain and spinal cord. Just as the cell bodies of the spinal nerves are located in specific segments of the spinal cord, so are the cell bodies (nuclei) of the CNs located in specific segments of the brain. Exceptions are the nuclei of the olfactory and optic nerves. The primary cell bodies of the olfactory nerve are located in the nasal epithelium, and those of the optic nerve are in the retina.

Autonomic Nervous System. The **autonomic nervous system (ANS)** is divided into the sympathetic and parasympathetic systems. The ANS governs involuntary functions of cardiac muscle, smooth muscle, and glands through both efferent and afferent pathways. The two systems function together to maintain a relatively balanced internal environment. The preganglionic cell bodies of the *sympathetic nervous system* (SNS) are located in spinal segments T1 through L2. The major neurotransmitter released by the postganglionic fibers of the SNS is norepinephrine, and the neurotransmitter released by the preganglionic fibers is acetylcholine.

The preganglionic cell bodies of the *parasympathetic nervous system* (PSNS) are located in the brainstem and the sacral spinal segments (S2 through S4). Acetylcholine is the neurotransmitter released at both preganglionic and postganglionic nerve endings. (The effects of the SNS and PSNS are compared in eTable 56-1 available on the website for this chapter.)

SNS stimulation activates the mechanisms required for the "fight-or-flight" response that occurs throughout the body. In

TABLE 56-3 CRANIAL NERVES

Nerve	Connection With Brain	Function
I Olfactory	Anterior ventral cerebrum	*Sensory:* from olfactory (smell)
II Optic	Lateral geniculate body of the thalamus	*Sensory:* from retina of eyes (vision)
III Oculomotor	Midbrain	*Motor:* to four eye movement muscles and levator palpebrae muscle *Parasympathetic:* smooth muscle in eyeball
IV Trochlear	Midbrain	*Motor:* to one eye movement muscle, the superior oblique muscle
V Trigeminal		
• Ophthalmic branch	Pons	*Sensory:* from forehead, eye, superior nasal cavity
• Maxillary branch	Pons	*Sensory:* from inferior nasal cavity, face, upper teeth, mucosa of superior mouth
• Mandibular branch	Pons	*Sensory:* from surfaces of jaw, lower teeth, mucosa of lower mouth, and anterior tongue *Motor:* to muscles of mastication
VI Abducens	Pons	*Motor:* to the lateral rectus of the eye
VII Facial	Junction of pons and medulla	*Motor:* to facial muscles of expression and cheek muscle *Sensory:* taste from anterior two thirds of tongue
VIII Vestibulocochlear		
• Vestibular branch	Junction of pons and medulla	*Sensory:* from equilibrium sensory organ, the vestibular apparatus
• Cochlear branch	Junction of pons and medulla	*Sensory:* from auditory sensory organ, the cochlea
IX Glossopharyngeal	Medulla	*Sensory:* from pharynx and posterior tongue, including taste *Motor:* to superior pharyngeal muscles
X Vagus	Medulla	*Sensory:* from much of viscera of thorax and abdomen *Motor:* to larynx and middle and inferior pharyngeal muscles *Parasympathetic:* heart, lungs, most of digestive system
XI Accessory	Medulla and superior spinal segments	*Motor:* to sternocleidomastoid and trapezius muscles
XII Hypoglossal	Medulla	*Motor:* to muscles of tongue

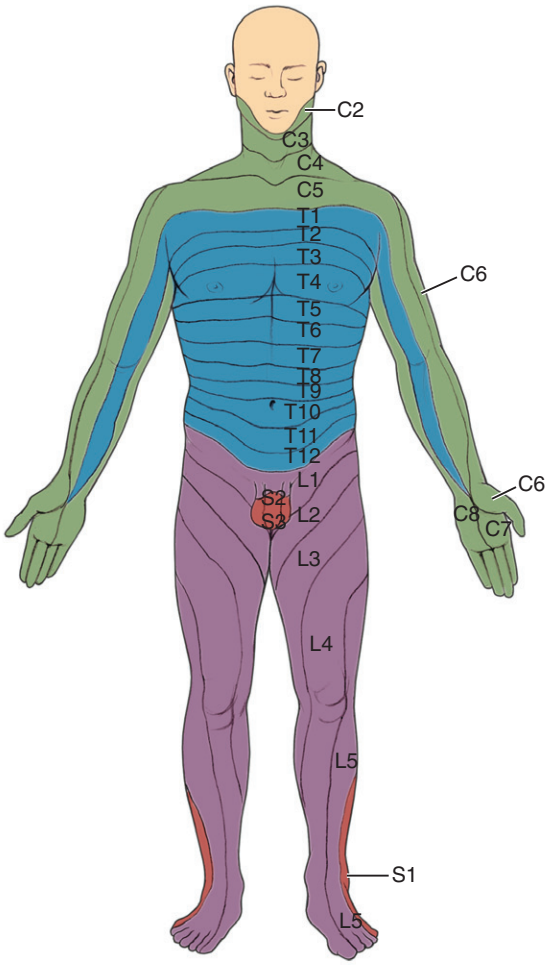

FIG. 56-6 Dermatomes of the body.

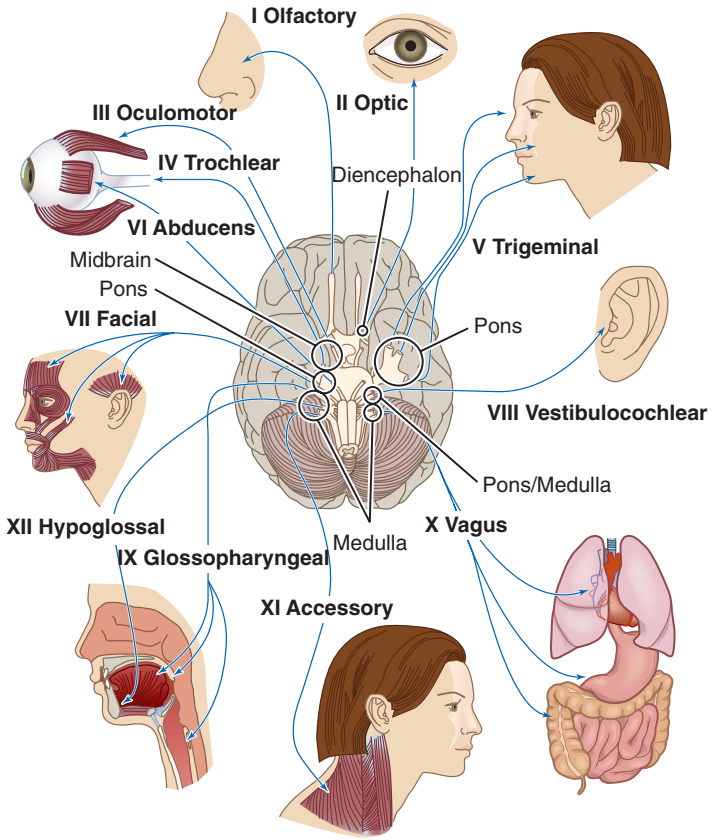

FIG. 56-7 The cranial nerves are numbered according to the order in which they leave the brain.

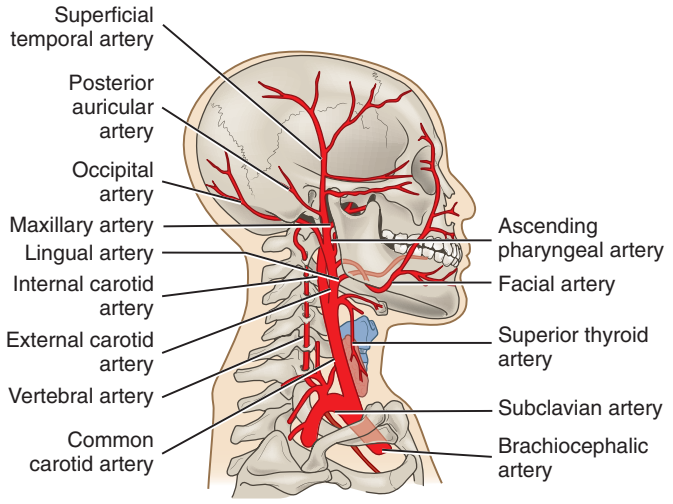

FIG. 56-8 Arteries of the head and neck. Brachiocephalic artery, right common carotid artery, right subclavian artery, and their branches. The major arteries to the head are the common carotid and vertebral arteries.

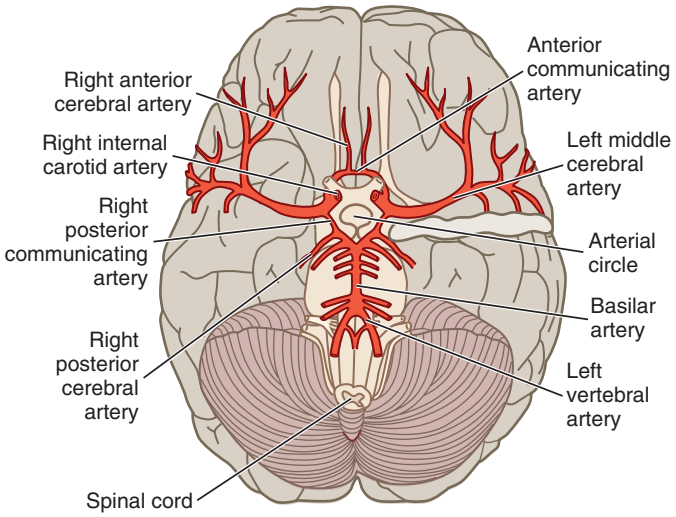

FIG. 56-9 Arteries at the base of the brain. The arteries that compose the circle of Willis are the two anterior cerebral arteries joined to each other by the anterior communicating cerebral artery and to the posterior cerebral arteries by the posterior communicating arteries.

contrast, the PSNS is geared to act in localized and discrete regions. It serves to conserve and restore the body's energy stores. The ANS provides dual and often reciprocal innervation to many structures. For example, the SNS increases the rate and force of heart contraction, and the PSNS decreases the rate and force.

Cerebral Circulation

Knowledge of the distribution of the brain's major arteries is essential for understanding and evaluating the signs and symptoms of cerebrovascular disease and trauma. The brain's blood supply arises from the internal carotid arteries (anterior circulation) and the vertebral arteries (posterior circulation), which are shown in Fig. 56-8.

The internal carotid arteries provide blood flow to the anterior and middle portions of the cerebrum. The vertebral arteries join to form the basilar artery and provide blood flow to the brainstem, cerebellum, and posterior cerebrum. The *circle of Willis* is formed by communicating arteries that join the basilar and internal carotid arteries (Fig. 56-9). The circle of Willis is a safety valve for regulating cerebral blood flow when differential pressures or vascular occlusions are present.

Superior to the circle of Willis, three pairs of arteries supply blood to the left and right hemispheres. The anterior cerebral artery feeds the medial and anterior portions of the frontal lobes. The middle cerebral artery feeds the outer portions of the frontal, parietal, and superior temporal lobes. The posterior cerebral artery feeds the medial portions of the occipital and inferior temporal lobes. Venous blood drains from the brain through the dural sinuses, which form channels that drain into the two jugular veins.

Blood-Brain Barrier. The **blood-brain barrier** is a physiologic barrier between blood capillaries and brain tissue.[5] This barrier protects the brain from harmful agents, while allowing nutrients and gases to enter. The structure of brain capillaries differs from that of other capillaries, so substances that normally pass into most tissues are prevented from entering brain tissue. Lipid-soluble compounds enter the brain easily, whereas water-soluble and ionized drugs enter the brain and the spinal cord slowly. Thus the blood-brain barrier affects the penetration of drugs. Only certain drugs can enter the CNS from the bloodstream.

Protective Structures

Meninges. The **meninges** consist of three protective membranes that surround the brain and spinal cord: dura mater, arachnoid, and pia mater (see eFig. 56-1 on the website for this chapter). The thick *dura mater* forms the outermost layer. The *falx cerebri* is a fold of the dura that separates the two cerebral hemispheres and slows expansion of brain tissue in conditions such as a rapidly growing tumor or acute hemorrhage. The *tentorium cerebelli* is a fold of dura that separates the cerebral hemispheres from the posterior fossa (which contains the brainstem and cerebellum). Expansion of mass lesions in the cerebrum forces the brain to herniate through the opening created by the brainstem. This is termed *infratentorial herniation* (see Fig. 57-4).

The *arachnoid* layer is a delicate membrane that lies between the dura mater and the *pia mater* (the delicate innermost layer of the meninges). The area between the arachnoid layer and the pia mater is the *subarachnoid space* and is filled with CSF. Structures such as arteries, veins, and cranial nerves passing to and from the brain and the skull must pass through the subarachnoid space. A larger subarachnoid space in the region of the third and fourth lumbar vertebrae is the area used to obtain CSF during a lumbar puncture.

Skull. The skull protects the brain from external trauma. It is composed of eight cranial bones and 14 facial bones. Although the top and sides of the inside of the skull are relatively smooth, the bottom surface is uneven. It has many ridges, prominences, and foramina (holes through which blood vessels and nerves enter the intracranial vault). The largest hole is the *foramen magnum,* through which the brainstem extends to the spinal cord. This foramen offers the only major space for the expansion of brain contents when increased intracranial pressure occurs.

Vertebral Column. The *vertebral column* protects the spinal cord, supports the head, and provides flexibility. The vertebral column is made up of 33 individual vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused into one), and 4 coccygeal

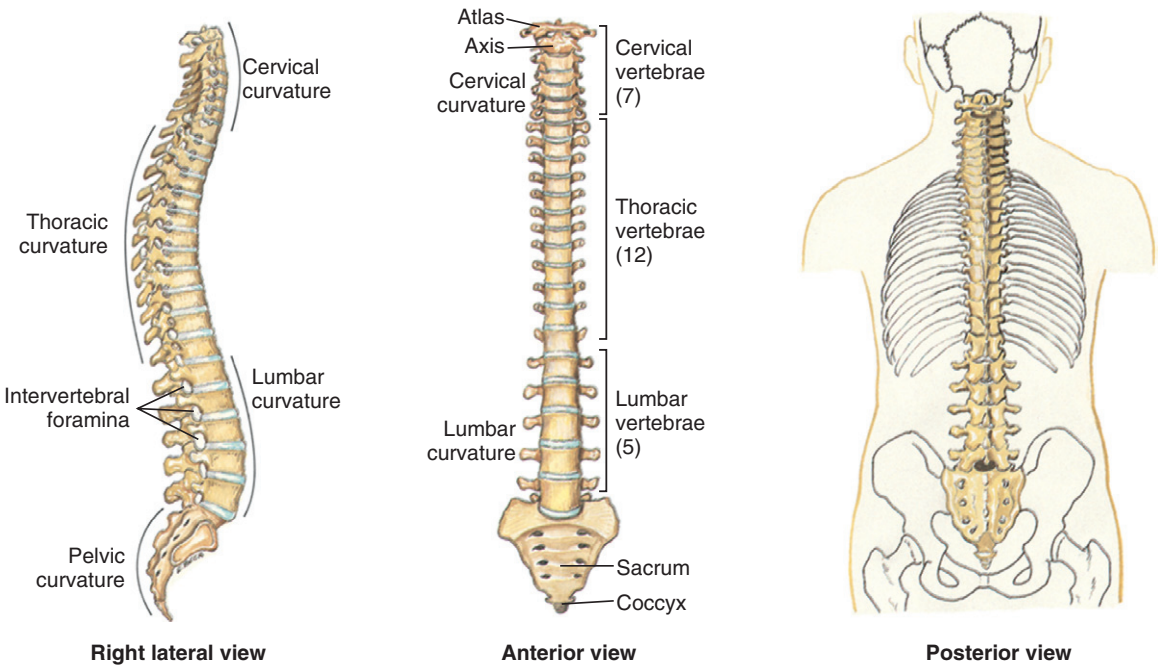

FIG. 56-10 The vertebral column (three views).

(fused into one). Each vertebra has a central opening through which the spinal cord passes. The vertebrae are held together by a series of ligaments. Intervertebral discs occupy the spaces between vertebrae. Fig. 56-10 shows the vertebral column in relation to the trunk.

GERONTOLOGIC CONSIDERATIONS

EFFECTS OF AGING ON NERVOUS SYSTEM

Several parts of the nervous system are affected by aging. In the CNS the gradual loss of neurons in certain areas of the brainstem, cerebellum, and cerebral cortex begins in early adulthood. With loss of neurons, the ventricles widen or enlarge, brain weight decreases,[6] cerebral blood flow decreases, and CSF production declines.

In the PNS, degenerative changes in myelin cause a decrease in nerve conduction. Coordinated neuromuscular activity, such as the maintenance of blood pressure in response to changing from a lying to a standing position, is altered with aging. As a result, older adults are more likely to experience orthostatic hypotension. Similarly, coordination of neuromuscular activity to maintain body temperature is also less efficient with aging. Older adults are less able to adapt to extremes in environmental temperature and are more vulnerable to both hypothermia and hyperthermia.

Additional relevant changes associated with aging include decreases in memory, vision, hearing, taste, smell, vibration and position sense, muscle strength, and reaction time. Sensory changes, including decreases in taste and smell perception, may result in decreased dietary intake in the older adult. Reduced hearing and vision can result in perceptual confusion. Problems with balance and coordination can put the older adult at risk for falls and subsequent fractures.

Changes in assessment findings result from age-related alterations in the various components of the nervous system (Table 56-4).

ASSESSMENT OF NERVOUS SYSTEM

Subjective Data

Important Health Information

Past Health History. Consider three points when taking a history of a patient with neurologic problems. First, avoid suggesting symptoms or asking leading questions. Second, the mode of onset and the course of the illness are especially important aspects of the history. Often the nature of a neurologic disease process can be described by these facts alone. Obtain all pertinent data in the history of the present illness, especially data related to the characteristics and progression of the symptoms. In some cases the history may include birth injury (e.g., cerebral palsy as a consequence of hypoxia). Third, if the patient is not considered a reliable historian, confirm or obtain the history from someone with firsthand knowledge of the patient.

Medications. Obtain a careful medication history, especially the use of sedatives, opioids, tranquilizers, and mood-elevating drugs. Many other drugs can also cause neurologic side effects.

Surgery or Other Treatments. Inquire about any surgery involving any part of the nervous system, such as head, spine, or sensory organs. If a patient had surgery, determine the date, cause, procedure, recovery, and current status.

Growth and developmental history can be important in ascertaining whether nervous system dysfunction was present at an early age. Specifically inquire about major developmental tasks such as walking and talking.

Functional Health Patterns. Key questions to ask a patient with a neurologic problem are presented in Table 56-5.

Health Perception–Health Management Pattern. Ask about the patient's health practices related to the nervous system, such as substance abuse, smoking, adequate nutrition, blood pressure control, safe participation in physical and recreational activities, and use of seat belts or helmets. Also ask about previous hospitalizations for neurologic problems.

TABLE 56-4 GERONTOLOGIC ASSESSMENT DIFFERENCES

Nervous System

Component	Changes	Differences in Assessment Findings
Central Nervous System		
Brain	↓ Cerebral blood flow and metabolism	Alterations in mental functioning.
	↓ Efficiency of temperature-regulating mechanism	Impaired ability to adapt to environmental temperature.
	↓ Neurotransmitters, loss of neurons	Conduction of nerve impulses slowed, response time slowed.
	↓ O_2 supply	Changes in gait and ambulation. Diminished kinesthetic sense.
	Cerebral tissue atrophy and ↑ size of ventricles	Altered balance, vertigo, syncope. ↑ Postural hypotension. Proprioception diminished. ↓ Sensory input.
Peripheral Nervous System		
Cranial and spinal nerves	Loss of myelin and ↓ conduction time	↓ Reaction time in specific nerves.
	Cellular degeneration, death of neurons	↓ Speed and intensity of neuronal reflexes.
Functional Divisions		
Motor	↓ Muscle bulk	Diminished strength and agility.
Sensory*	↓ Sensory receptors	Diminished sense of touch, pain, and temperature.
	↓ Electrical activity	Slowing of or alteration in sensory reception.
	Atrophy of taste buds	Signs of malnutrition, weight loss.
	Degeneration and loss of fibers in olfactory bulb	Diminished sense of smell.
	Degenerative changes in nerve cells in inner ear, cerebellum, and proprioceptive pathways	Poor ability to maintain balance, widened gait.
Reflexes	↓ Deep tendon reflexes	Below-average reflex score.
	↓ Sensory conduction velocity	Sluggish reflexes, slowing of reaction time.
Reticular Formation		
Reticular activating system	Modification of hypothalamic function, ↓ stage IV sleep	Disturbances in sleep patterns.
Autonomic Nervous System		
Sympathetic nervous system and parasympathetic nervous system	Morphologic features of ganglia, slowing of autonomic nervous system responses	Orthostatic hypotension, systolic hypertension.

*Specific changes related to the eye are listed in Table 21-1, and specific changes related to the ear are listed in Table 21-7.
ANS, Autonomic nervous system.

CASE STUDY

Patient Introduction

iStockphoto/Thinkstock

A.J. is a 66-yr-old white woman who arrives in the emergency department after falling in the middle of the night when she tried to get up to go to the bathroom. She states that she fell because she could not control her left leg. Her husband brought her to the hospital, but states that he had a really hard time getting her to the car.

Critical Thinking

As you read through this assessment chapter, think about A.J.'s concerns with the following questions in mind:

1. What are the possible causes for her acute leg weakness?
2. What type of assessment would be most appropriate for A.J.: comprehensive, focused, or emergency? What would be your priority assessment?
3. What questions would you ask A.J.?
4. What should be included in the physical assessment? What would you be looking for?
5. What diagnostic studies might you expect to be ordered?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg.*

If the patient has an existing neurologic problem, assess how it affects daily living and the ability to carry out self-care. After a careful review of information, ask someone who knows the patient well whether he or she has noticed any mental or physical changes in the patient. The patient with a neurologic problem may not be aware of it or may be a poor historian.

GENETIC RISK ALERT

- Huntington's disease is a genetically transmitted, autosomal dominant disorder.
- Major neurologic disorders that may have a genetic basis are multiple sclerosis, headaches, Parkinson's disease, and Alzheimer's disease. The presence of these problems in a family history increases the likelihood of similar problems occurring in the patient.
- A careful family history may determine whether a neurologic problem has a genetic basis.

Nutritional-Metabolic Pattern. Neurologic problems can result in poor nutrition. Problems related to chewing, swallowing, facial nerve paralysis, and muscle coordination could make it difficult for the patient to ingest adequate nutrients.[7] Also, certain vitamins such as thiamine (B_1), niacin, and pyridoxine (B_6) are essential for the maintenance and health of the CNS. Deficiencies in one or more of these vitamins could result in such nonspecific complaints as depression, apathy, neuritis, weakness, mental confusion, and irritability. Cobalamin (vitamin B_{12}) deficiency can occur in older adults, who tend to have problems with vitamin absorption from both supplements and natural food sources such as meat, fish, and poultry. Untreated, cobalamin deficiency can cause mental function decline.

Elimination Pattern. Bowel and bladder problems are often associated with neurologic problems such as stroke, head injury, spinal cord injury, multiple sclerosis, and dementia. It is impor-

TABLE 56-5 HEALTH HISTORY

Nervous System

Health Perception–Health Management
- What are your usual daily activities?
- Do you use alcohol, tobacco, or recreational drugs?*
- What safety practices do you perform in a car? On a motorcycle? On a bicycle?
- Do you have hypertension? If so, is it controlled?
- Have you ever been hospitalized for a neurologic problem?*

Nutritional-Metabolic
- Are you able to feed yourself?
- Do you have any problems getting adequate nutrition because of chewing or swallowing difficulties, facial nerve paralysis, or poor muscle coordination?*
- Give a 24-hr dietary recall.

Elimination
- Do you have incontinence of your bowels or bladder?*
- Do you ever experience problems with hesitancy, urgency, retention?*
- Do you postpone defecation?*
- Do you take any medication to manage neurologic problems? If so, what?

Activity-Exercise
- Describe any problems you experience with usual activities and exercise as a result of a neurologic problem.
- Do you have weakness or lack of coordination?*
- Are you able to perform your personal hygiene needs independently?*

Sleep-Rest
- Describe your sleep pattern.
- When you have trouble sleeping, what do you do?

Cognitive-Perceptual
- Have you noticed any changes in your memory?*
- Do you experience dizziness, heat or cold sensitivity, numbness, or tingling?*
- Do you have chronic pain?*
- Do you have any difficulty with verbal or written communication?*
- Have you noticed any changes in vision or hearing?*

Self-Perception–Self-Concept
- How do you feel about yourself, about who you are?
- Describe your general emotional pattern.

Role-Relationship
- Have you experienced changes in roles such as spouse, parent, or breadwinner?*

Sexuality-Reproductive
- Are you dissatisfied with sexual functioning?*
- Are problems related to sexual functioning causing tension in an important relationship?*
- Do you feel the need for professional counseling related to your sexual functioning?*

Coping–Stress Tolerance
- Describe your usual coping pattern.
- Do you think your present coping pattern is adequate to meet the stressors of your life?*
- What needs are unmet by your current support system?

Value-Belief
- Describe any culturally specific beliefs and attitudes that may influence your care.

*If yes, describe.

tant to determine if the bowel or bladder problem was present before or after the neurologic event to plan appropriate interventions. Incontinence of urine and feces and urinary retention are the most common elimination problems associated with a neurologic problem or its treatment.[8] For example, nerve root compression (as occurs in cauda equina conditions) leads to a sudden onset of incontinence. Document key details, such as number of episodes, accompanying sensations or lack of sensations, and measures to control the problem.

Activity-Exercise Pattern. Many neurologic disorders can cause problems in the patient's mobility, strength, and coordination. Neurologic problems can result in changes in the patient's usual activity and exercise patterns. These problems can also result in falls.[9] Assess the person's activities of daily living, since neurologic diseases can affect the ability to perform motor tasks, which increases the possibility of injury.

Sleep-Rest Pattern. Sleep pattern alteration can be both a cause and a response to neurologic problems. Pain and reduced ability to change position because of muscle weakness and paralysis could interfere with sleep quality. Hallucinations resulting from dementia or drugs can also interrupt sleep. Carefully assess and document the patient's sleep pattern and bedtime routines.

Cognitive-Perceptual Pattern. Because the nervous system controls cognition and sensory integration, many neurologic disorders affect these functions. Assess memory, language, calculation ability, problem-solving ability, insight, and judgment. Ask the patient hypothetical questions such as, "What is a reasonable price for a cup of coffee?" or "What would you do if you saw a car crash outside your house?" Often a structured mental status questionnaire is used to evaluate these functions and provide baseline data.

Delirium is an acute and transient disorder of cognition that can be seen at any time during a patient's illness. As discussed in Chapter 60, delirium is often an early indicator of various illnesses (see Table 60-14). The Confusion Assessment Method tool is used to assess for delirium (see Table 60-16).

Assess a person's ability to use and understand language. Appropriateness of responses is a useful indicator of cognitive and perceptual ability. Determine the patient's understanding and ability to carry out necessary treatments. Neurologic-related cognitive changes can interfere with the patient's understanding of the disease and adherence to related treatment.

Pain is commonly associated with many neurologic problems and is often the reason a patient seeks care. Carefully assess the patient's pain. (Pain and pain assessment are discussed in Chapter 9.)

Self-Perception–Self-Concept Pattern. Neurologic diseases can drastically alter control over one's life and create dependency on others for meeting daily needs. Also, the patient's physical appearance and emotional control can be affected. Sensitively inquire about the patient's evaluation of self-worth, perception of abilities, body image, and general emotional pattern.

Role-Relationship Pattern. Physical impairments such as weakness and paralysis can alter or limit participation in usual roles and activities. Cognitive changes can permanently alter a person's ability to maintain previous roles. These changes can dramatically affect the patient, caregiver, and family. Ask patients if their role (e.g., spouse or breadwinner) has changed as a result of their neurologic problems.

Sexuality-Reproductive Pattern. Assess the person's ability to participate in sexual activity because many neurologic disorders can affect sexual response. Cerebral lesions may inhibit the desire phase or the reflex responses of the excitement phase. The hypothalamus stimulates the pituitary gland to release hormones that influence sexual desire. Brainstem and spinal cord lesions may partially or completely interrupt the desire or ability to have intercourse. Neuropathies and spinal cord lesions may prevent reflex activities of the sexual response or affect sensation and decrease desire. Despite neurologically related changes in sexual function, many persons can achieve satisfying expression of intimacy and affection.

Coping–Stress Tolerance Pattern. The physical sequelae of a neurologic problem can seriously strain a patient's coping patterns. Often the problem is chronic and requires that the patient learn new coping skills. Assess the patient's usual coping pattern to determine if coping skills are adequate to meet the stress of a problem. Also assess the patient's support system.

Value-Belief Pattern. Many neurologic problems have serious, long-term, life-changing effects. Determine what these effects are, since they can strain the patient's belief system. Also determine if any religious or cultural beliefs could interfere with the planned treatment regimen.

Objective Data

Physical Examination. The standard neurologic examination helps determine the presence, location, and nature of disease of the nervous system. The examination assesses six categories of functions: mental status, cranial nerve function, motor function, sensory function, cerebellar function, and reflexes. Develop a consistent pattern of completing the neurologic examination so you remember to include each element every time you examine a patient.

Mental Status. Assessment of mental status (cerebral function) gives a general impression of how the patient is functioning. It involves determining complex and high-level cerebral functions that are governed by many areas of the cerebral cortex. Much of the mental status examination can be assessed as you interact with the patient. For example, assess language and memory when asking the patient for details of the illness and significant past events. Consider the patient's cultural and educational background when evaluating mental status.

The components of the mental status examination include:

- *General appearance and behavior:* This component includes level of consciousness (awake, asleep, comatose), motor activity, body posture, dress and hygiene, facial expression, and speech pattern.
- *Cognition:* Note orientation to time, place, person, and situation, as well as memory, general knowledge, insight, judgment, problem solving, and calculation. Common questions are "Who were the last three presidents?" "Does a rock float on water?" "How much money is a quarter, two dimes, and a nickel?" Consider whether the patient's plans and goals match the physical and mental capabilities. Note the presence of factors affecting intellectual capacity such as cognitive impairment, hallucinations, delusions, and dementia.
- *Mood and affect:* Note any agitation, anger, depression, or euphoria and the appropriateness of these states. Use suitable questions to bring out the patient's feelings.

Cranial Nerves. Testing each CN is an essential part of the neurologic examination (see Table 56-3).

Olfactory Nerve. After determining that both nostrils are patent, test the olfactory nerve (CN I) by asking the patient to close one nostril and identify easily recognized odors (e.g., coffee). Do the same for the other nostril. Chronic rhinitis, sinusitis, and heavy smoking may decrease the sense of smell. Disturbance in ability to smell may be associated with a tumor involving the olfactory bulb, or it may be the result of a basilar skull fracture that has damaged the olfactory fibers as they pass through the delicate cribriform plate of the skull.

Optic Nerve. Assess visual fields and acuity to determine the function of the optic nerve (CN II). Examine each eye independently. Position yourself opposite the patient and ask him or her to look directly at the bridge of your nose and indicate when an object (finger, pencil tip) presented from the periphery of each of the visual fields is seen (Fig. 56-11). Visual field defects may arise from lesions of the optic nerve, optic chiasm, or tracts

CASE STUDY—cont'd

Subjective Data

iStockphoto/Thinkstock

A subjective assessment of A.J. revealed the following information:

PMH: Hyperlipidemia, hypertension.

Medications: pravastatin 40 mg/day PO; lisinopril 10 mg/day PO.

Health Perception–Health Management: Smokes one pack of cigarettes per day since she was 28 yr old. Drinks alcohol occasionally. Hypertension controlled when on medication but has not taken her lisinopril for a few weeks because she did not have enough money for the refill and was waiting for her next Social Security check. Has never been hospitalized for a neurologic problem.

Nutritional-Metabolic: A.J. is 5 ft, 3 in tall and weighs 160 lb.

Activity-Exercise: States that up until tonight she was able to walk slowly, but her knees and hips hurt.

Cognitive-Perceptual: States had a brief episode of left-sided weakness and tingling of the face, arm, and hand 3 mo ago. The symptoms totally resolved and she did not seek treatment. Denies dizziness, change in hearing, or memory deficits.

Coping–Stress Tolerance: Is depressed and fearful. Concerned she is having a stroke and she does not know if she has enough money to cover the copay for coming to the emergency department.

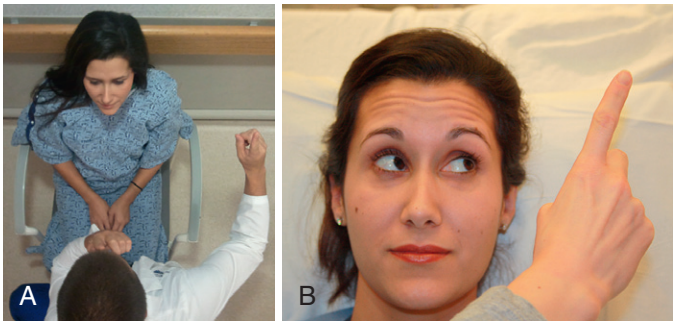

FIG. 56-11 **A,** Nurse checking visual fields. **B,** Nurse checking extraocular movement (EOM).

that extend through the temporal, parietal, or occipital lobes. Visual field changes resulting from brain lesions are usually either a *hemianopsia* (one half of the visual field is affected), a *quadrantanopsia* (one fourth of the visual field is affected), or monocular.

Test visual acuity by asking the patient to read a Snellen chart. Record the number on the lowest line that the patient can read with 50% accuracy. The patient who wears glasses should wear them during testing, unless they are used only for close reading. If a Snellen chart is not available, ask the patient to read newsprint for a gross assessment of acuity. Record the distance from the patient to the newsprint required for accurate reading. Acuity may not be testable by these means if the patient does not read English or is aphasic.

Oculomotor, Trochlear, and Abducens Nerves. Because the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves all help move the eye, they are tested together. Ask the person to hold the head steady and to follow the movement of your finger, pen, or penlight only with the eyes. Hold the target back about 12 inches so the person can focus on it comfortably. Move the target to each of the six positions (right and up, right, right and down, left and up, left, left and down), hold it momentarily, and then move back to center. Progress clockwise. A normal response is parallel tracking of the object with both eyes.

With weakness or paralysis of one of the eye muscles, the eyes do not move together, and the patient has a *disconjugate gaze.* The presence and direction of *nystagmus* (fine, rapid jerking movements of the eyes) are observed at this time, even though this condition most often indicates vestibulocerebellar problems.

Test other functions of the oculomotor nerve by checking for pupillary constriction and *accommodation* (pupils constricting with near vision). To test pupillary constriction, shine a light into the pupil of one eye and look for ipsilateral constriction of the same pupil and contralateral (consensual) constriction of the opposite eye. Note the size and shape of the pupils. The optic nerve must be intact for this reflex to occur.

Because the oculomotor nerve exits at the top of the brainstem at the tentorial notch, it can be easily compressed by expanding mass lesions. When this occurs, sympathetic input to the pupil is unopposed and the pupil remains dilated. The lack of pupillary constriction is an early sign of central herniation (see Chapter 57).

Two abbreviations commonly used to record the reaction of the pupils are *PERRL* (*P*upils are *E*qual [in size], *R*ound, and *R*eactive to *L*ight) and *PERRLA* (*P*upils are *E*qual, *R*ound, and *R*eactive to *L*ight and *A*ccommodation). The PERRL abbreviation is appropriate when accommodation cannot be assessed such as in an unconscious patient. Convergence and accommodation are tested by having the patient focus on the examiner's finger as it moves toward the patient's nose.

Newly developed tools such as the pupilometer are being explored for their ability to objectively evaluate the pupillary response (Fig. 56-12). The pupilometer measures the pupil's response to a visual stimulus (e.g., light).

Another function of the oculomotor nerve is to keep the eyelid open. Damage to the nerve can cause *ptosis* (drooping eyelid), pupillary abnormalities, and eye muscle weakness.

Trigeminal Nerve. The sensory component of the trigeminal nerve (CN V) is tested with the patient's eyes closed, by having the patient identify light touch and pinprick in each of the three

FIG. 56-12 A pupilometer can be used to measure the pupillary response using a light stimulus.

divisions (ophthalmic, maxillary, and mandibular) of the nerve on both sides of the face. Test the motor component by asking the patient to clench the teeth and palpating the masseter muscles just above the mandibular angle. The corneal reflex test evaluates CN V and CN VII simultaneously. Initially, assess blink-to-threat in the unconscious patient. A drop of saline may be applied to the cornea to assess movement of the eyelid as evidence of corneal reflex. The sensory component of this reflex (corneal sensation) is innervated by the ophthalmic division of CN V. The motor component (eye blink) is innervated by the facial nerve (CN VII).

Facial Nerve. The facial nerve (CN VII) innervates the muscles of facial expression. Test its function by asking the patient to raise the eyebrows, close the eyes tightly, purse the lips, draw back the corners of the mouth in an exaggerated smile, and frown. Note any asymmetry in the facial movements because they can indicate damage to the facial nerve. Although taste discrimination of salt and sugar in the anterior two thirds of the tongue is a function of this nerve, it is not routinely tested unless a peripheral nerve lesion is suspected.

Vestibulocochlear (Acoustic) Nerve. The cochlear portion of the vestibulocochlear nerve (CN VIII) is tested by having the patient close the eyes and indicate when he or she hears the rustling of the examiner's fingertips. For more precise assessment of hearing, perform the Weber and Rinne tests or use an audiometer (see Chapter 21).

The vestibular portion of this nerve is not routinely tested unless the patient complains of dizziness, vertigo, or unsteadiness or has auditory dysfunction. In the unconscious patient the oculocephalic reflex (movement of the eyes when the head is briskly turned to the side) may be assessed.

Glossopharyngeal and Vagus Nerves. The glossopharyngeal and vagus nerves (CN IX and X) are tested together because both innervate the pharynx. Test the gag reflex (bilateral contraction of the palatal muscles) by touching the sides of the posterior pharynx or soft palate with a tongue blade. Assess the sensory component of the glossopharyngeal nerve and the major motor component of the vagus nerve. It is important to assess the gag reflex in patients who have a decreased level of consciousness, a brainstem lesion, or a disease involving the throat musculature. If the reflex is weak or absent, the patient is in danger of aspirating food or secretions. The strength and efficiency of swallowing are important to test in these patients for the same reason.

Another test for the awake, cooperative patient is to have the patient phonate by saying "ah," and note the bilateral symmetry of elevation of the soft palate. If the patient is endotracheally intubated, the cough reflex (elicited when the suction catheter contacts the *carina* of the respiratory tree) is a method of assessing the vagus nerve.

Accessory Nerve. Test the accessory nerve (CN XI) by asking the patient to shrug the shoulders and to turn the head to either side against resistance. There should be smooth contraction of the sternocleidomastoid and trapezius muscles. Also note symmetry, atrophy, or fasciculation of the muscle.

Hypoglossal Nerve. Test the hypoglossal nerve (CN XII) by asking the patient to protrude the tongue. It should protrude in the midline. Next ask the patient to move the tongue up and down and side to side. Finally, the patient should also be able to push the tongue to either side against the resistance of a tongue blade. Again, note any asymmetry, atrophy, or fasciculation.

Motor System. The motor system examination includes assessment of strength, tone, coordination, and symmetry of the major muscle groups. Test muscle strength by asking the patient to push and pull against the resistance of your arm as it opposes flexion and extension of the patient's muscle. Ask the patient to offer resistance at the shoulders, elbows, wrists, hips, knees, and ankles. Mild weakness of the arm is demonstrated by downward drifting of the arm or pronation of the palm *(pronator drift)*. Note any weakness or asymmetry of strength between the same muscle groups of the right and left sides.

Test muscle tone by passively moving the limbs through their range of motion. There should be a slight resistance to these movements. Abnormal tone is described as *hypotonia* (flaccidity) or *hypertonia* (spasticity). Note any involuntary movements such as tics, tremor, *myoclonus* (spasm of muscles), *athetosis* (slow, writhing, involuntary movements of extremities), *chorea* (involuntary, purposeless, rapid motions), and *dystonia* (impairment of muscle tone).

Test cerebellar function by assessing balance and coordination. A good screening test for both balance and muscle strength is to observe the patient's stature (posture while standing) and gait. Note the pace and rhythm of the gait and observe for normal symmetric and oppositional arm swing. The patient's ability to ambulate helps to determine the level of nursing care required and the risk of falling.

The finger-to-nose test (having the patient alternately touch the nose, then touch the examiner's finger) and the heel-to-shin test (having the patient stroke the heel of one foot up and down the shin of the opposite leg) test coordination and cerebellar function. Reposition your finger while the patient is touching the nose so that the patient must adjust to a new distance each time your finger is touched. These movements should be performed smoothly and accurately. Other tests include asking the patient to pronate and supinate both hands rapidly and to do a shallow knee bend, first on one leg and then on the other. Note dysarthria or slurred speech because it is a sign of incoordination of the speech muscles.

Sensory System. Several modalities are tested in the somatic sensory examination. Each modality is carried by a specific ascending pathway in the spinal cord before it reaches the sensory cortex. As a rule, perform the examination with the patient's eyes closed and avoid providing the patient with clues. Ask "How does this feel?" rather than "Is this sharp?" In the routine neurologic examination, sensory testing of the anterior torso, posterior torso, and the four extremities is sufficient. However, if a disturbance in sensory function of the skin is identified, the boundaries of that dysfunction should be carefully delineated along the dermatome.

Touch, Pain, and Temperature. Light touch is usually tested first using a cotton wisp or light pin prick. Gently touch each of the four extremities and ask the patient to indicate when he or she feels the stimulus. Test pain by alternately touching the skin with the sharp and dull end of a pin. Tell the patient to respond "sharp" or "dull." Evaluate each limb separately.

Extinction is assessed by simultaneously touching both sides of the body symmetrically. Normally, the simultaneous stimuli are both perceived (sensed). An abnormal response occurs when the patient perceives the stimulus on only one side. The other stimulus is "extinguished."

The sensation of temperature (only to be tested when the response to deep pain is abnormal) can be tested by applying tubes of warm and cold water to the skin and asking the patient to identify the stimuli with the eyes closed. If pain sensation is intact, assessment of temperature sensation may be omitted because both sensations are carried by the same ascending pathways.

Vibration Sense. Assess vibration sense by applying a vibrating tuning fork to the fingernails and the bony prominences of the hands, legs, and feet. Ask the patient if the vibration or "buzz" is felt. Then ask the patient to indicate when the vibration ceases.

Position Sense. Assess position sense *(proprioception)* by placing your thumb and forefinger on either side of the patient's forefinger or great toe and gently moving his or her digit up or down. Ask the patient to indicate the direction in which the digit is moved.

Another test of proprioception is the Romberg test. Ask the patient to stand with feet together and then close his or her eyes. If the patient is able to maintain balance with the eyes open but sways or falls with the eyes closed (i.e., a positive Romberg test), vestibulocochlear dysfunction or disease in the posterior columns of the spinal cord may be indicated. Be aware of patient safety during this test.

Cortical Sensory Functions. Several tests evaluate cortical integration of sensory perceptions (which occurs in the parietal lobes). Assess *two-point discrimination* by placing the two points of a calibrated compass on the tips of the fingers and toes. The minimum recognizable separation is 4 to 5 mm in the fingertips and a greater degree of separation elsewhere. This test is important in diagnosing diseases of the sensory cortex and PNS.

Graphesthesia (ability to feel writing on skin) is tested by having the patient identify numbers traced on the palm of the hands. *Stereognosis* (ability to perceive the form and nature of objects) is tested by having the patient close the eyes and identify the size and shape of easily recognized objects (e.g., coins, keys, safety pin) placed in the hands.

Reflexes. Tendons have receptors that are sensitive to stretch. A reflex contraction of the skeletal muscle occurs when the tendon is stretched. In general, the biceps, triceps, brachioradialis, and patellar and Achilles tendon reflexes are tested. Initiate a simple muscle stretch reflex by briskly tapping the tendon of a stretched muscle, usually with a reflex hammer (Fig. 56-13). The response (muscle contraction of the corresponding muscle) is measured as follows: 0/5 = absent, 1/5 = weak response, 2/5 = normal response, 3/5 = exaggerated response,

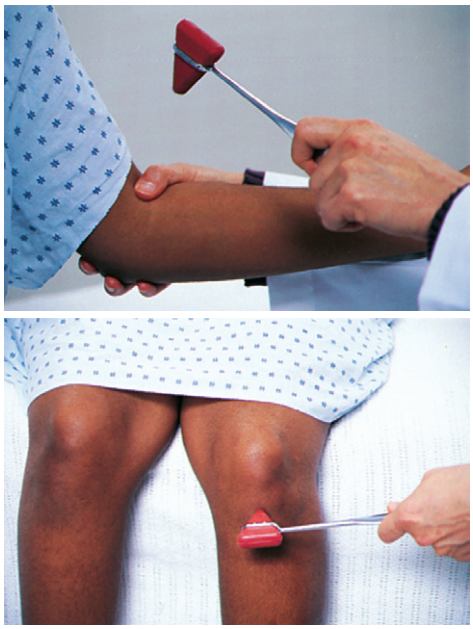

FIG. 56-13 The examiner strikes a swift blow over a stretched tendon to elicit a stretch reflex. **A,** Biceps reflex. **B,** Patellar reflex.

and 4/5 = hyperreflexia with clonus. *Clonus,* an abnormal response, is a continued rhythmic contraction of the muscle with continuous application of the stimulus.

Elicit the *biceps reflex,* with the patient's arm partially flexed and palm up, by placing your thumb over the biceps tendon in the antecubital space and striking the thumb with a hammer. The normal response is flexion of the arm at the elbow or contraction of the biceps muscle that can be felt by your thumb.

Elicit the *triceps reflex* by striking the triceps tendon above the elbow while the patient's arm is flexed. The normal response is extension of the arm or visible contraction of the triceps.

Elicit the *brachioradialis reflex* by striking the radius 3 to 5 cm above the wrist while the patient's arm is relaxed. The normal response is flexion and supination at the elbow or visible contraction of the brachioradialis muscle.

Elicit the *patellar reflex* by striking the patellar tendon just below the patella. The patient can be sitting or lying as long as the leg being tested hangs freely. The normal response is extension of the leg with contraction of the quadriceps.

Elicit the *Achilles tendon reflex* by striking the Achilles tendon while the patient's leg is flexed at the knee and the foot is gently dorsiflexed, by the examiner, at the ankle. The normal response is plantar flexion at the ankle.

A *focused assessment* is used to evaluate the status of previously identified neurologic problems and to monitor for signs of new problems (see Table 3-6). A focused assessment of the neurologic system is presented in the box on p. 1351.

Table 56-6 is an example of a normal neurologic physical assessment. Abnormal assessment findings of the neurologic system are presented in Table 56-7.

DIAGNOSTIC STUDIES OF NERVOUS SYSTEM

Numerous diagnostic studies are available to assess the nervous system. Tables 56-8 and 56-9 present the most common studies, and select studies are described in more detail below.

TABLE 56-6 NORMAL PHYSICAL ASSESSMENT OF NERVOUS SYSTEM*

Parameter	Findings
Mental status	• Alert and oriented, orderly thought processes. • Appropriate mood and affect.
Cranial nerves†	• Smell intact to soap or coffee. • Visual fields full to confrontation. • Intact extraocular movements. • No nystagmus. Pupils equal, round, reactive to light and accommodation. • Intact facial sensation to light touch and pinprick. • Facial movements full. • Intact gag and swallow reflexes. Symmetric smile. Midline protrusion of tongue. • Full strength with head turning and shoulder shrugging.
Motor system	• Normal gait and station. Normal tandem walk. Negative Romberg test. • Normal and symmetric muscle bulk, tone, and strength. • Smooth performance of finger-nose, heel-shin movements.
Sensory system	• Intact sensation to light touch, position sense, pinprick, heat and cold.
Reflexes‡	• Biceps, triceps, brachioradialis, patellar, and Achilles tendon reflexes 2/5 bilaterally. • Downgoing toes with plantar stimulation.

*If some portion of the neurologic examination was not done, this should be indicated (e.g., "Smell not tested").
†May also be recorded as "CN I to XII intact."
‡May also be recorded as drawing of stick figure indicating reflex strength at appropriate sites.

CASE STUDY—cont'd

Objective Data: Physical Examination

iStockphoto/Thinkstock

A physical assessment of A.J. reveals the following:

- BP 180/110, HR 94, RR 22, T 37°C
- Alert, oriented, and able to answer questions appropriately but mild slowness in responding
- Left-sided arm weakness (3/5) and leg weakness (4/5)
- NIH Stroke score is 3

As you continue to read this chapter, consider diagnostic studies you would anticipate being performed for A.J.

Cerebrospinal Fluid Analysis

CSF analysis provides information about a variety of CNS diseases. Normal CSF fluid is clear, colorless, odorless, and free of red blood cells and contains little protein. Normal CSF values are listed in Table 56-9. CSF may be obtained through lumbar puncture or ventriculostomy.

Lumbar Puncture. Lumbar puncture is the most common method of sampling CSF. A lumbar puncture is contraindicated in the presence of increased intracranial pressure or infection at the site of puncture.

Before the procedure, have the patient void. Most commonly, the patient is side lying. However, a seated position may also be used. Inform the patient that, as a sterile needle is passed between two lumbar vertebrae, he or she may feel temporary pain radiating down the leg.

TABLE 56-7 ASSESSMENT ABNORMALITIES

Nervous System

Finding	Description	Possible Etiology and Significance
Mental Status		
Altered consciousness	Stuporous, mute, diminished response to verbal cues or pain	Intracranial lesions, metabolic disorder, psychiatric disorders
Anosognosia	Inability to recognize bodily defect or disease	Lesions in right parietal cortex
Speech		
Aphasia, dysphasia	Loss of or impaired language faculty (comprehension, expression, or both)	Left cerebral cortex lesion
Dysarthria	Lack of coordination in articulating speech	Cerebellar or cranial nerve lesion Antiseizure drugs, sedatives, hypnotic drug toxicity (including alcohol)
Eyes		
Anisocoria	Inequality of pupil size	Optic nerve injury
Diplopia	Double vision	Lesions affecting nerves of extraocular muscles, cerebellar damage
Homonymous hemianopsia	Loss of vision in one side of visual field	Lesions in the contralateral occipital lobe
Cranial Nerves		
Dysphagia	Difficulty in swallowing	Lesions involving motor pathways of CNs IX, X (including lower brainstem)
Ophthalmoplegia	Paralysis of eye muscles	Lesions in brainstem
Papilledema	"Choked disc," swelling of optic nerve head	Increase in intracranial pressure
Motor System		
Apraxia	Inability to perform learned movements despite having desire and physical ability to perform them	Cerebral cortex lesion
Ataxia	Lack of coordination of movement	Lesions of sensory or motor pathways, cerebellum Antiseizure drugs, sedatives, hypnotic drug toxicity (including alcohol)
Dyskinesia	Impairment of voluntary movement, resulting in fragmentary or incomplete movements	Disorders of basal ganglia, idiosyncratic reaction to psychotropic drugs
Hemiplegia	Paralysis on one side	Stroke and other lesions involving motor cortex
Nystagmus	Jerking or bobbing of eyes as they track moving object	Lesions in cerebellum, brainstem, vestibular system Antiseizure drugs, sedatives, hypnotic toxicity (including alcohol)
Sensory System		
Analgesia	Loss of pain sensation	Lesion in spinothalamic tract or thalamus, specific medications
Anesthesia	Absence of sensation	Lesions in spinal cord, thalamus, sensory cortex, or peripheral sensory nerve Specific medications
Paresthesia	Alteration in sensation	Lesions in the posterior column or sensory cortex
Astereognosis	Inability to recognize form of object by touch	Lesions in parietal cortex
Reflexes		
Extensor plantar response	Upgoing toes with plantar stimulation	Suprasegmental or upper motor neuron lesion
Deep tendon reflexes	Diminished or absent motor response	Lower motor neuron lesions
Spinal Cord		
Bladder dysfunction		
• Atonic (autonomous)	Absence of muscle tone and contractility, enlargement of capacity, no sensation of discomfort, overflow with large residual, inability to voluntarily empty	Early stage of spinal cord injury
• Hypotonic	More ability than atonic bladder but less than normal	Interruption of afferent pathways from bladder
• Hypertonic	Increase in muscle tone, diminished capacity, reflex emptying, dribbling, incontinence	Lesions in pyramidal tracts (efferent pathways)
Paraplegia	Paralysis of lower extremities	Spinal cord transection or mass lesion (thoracolumbar region)
Tetraplegia (quadriplegia)	Paralysis of all extremities	Spinal cord transection or mass lesion (cervical region)

FOCUSED ASSESSMENT

Nervous System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Blackouts/loss of memory	Y	N
Weakness, numbness, tingling in arms or legs	Y	N
Headaches, especially new onset	Y	N
Loss of balance/coordination	Y	N
Orientation to person, place, and time	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values.

Lumbar puncture	✓
CT or MRI of brain	✓
EEG	✓

Objective: Physical Examination

Inspect/Observe

General level of consciousness/orientation	✓
Oropharynx for gag reflex and soft palate movement	✓
Peripheral sensation of light touch and pinprick (face, hands, feet)	✓
Smell with an alcohol wipe	✓
Eyes for extraocular movements, PERRLA, peripheral vision, nystagmus	✓
Gait for smoothness and coordination	✓

Palpate

Strength of neck, shoulders, arms, and legs full and symmetric	✓

Percuss

Reflexes	✓

CT, Computed tomography; *EEG,* electroencephalogram; *MRI,* magnetic resonance imaging; *PERRLA,* pupils equal, round, and reactive to light and accommodation.

A manometer is attached to the needle to obtain a CSF pressure. CSF is withdrawn in a series of tubes and sent for analysis. Monitor for headache intensity, meningeal irritation *(nuchal rigidity),* or signs and symptoms of local trauma (e.g., hematoma, pain).

Radiologic Studies

Computed Tomography. Computed tomography (CT) scans provide a rapid means of obtaining radiographic images of the brain (see Fig. 56-15, *A*). When viewed in succession, these images provide a three-dimensional representation of the intracranial contents. Denser material appears white, whereas fluid and air appear dark or black. Brain CT can be completed both with and without contrast media in only a few minutes.

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) provides greater detail than CT and improved resolution (detail) of the intracranial structures (see Fig. 56-15, *B*). However, MRI requires a longer time to complete and may not be appropriate in life-threatening emergencies. Techniques of functional MRI (fMRI) provide time-related (temporal) images that can be used to evaluate how the brain responds to various stimuli.

Cerebral Angiography. Cerebral angiography is indicated when vascular lesions or tumors are suspected. A catheter is inserted into the femoral (sometimes brachial) artery and passed through the aortic arch and into the base of a carotid or a vertebral artery for injection of contrast media. Timed-sequence radiographic images are obtained as contrast flows through arteries, smaller vessels, and veins (see Fig. 56-14). This study can help to identify and localize abscesses, aneurysms, hematomas, arteriovenous malformations, arterial spasm, and certain tumors.

Because this is an invasive procedure, adverse reactions may occur. The patient may have an allergic (anaphylactic) reaction to the contrast medium. This reaction usually occurs immediately after injection of the contrast medium and may require emergency resuscitation measures in the procedure room. Once the patient returns to his or her room after the procedure, observe for bleeding at the catheter puncture site (usually the groin).

CASE STUDY—cont'd

Objective Data: Diagnostic Studies

iStockphoto/Thinkstock

The emergency department physician immediately orders a stat CT scan of the head. The CT scan rules out a hemorrhagic stroke. Stat laboratory test results include a blood glucose of 138 mg/dL, and PT/INR of 12.0/1.1.

Case study continued in Ch. 58 on p. 1410.

Electrographic Studies

Electroencephalography. *Electroencephalography* (EEG) involves recording electrical activity of the surface cortical neurons of the brain by electrodes placed on specific areas of the scalp. Specific tests may be done to evaluate the brain's electrical response to lights and loud noises. This test is done to evaluate not only cerebral disease but also the CNS effects of many metabolic and systemic diseases. Among the cerebral diseases assessed by EEG are seizure disorders, sleep disorders, cerebrovascular lesions, and brain injury. Prolonged EEG monitoring is becoming a common test to diagnose and treat seizure disorders.[10] An EEG is noninvasive. Assure patients that there is no risk of electric shock.

Electromyography and Nerve Conduction Studies. *Electromyography* (EMG) is the recording of electrical activity associated with innervation of skeletal muscle. Needle electrodes are inserted into the muscle to record specific motor units because recording from the skin is not sufficient. Normal muscle at rest shows no electrical activity. Electrical activity occurs only when the muscle contracts. This activity may be altered in diseases of muscle itself (e.g., myopathic conditions) or in disorders of muscle innervation (e.g., segmental or LMN lesions, peripheral neuropathic conditions).

Nerve conduction studies involve applying a brief electrical stimulus to a distal portion of a sensory or mixed nerve and recording the resulting wave of depolarization at some point proximal to the stimulation. For example, a stimulus can be applied to the forefinger and a recording electrode placed over the median nerve at the wrist. The time between the stimulus onset and the initial wave of depolarization at the recording electrode is measured. This is termed *nerve conduction velocity.* Damaged nerves have slower conduction velocities.

TABLE 56-8 DIAGNOSTIC STUDIES

Nervous System

Study	Description and Purpose	Nursing Responsibility
Cerebrospinal Fluid Analysis		
Lumbar puncture	CSF is aspirated by needle insertion in L3-4 or L4-5 interspace to assess many CNS diseases (see Table 56-9).	Ensure that patient does not have signs of increased ICP because of the risk of downward herniation from CSF removal. Patient assumes and maintains lateral recumbent position. Use strict aseptic technique. Ensure labeling of CSF specimens in proper sequence. Encourage fluids. Monitor neurologic signs and VS. Administer analgesia as needed.
Radiology		
Skull and spine x-rays	Simple x-ray of skull and spinal column is done to detect fractures, bone erosion, calcifications, abnormal vascularity.	Explain that procedure is noninvasive. Explain positions to be assumed.
Cerebral angiography	Serial x-ray visualization of intracranial and extracranial blood vessels is performed to detect vascular lesions and tumors of brain (Fig. 56-14). Contrast medium is used.	*Preprocedure:* Assess patient for stroke risk before procedure, since thrombi may be dislodged during procedure. Withhold preceding meal. Explain that patient will have hot flush of head and neck when contrast medium is injected. Administer premedication. Explain need to be absolutely still during procedure. *Postprocedure:* Monitor neurologic signs and VS every 15-30 min for first 2 hr, every hour for next 6 hr, then every 2 hr for 24 hr. Maintain bed rest until patient is alert and VS are stable. Report any neurologic status changes.
Computed tomography (CT) scan	Computer-assisted x-ray of multiple cross sections of body parts to detect problems such as hemorrhage, tumor, cyst, edema, infarction, brain atrophy, and other abnormalities (Fig. 56-15, *A*). Contrast media may be used to enhance visualization of brain structures.	Assess for contraindications to contrast media, including allergy to shellfish, iodine, or dye. Explain appearance of scanner. Instruct patient to remain still during procedure.
Magnetic resonance imaging (MRI)	Imaging of brain, spinal cord, and spinal canal by means of magnetic energy (Fig. 56-15, *B*). Used to detect strokes, multiple sclerosis, tumors, trauma, herniation, and seizures. No invasive procedures are required. Contrast media may be used to enhance visualization. Has greater contrast in images of soft tissue structures than CT scan.	Screen patient for metal parts and pacemaker in body. Instruct patient on need to lie very still for up to 1 hr. Sedation may be necessary if patient is claustrophobic.
Magnetic resonance angiography (MRA)	Uses differential signal characteristics of flowing blood to evaluate extracranial and intracranial blood vessels. Provides both anatomic and hemodynamic information. Can be used in conjunction with contrast media.	Similar to MRI (see above).
Positron emission tomography (PET)	Measures metabolic activity of brain to assess cell death or damage. Uses radioactive material that shows up as a bright spot on the image (see Fig. 16-7). Used for patients with stroke, Alzheimer's disease, seizure disorders, Parkinson's disease, and tumors.	Explain procedure to patient. Explain that two IV lines will be inserted. Instruct patient not to take sedatives or tranquilizers. Have patient empty bladder before procedure. Patient may be asked to perform different activities during test.
Single-photon emission computed tomography (SPECT)	A method of scanning similar to PET, but it uses more stable substances and different detectors. Radiolabeled compounds are injected, and their photon emissions can be detected. Images made are accumulation of labeled compound. Used to visualize blood flow or O_2 or glucose metabolism in the brain. Useful in diagnosing strokes, brain tumors, and seizure disorders.	Similar to PET (see above).
Myelogram	X-ray of spinal cord and vertebral column after injection of contrast medium into subarachnoid space. Used to detect spinal lesions (e.g., herniated or ruptured disc, spinal tumor).	*Preprocedure:* Administer sedative as ordered. Instruct patient to empty bladder. Inform patient that test is performed with patient on tilting table that is moved during test. *Postprocedure:* Patient should lie flat for a few hours. Encourage fluids. Monitor neurologic signs and VS. Headache, nausea, and vomiting may occur after procedure.

TABLE 56-8 DIAGNOSTIC STUDIES—cont'd

Nervous System

Study	Description and Purpose	Nursing Responsibility
Electrographic Studies		
Electroencephalography (EEG)	Electrical activity of brain is recorded by scalp electrodes to evaluate seizure disorders, cerebral disease, CNS effects of systemic diseases, brain death.	Inform patient that procedure is noninvasive and without danger of electric shock. Determine whether any medications (e.g., tranquilizers, antiseizure drugs) should be withheld. Resume medications and instruct patient to wash electrode paste out of hair after test.
Magnetoencephalography (MEG)	Uses a biomagnetometer to detect magnetic fields generated by neural activity. It can accurately pinpoint the part of the brain involved in a stroke, seizure, or other disorder or injury. Measures extracranial magnetic fields and scalp electric field (EEG).	MEG, a passive sensor, does not make physical contact with patient. Explain procedure to patient.
Electromyography (EMG) and nerve conduction studies	Electrical activity associated with nerve and skeletal muscle is recorded by insertion of needle electrodes to detect muscle and peripheral nerve disease.	Inform patient that pain and discomfort are associated with insertion of needles.
Evoked potentials	Electrical activity associated with nerve conduction along sensory pathways is recorded by electrodes placed on skin and scalp. Stimulus generates the impulse. Procedure is used to diagnose disease (e.g., multiple sclerosis), locate nerve damage, and monitor function intraoperatively.	Explain procedure to patient.
Ultrasound		
Carotid duplex studies	Combined ultrasound and pulsed Doppler technology. Probe is placed over the carotid artery and slowly moved along the course of the common carotid artery. Frequency of reflected ultrasound signal corresponds to the blood velocity. Increased blood flow velocity can indicate stenosis of a vessel.	Explain procedure to patient. Duplex scanning is a noninvasive study that evaluates the degree of stenosis of the carotid and vertebral arteries.
Transcranial Doppler	Same technology as carotid duplex, but evaluates blood flow velocities of the intracranial blood vessels. Probe is placed on the skin at various "windows" in the skull (areas in the skull that have only a thin bony covering) to register velocities of the blood vessels.	Explain procedure to patient. Noninvasive technique that is useful in assessing vasospasm associated with subarachnoid hemorrhage, altered intracranial blood flow dynamics associated with occlusive vascular disease, presence of emboli, and cerebral autoregulation.

CNS, Central nervous system; *CSF,* cerebrospinal fluid; *ICP,* intracranial pressure.

TABLE 56-9 NORMAL CEREBROSPINAL FLUID VALUES

Parameter	Normal Value
Specific gravity	1.007
pH	7.35
Appearance	Clear, colorless
Red blood cells (RBCs)	None
White blood cells (WBCs)	0-5 cells/μL (0-5 × 10^6 cells/L)
Protein	
• Lumbar	15-45 mg/dL (0.15-0.45 g/L)
• Cisternal	15-25 mg/dL (0.15-0.25 g/L)
• Ventricular	5-15 mg/dL (0.05-0.15 g/L)
Glucose	40-70 mg/dL (2.2-3.9 mmol/L)
Microorganisms	None
Pressure	60-150 mm H_2O

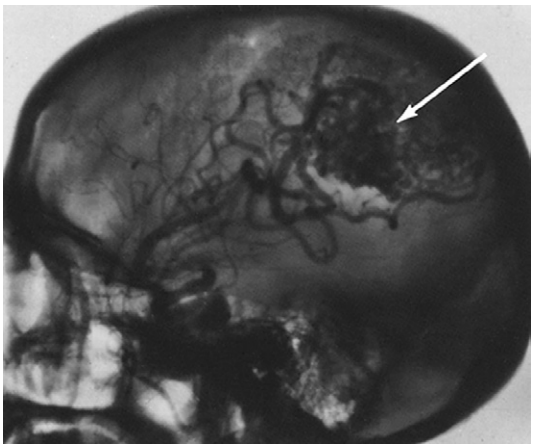

FIG. 56-14 Cerebral angiogram illustrating an arteriovenous malformation *(arrow).*

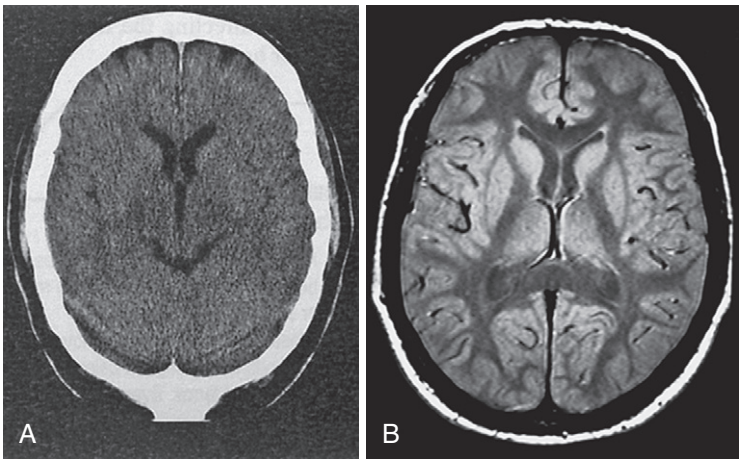

FIG. 56-15 Normal images of the brain. **A,** Computed tomography scan. **B,** Magnetic resonance imaging.

Evoked Potentials. *Evoked potentials* are recordings of electrical activity associated with nerve conduction along sensory pathways. The electrical activity is generated by a specific sensory stimulus related to the type of study (e.g., clicking sounds for auditory evoked potentials, mild electrical pulses for somatosensory evoked potentials).[11] Electrodes placed on specific areas of the skin and the scalp record the electrical activity. Increases in the normal time from stimulus onset to a given peak (latency) indicate slowed nerve conduction or nerve damage.

This technique is useful in diagnosing abnormalities of the visual or auditory systems because it reveals whether a sensory impulse is reaching the appropriate part of the brain. Indications for these tests include evaluation of consciousness, multiple sclerosis (optic neuritis), and acoustic neuroma.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In a patient with a disease that affects the myelin sheath of nerves, such as multiple sclerosis, the glial cells affected are the
   - **a.** microglia.
   - **b.** astrocytes.
   - **c.** ependymal cells.
   - **d.** oligodendrocytes.
2. Drugs or diseases that impair the function of the extrapyramidal system may cause loss of
   - **a.** sensations of pain and temperature.
   - **b.** regulation of the autonomic nervous system.
   - **c.** integration of somatic and special sensory inputs.
   - **d.** automatic movements associated with skeletal muscle activity.
3. An obstruction of the anterior cerebral arteries will affect functions of
   - **a.** visual imaging.
   - **b.** balance and coordination.
   - **c.** judgment, insight, and reasoning.
   - **d.** visual and auditory integration for language comprehension.
4. Paralysis of lateral gaze indicates a lesion of cranial nerve
   - **a.** II.
   - **b.** III.
   - **c.** IV.
   - **d.** VI.
5. A result of stimulation of the parasympathetic nervous system is *(select all that apply)*
   - **a.** constriction of the bronchi.
   - **b.** dilation of skin blood vessels.
   - **c.** increased secretion of insulin.
   - **d.** increased blood glucose levels.
   - **e.** relaxation of the urinary sphincters.
6. Assessment of muscle strength of older adults cannot be compared with that of younger adults because
   - **a.** stroke is more common in older adults.
   - **b.** nutritional status is better in young adults.
   - **c.** most young people exercise more than older people.
   - **d.** aging leads to a decrease in muscle bulk and strength.
7. Data regarding mobility, strength, coordination, and activity tolerance are important for the nurse to obtain because
   - **a.** many neurologic diseases affect one or more of these areas.
   - **b.** patients are less able to identify other neurologic impairments.
   - **c.** these are the first functions to be affected by neurologic diseases.
   - **d.** aspects of movement are the most important function of the nervous system.

8. During neurologic testing, the patient is able to perceive pain elicited by pinprick. Based on this finding, the nurse may omit testing for
   a. position sense.
   b. patellar reflexes.
   c. temperature perception.
   d. heel-to-shin movements.
9. A patient's eyes jerk while the patient looks to the left. You will record this finding as
   a. nystagmus.
   b. CN VI palsy.
   c. oculocephalia.
   d. ophthalmic dyskinesia.
10. The nurse is caring for a patient with peripheral neuropathy who is going to have EMG studies tomorrow morning. The nurse should
    a. ensure the patient has an empty bladder.
    b. instruct the patient that there is no risk of electric shock.
    c. ensure the patient has no metallic jewelry or metal fragments.
    d. instruct the patient that she or he may experience pain during the study.

1. d, 2. d, 3. c, 4. d, 5. a, b, c, e, 6. d, 7. a, 8. c, 9. a, 10. b

LEARNING OUTCOMES

1. Explain the physiologic mechanisms that maintain normal intracranial pressure.
2. Describe the common etiologies, clinical manifestations, and collaborative care of the patient with increased intracranial pressure.
3. Describe the collaborative and nursing management of the patient with increased intracranial pressure.
4. Differentiate types of head injury by mechanism of injury and clinical manifestations.
5. Describe the collaborative care and nursing management of the patient with a head injury.
6. Compare the types, clinical manifestations, and collaborative care of patients with brain tumors.
7. Discuss the nursing management of the patient with a brain tumor.
8. Describe the nursing management of the patient undergoing cranial surgery.
9. Differentiate among the primary causes, collaborative care, and nursing management of brain abscess, meningitis, and encephalitis.

unconsciousness, p. 1359

Acute intracranial problems include diseases and disorders that can increase intracranial pressure (ICP). This chapter discusses the mechanisms that maintain normal ICP and increase ICP. In addition, head injury, brain tumors, and cerebral inflammatory disorders are discussed.

INTRACRANIAL PRESSURE

Understanding the dynamics associated with ICP is important in caring for patients with many different neurologic problems. The skull is like a closed box with three essential volume components: brain tissue, blood, and cerebrospinal fluid (CSF) (Fig. 57-1). The intracellular and extracellular fluids of brain tissue make up approximately 78% of this volume. Blood in the arterial, venous, and capillary network makes up 12% of the volume, and the remaining 10% is the volume of the CSF.

Primary versus secondary injury is another important concept in understanding ICP. *Primary injury* occurs at the initial time of an injury (e.g., impact of car accident,

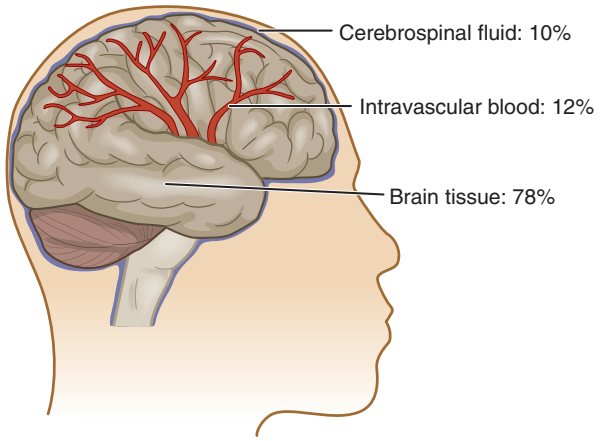

FIG. 57-1 Components of the brain.

blunt-force trauma) that results in displacement, bruising, or damage of the three components. *Secondary injury* is the resulting hypoxia, ischemia, hypotension, edema, or increased ICP that follows the primary injury. Secondary injury, which could occur several hours to days after the initial injury, is a primary concern when managing brain injury. Nursing management of the patient with an acute intracranial problem must include management of secondary injury, and thus increased ICP.

Regulation and Maintenance of Intracranial Pressure

Normal Intracranial Pressure. **Intracranial pressure (ICP)** is the hydrostatic force measured in the brain CSF compartment. Under normal conditions in which intracranial volume remains relatively constant, the balance among the three components (brain tissue, blood, CSF) maintains the ICP. Factors that influence ICP under normal circumstances are changes in (1) arterial pressure; (2) venous pressure; (3) intraabdominal and intrathoracic pressure; (4) posture; (5) temperature; and (6) blood gases, particularly carbon dioxide levels. The degree to which these factors increase or decrease the ICP depends on the brain's ability to adapt to changes.

The Monro-Kellie doctrine states that the three components must remain at a relatively constant volume within the closed skull structure. If the volume of any one of the three components increases within the cranial vault and the volume from another component is displaced, the total intracranial volume will not change.[1] This hypothesis is only applicable in situations in which the skull is closed. The hypothesis is not valid in persons with displaced skull fractures or hemicraniectomy.

ICP can be measured in the ventricles, subarachnoid space, subdural space, epidural space, or brain tissue using a pressure transducer.[2] Normal ICP ranges from 5 to 15 mm Hg. A sustained pressure greater than 20 mm Hg is considered abnormal and must be treated.

Normal Compensatory Adaptations. In applying the Monro-Kellie doctrine, the body can adapt to volume changes within the skull in three different ways to maintain a normal ICP. First, compensatory mechanisms can include changes in the CSF volume. The CSF volume can be changed by altering CSF absorption or production and by displacing CSF into the spinal subarachnoid space. Second, changes in intracranial blood volume can occur through the collapse of cerebral veins and dural sinuses, regional cerebral vasoconstriction or dilation, and changes in venous outflow. Third, brain tissue volume compensates through distention of the dura or compression of brain tissue.

Initially an increase in volume produces no increase in ICP as a result of these compensatory mechanisms. However, the ability to compensate for changes in volume is limited. As the volume increase continues, the ICP rises and decompensation ultimately occurs, resulting in compression and ischemia.

TABLE 57-1 CALCULATION OF CEREBRAL PERFUSION PRESSURE

$$CPP = MAP - ICP$$

$$MAP = DBP + 1/3\,(SBP - DBP) \text{ or } = \frac{SBP + 2\,(DBP)}{3}$$

Example: Systemic blood pressure = 122/84 mm Hg
MAP = 97 mm Hg
ICP = 12 mm Hg
CPP = 85 mm Hg

CPP, Cerebral perfusion pressure; *DBP,* diastolic blood pressure; *ICP,* intracranial pressure; *MAP,* mean arterial pressure; *SBP,* systolic blood pressure.

Cerebral Blood Flow

Cerebral blood flow (CBF) is the amount of blood in milliliters passing through 100 g of brain tissue in 1 minute. The global CBF is approximately 50 mL/min/100 g of brain tissue.[3] The maintenance of blood flow to the brain is critical because the brain requires a constant supply of oxygen and glucose. The brain uses 20% of the body's oxygen and 25% of its glucose.[4]

Autoregulation of Cerebral Blood Flow. The brain regulates its own blood flow in response to its metabolic needs despite wide fluctuations in systemic arterial pressure. *Autoregulation* is the automatic adjustment in the diameter of the cerebral blood vessels by the brain to maintain a constant blood flow during changes in arterial blood pressure (BP). The purpose of autoregulation is to ensure a consistent CBF to provide for the metabolic needs of brain tissue and to maintain cerebral perfusion pressure within normal limits.

The lower limit of systemic arterial pressure at which autoregulation is effective in a normotensive person is a mean arterial pressure (MAP) of 70 mm Hg. Below this, CBF decreases, and symptoms of cerebral ischemia, such as syncope and blurred vision, occur. The upper limit of systemic arterial pressure at which autoregulation is effective is a MAP of 150 mm Hg.[3] When this pressure is exceeded, the vessels are maximally constricted, and further vasoconstrictor response is lost.

The *cerebral perfusion pressure* (CPP) is the pressure needed to ensure blood flow to the brain. CPP is equal to the MAP minus the ICP (CPP = MAP – ICP) (see example in Table 57-1). This formula is clinically useful, although it does not consider the effect of cerebrovascular resistance. Cerebrovascular resistance, generated by the arterioles within the cranium, links CPP and blood flow as follows: CPP = Flow × Resistance.

When cerebrovascular resistance is high, blood flow to brain tissue is impaired. Transcranial Doppler is a noninvasive technique used in intensive care units (ICUs) to monitor changes in cerebrovascular resistance.

As the CPP decreases, autoregulation fails and CBF decreases. Normal CPP is 60 to 100 mm Hg. A CPP of less than 50 mm Hg is associated with ischemia and neuronal death. A CPP of less than 30 mm Hg results in ischemia and is incompatible with life.

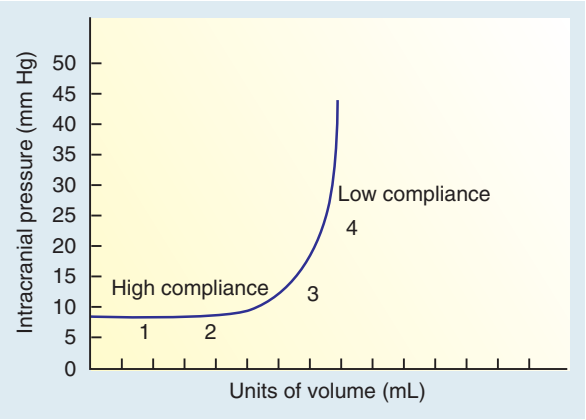

FIG. 57-2 Intracranial pressure-volume curve. (See text for descriptions of *1, 2, 3,* and *4.*)

Normally, autoregulation maintains an adequate CBF and perfusion pressure primarily by adjusting the diameter of cerebral blood vessels and metabolic factors that affect ICP. It is critical to maintain MAP when ICP is elevated.

Remember that CPP may not reflect perfusion pressure in all parts of the brain. There may be local areas of swelling and compression limiting regional perfusion pressure. Thus a higher CPP may be needed for these patients to prevent localized tissue damage. For example, a patient with an acute stroke may require a higher BP, increasing MAP and CPP, in order to increase perfusion to the brain and prevent further tissue damage.

Pressure Changes. The relationship of pressure to volume is depicted in the pressure-volume curve (Fig. 57-2). The curve is affected by the brain's compliance. *Compliance* is the expandability of the brain. It is represented as the volume increase for each unit increase in pressure. With low compliance, small changes in volume result in greater increases in pressure.

$$\text{Compliance} = \text{Volume} / \text{Pressure}$$

The concept of the pressure-volume curve can be used to represent the stages of increased ICP. At stage 1 on the curve, there is high compliance. The brain is in total compensation, with accommodation and autoregulation intact. An increase in volume (in brain tissue, blood, or CSF) does not increase the ICP.

At stage 2, the compliance is beginning to decrease, and an increase in volume places the patient at risk of increased ICP and secondary injury. At stage 3, there is significant reduction in compliance. Any small addition of volume causes a great increase in ICP. Compensatory mechanisms fail, there is a loss of autoregulation, and the patient exhibits manifestations of increased ICP (e.g., headache, changes in level of consciousness or pupil responsiveness).

With a loss of autoregulation, the body attempts to maintain cerebral perfusion by increasing systolic BP. However, decompensation is imminent. The patient's response is characterized by systolic hypertension with a widening pulse pressure, bradycardia with a full and bounding pulse, and altered respirations. This is known as *Cushing's triad* and is a neurologic emergency.

As the patient enters stage 4, the ICP rises to lethal levels with little increase in volume. *Herniation* occurs as the brain tissue is forcibly shifted from the compartment of greater pressure to a compartment of lesser pressure. In this situation, intense pressure is placed on the brainstem, and if herniation continues, brainstem death is imminent.

Factors Affecting Cerebral Blood Flow. Carbon dioxide, oxygen, and hydrogen ion concentration affect cerebral blood vessel tone. An increase in the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) relaxes smooth muscle, dilates cerebral vessels, decreases cerebrovascular resistance, and increases CBF. A decrease in $PaCO_2$ constricts cerebral vessels, increases cerebrovascular resistance, and decreases CBF.

Cerebral oxygen tension of less than 50 mm Hg results in cerebrovascular dilation. This dilation decreases cerebrovascular resistance, increases CBF, and increases oxygen tension. However, if oxygen tension is not increased, anaerobic metabolism begins, resulting in an accumulation of lactic acid. As lactic acid increases and hydrogen ions accumulate, the environment becomes more acidic. Within this acidic environment, further vasodilation occurs in a continued attempt to increase blood flow. The combination of a severely low partial pressure of oxygen in arterial blood (PaO_2) and an elevated hydrogen ion concentration (acidosis), which are both potent cerebral vasodilators, may produce a state where autoregulation is lost and compensatory mechanisms fail to meet tissue metabolic demands.

CBF can be affected by cardiac or respiratory arrest, systemic hemorrhage, and other pathophysiologic states (e.g., diabetic coma, encephalopathies, infections, toxicities). Regional CBF can also be affected by trauma, tumors, cerebral hemorrhage, or stroke. When regional or global autoregulation is lost, CBF is no longer maintained at a constant level but is directly influenced by changes in systemic BP, hypoxia, or catecholamines.

INCREASED INTRACRANIAL PRESSURE

Any patient who becomes unconscious acutely, regardless of the cause, should be suspected of having increased ICP.

Mechanisms of Increased Intracranial Pressure

Increased ICP is a potentially life-threatening situation that results from an increase in any or all of the three components (brain tissue, blood, CSF) within the skull. Elevated ICP is clinically significant because it diminishes CPP, increases risks of brain ischemia and infarction, and is associated with a poor prognosis.[5] Common causes of increased ICP include a mass (e.g., hematoma, contusion, abscess, tumor) and cerebral edema (associated with brain tumors, hydrocephalus, head injury, or brain inflammation).

These cerebral insults, which may result in hypercapnia, cerebral acidosis, impaired autoregulation, and systemic hypertension, increase the formation and spread of cerebral edema. This edema distorts brain tissue, further increasing the ICP, and leads to even more tissue hypoxia and acidosis. Fig. 57-3 illustrates the progression of increased ICP.

It is critical to maintain CBF to preserve tissue and thus minimize secondary injury. Sustained increases in ICP result in brainstem compression and herniation of the brain from one compartment to another.

Displacement and herniation of brain tissue can cause a potentially reversible process to become irreversible. Ischemia and edema are further increased, compounding the preexisting problem. Compression of the brainstem and cranial nerves may be fatal. (Fig. 57-4 illustrates types of herniation.) Herniation

PATHOPHYSIOLOGY MAP

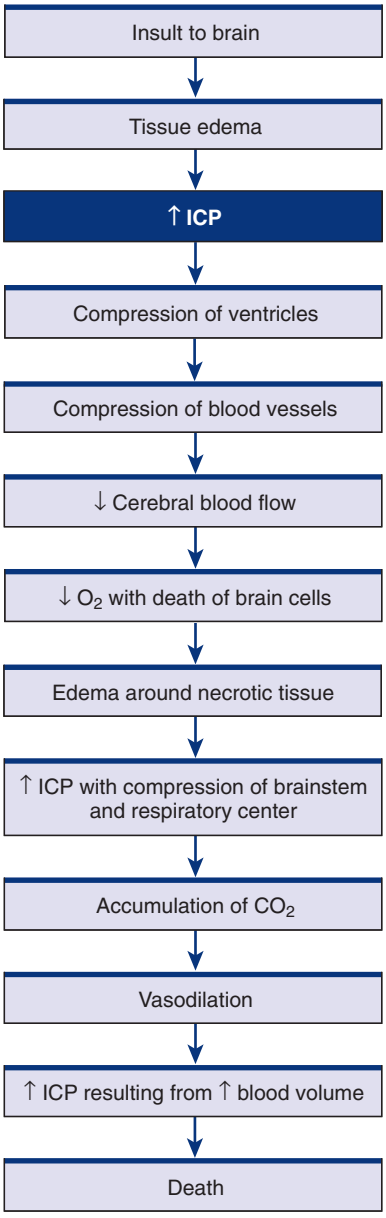

FIG. 57-3 Progression of increased intracranial pressure *(ICP)*.

forces the cerebellum and the brainstem downward through the foramen magnum. If compression of the brainstem is unrelieved, respiratory arrest will occur due to compression of the respiratory control center in the medulla.

Cerebral Edema

As shown in Table 57-2, there are a variety of causes of **cerebral edema** (increased accumulation of fluid in the extravascular spaces of brain tissue). Regardless of the cause, cerebral edema results in an increase in tissue volume that can increase ICP. The extent and severity of the original insult are factors that determine the degree of cerebral edema.

There are three types of cerebral edema: vasogenic, cytotoxic, and interstitial. The same patient may have more than one type.

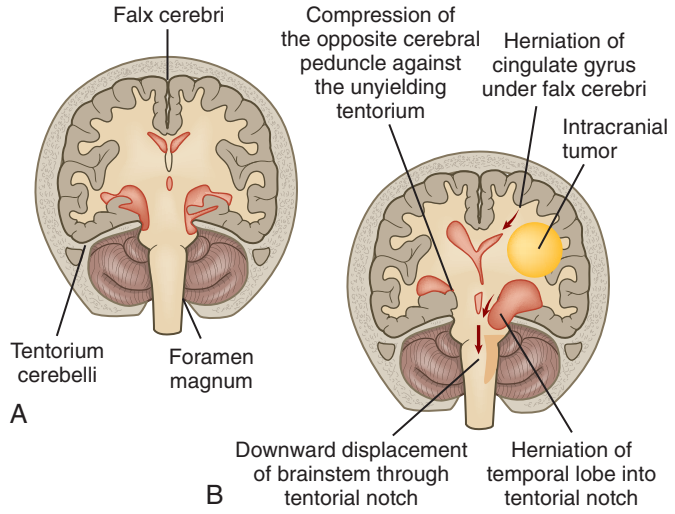

FIG. 57-4 Herniation. **A,** Normal relationship of intracranial structures. **B,** Shift of intracranial structures.

TABLE 57-2 CAUSES OF CEREBRAL EDEMA

Mass Lesions
- Brain abscess
- Brain tumor (primary or metastatic)
- Hematoma (intracerebral, subdural, epidural)
- Hemorrhage (intracerebral, cerebellar, brainstem)

Head Injuries and Brain Surgery
- Contusion
- Hemorrhage
- Posttraumatic brain swelling

Cerebral Infections
- Meningitis
- Encephalitis

Vascular Insult
- Anoxic and ischemic episodes
- Cerebral infarction (thrombotic or embolic)
- Venous sinus thrombosis

Toxic or Metabolic Encephalopathic Conditions
- Lead or arsenic intoxication
- Hepatic encephalopathy
- Uremia

Vasogenic Cerebral Edema. *Vasogenic cerebral edema,* the most common type of cerebral edema, occurs mainly in the white matter and is characterized by leakage of macromolecules from the capillaries into the surrounding extracellular space. This results in an osmotic gradient that favors the flow of fluid from the intravascular to the extravascular space. A variety of insults, such as brain tumors, abscesses, and ingested toxins, may cause an increase in the permeability of the blood-brain barrier and produce an increase in the extracellular fluid volume. The speed and extent of the spread of the edema fluid are influenced by the systemic BP, the site of the brain injury, and the extent of the blood-brain barrier defect.

This edema may produce a continuum of symptoms ranging from headache to disturbances in consciousness, including **coma** (profound state of unconsciousness) and focal neurologic deficits. It is important to recognize that although a headache may seem to be a benign symptom, in cases of cerebral edema it can quickly progress to coma and death. Therefore you must be vigilant in your assessment.

Cytotoxic Cerebral Edema. *Cytotoxic cerebral edema* results from disruption of the integrity of the cell membranes. It develops from destructive lesions or trauma to brain tissue resulting in cerebral hypoxia or anoxia and syndrome of inappropriate

antidiuretic hormone (SIADH) secretion. In this type of edema the blood-brain barrier remains intact, with cerebral edema occurring as a result of a fluid and protein shift from the extracellular space directly into the cells, with subsequent swelling and loss of cellular function.

Interstitial Cerebral Edema. *Interstitial cerebral edema* is usually a result of hydrocephalus. *Hydrocephalus* is a build up of fluid in the brain and is manifested by ventricular enlargement. It can be due to excess CSF production, obstruction of flow, or an inability to reabsorb the CSF. Hydrocephalus treatment usually consists of a ventriculostomy or ventriculoperitoneal shunt. (Management of hydrocephalus is discussed later in this chapter.)

Clinical Manifestations

The clinical manifestations of increased ICP can take many forms, depending on the cause, location, and rate of increases in ICP.

Change in Level of Consciousness. The *level of consciousness* (LOC) is the most sensitive and reliable indicator of the patient's neurologic status. Changes in LOC are a result of impaired CBF, which deprives the cells of the cerebral cortex and the reticular activating system (RAS) of oxygen. The RAS is located in the brainstem, with neural connections to many parts of the nervous system. An intact RAS can maintain a state of wakefulness even in the absence of a functioning cerebral cortex. Interruptions of impulses from the RAS or alterations in functioning of the cerebral hemispheres can cause **unconsciousness** (abnormal state of complete or partial unawareness of self or environment).

The patient's state of consciousness is defined by both the behavior and the pattern of brain activity recorded by an electroencephalogram (EEG). A change in consciousness may be dramatic, as in coma, or subtle, such as a flattening of affect, change in orientation, or decrease in level of attention. In the deepest state of unconsciousness (i.e., coma), the patient does not respond to painful stimuli. Corneal and pupillary reflexes are absent. The patient cannot swallow or cough and is incontinent of urine and feces. The EEG pattern demonstrates suppressed or absent neuronal activity.

Changes in Vital Signs. Changes in vital signs are caused by increasing pressure on the thalamus, hypothalamus, pons, and medulla. Manifestations such as *Cushing's triad* (systolic hypertension with a widening pulse pressure, bradycardia with a full and bounding pulse, and irregular respirations) may be present but often do not appear until ICP has been increased for some time or is suddenly and markedly increased (e.g., head trauma). Always recognize Cushing's triad as a medical emergency, since this is a sign of brainstem compression and impending death. A change in body temperature may also occur because increased ICP affects the hypothalamus.

Ocular Signs. Compression of cranial nerve (CN) III, the oculomotor nerve, results in dilation of the pupil on the same side *(ipsilateral)* as the mass lesion, sluggish or no response to light, inability to move the eye upward, and ptosis of the eyelid. These signs can be the result of the brain shifting from midline, compressing the trunk of CN III, and paralyzing the muscles controlling pupillary size and shape. In this situation, a fixed, unilateral, dilated pupil is considered a neurologic emergency that indicates herniation of the brain.

Other cranial nerves may also be affected, such as the optic (CN II), trochlear (CN IV), and abducens (CN VI) nerves. Signs of dysfunction of these cranial nerves include blurred vision, diplopia, and changes in extraocular eye movements. Central herniation may initially manifest as sluggish but equal pupil response. Uncal herniation may cause a dilated unilateral pupil. *Papilledema* (an edematous optic disc seen on retinal examination) is also noted and is a nonspecific sign associated with persistent increases in ICP.

Decrease in Motor Function. As the ICP continues to rise, the patient manifests changes in motor ability. A *contralateral* (opposite side of the mass lesion) hemiparesis or hemiplegia may develop, depending on the location of the source of the increased ICP. If painful stimuli are used to elicit a motor response, the patient may localize to the stimuli or withdraw from it.

Noxious stimuli may also elicit *decorticate* (flexor) or *decerebrate* (extensor) posturing (Fig. 57-5). Decorticate posture consists of internal rotation and adduction of the arms with flexion of the elbows, wrists, and fingers as a result of interruption of voluntary motor tracts in the cerebral cortex. Extension of the legs may also be seen. A decerebrate posture may indicate more serious damage and results from disruption of motor fibers in the midbrain and brainstem. In this position, the arms are stiffly extended, adducted, and hyperpronated. There is also hyperextension of the legs with plantar flexion of the feet.

Headache. Although the brain itself is insensitive to pain, compression of other intracranial structures, such as the walls of arteries and veins and the cranial nerves, can produce headache. The headache is often continuous but worse in the morning. Straining, agitation, or movement may accentuate the pain.

Vomiting. Vomiting, usually not preceded by nausea, is often a nonspecific sign of increased ICP. This is called unexpected

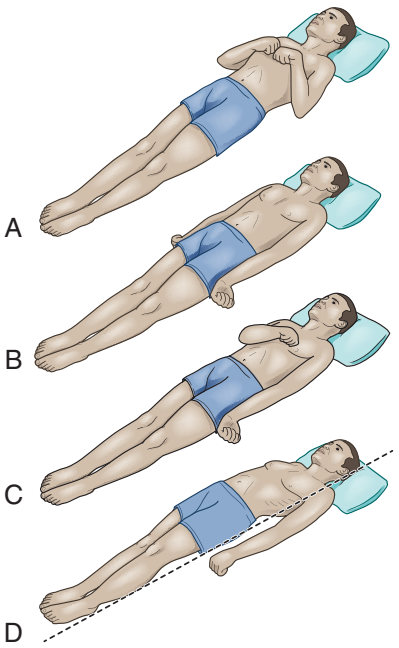

FIG. 57-5 Decorticate and decerebrate posturing. **A,** Decorticate response. Flexion of arms, wrists, and fingers with adduction in upper extremities. Extension, internal rotation, and plantar flexion in lower extremities. **B,** Decerebrate response. All four extremities in rigid extension, with hyperpronation of forearms and plantar flexion of feet. **C,** Decorticate response on right side of body and decerebrate response on left side of body. **D,** Opisthotonic posturing.

vomiting and is related to pressure changes in the cranium. Projectile vomiting may also occur and is related to increased ICP.

Complications

The major complications of uncontrolled increased ICP are inadequate cerebral perfusion and cerebral herniation (see Fig. 57-4). To better understand cerebral herniation, two important structures in the brain must be described. The *falx cerebri* is a thin wall of dura that folds down between the cortex, separating the two cerebral hemispheres. The *tentorium cerebelli* is a rigid fold of dura that separates the cerebral hemispheres from the cerebellum (see Fig. 57-4). It is called the tentorium (meaning tent) because it forms a tentlike cover over the cerebellum.

Tentorial herniation (central herniation) occurs when a mass lesion in the cerebrum forces the brain to herniate downward through the opening created by the brainstem. *Uncal herniation* occurs when there is lateral and downward herniation. *Cingulate herniation* occurs when there is lateral displacement of brain tissue beneath the falx cerebri.

Diagnostic Studies

Diagnostic studies can identify the cause of increased ICP (Table 57-3). Computed tomography (CT) and magnetic resonance imaging (MRI) have revolutionized the diagnosis of increased ICP. These tests are used to differentiate the many conditions that can cause increased ICP and to assess the effect of treatment.

Additional tests include EEG, cerebral angiography, ICP measurement, brain tissue oxygenation measurement via the LICOX catheter (described later), transcranial Doppler studies, and evoked potential studies. Positron emission tomography (PET) is also used to diagnose the cause of increased ICP. In general, a lumbar puncture is not performed when increased ICP is suspected. The reason for this is that cerebral herniation could occur from the sudden release of the pressure in the skull from the area above the lumbar puncture.

In some institutions a hand-held Infrascanner can be used to detect life-threatening intracranial bleeding. The scanner directs a wavelength of light that can penetrate tissue and bone. Blood from intracranial hematomas absorbs the light differently than other areas of the brain.

TABLE 57-3 COLLABORATIVE CARE

Increased Intracranial Pressure

Diagnostic

- History and physical examination
- Vital signs, neurologic assessments, ICP measurements
- Skull, chest, and spinal x-ray studies
- CT scan, MRI, cerebral angiography, EEG, PET
- Transcranial Doppler studies
- Infrascanner
- ECG
- Evoked potential studies
- Laboratory studies, including CBC, coagulation profile, electrolytes, serum creatinine, ABGs, ammonia level, drug and toxicology screen, CSF analysis for protein, cells, glucose*

Collaborative Therapy

- Elevation of head of bed to 30 degrees with head in a neutral position
- Intubation and mechanical ventilation
- ICP monitoring
- Cerebral oxygenation monitoring ($PbtO_2$, $SjvO_2$)
- Maintenance of PaO_2 ≥100 mm Hg
- Maintenance of fluid balance and assessment of osmolality
- Maintenance of systolic arterial pressure between 100 and 160 mm Hg
- Maintenance of CPP >60 mm Hg
- Reduction of cerebral metabolism (e.g., high-dose barbiturates)
- Drug therapy
  - Osmotic diuretic (mannitol)
  - Hypertonic saline
  - Antiseizure drugs (e.g., phenytoin [Dilantin])
  - Corticosteroids (dexamethasone [Decadron]) for brain tumors, bacterial meningitis
  - Histamine (H_2)-receptor antagonist (e.g., cimetidine [Tagamet]) or proton pump inhibitor (e.g., pantoprazole [Protonix]) to prevent GI ulcers and bleeding

*A lumbar puncture to obtain CSF for analysis should not be done if there is a possibility of herniation.

CPP, Cerebral perfusion pressure; *ICP,* intracranial pressure; *PaO_2,* partial pressure of oxygen in arterial blood; *$PbtO_2$,* pressure of oxygen in brain tissue; *$SjvO_2$,* jugular venous oxygen saturation.

Monitoring Intracranial Pressure and Cerebral Oxygenation

Indications for Intracranial Pressure Monitoring. ICP monitoring is used to guide clinical care when the patient is at risk for or has elevations in ICP. It may be used in patients with a variety of neurologic insults, including hemorrhage, stroke, tumor, infection, or traumatic brain injury. ICP should be monitored in patients admitted with a Glasgow Coma Scale (GCS) score of 8 or less and an abnormal CT scan or MRI (hematomas, contusion, edema). (The GCS is presented later in Table 57-5.)

Methods of Measuring Intracranial Pressure. Patients with conditions known to elevate ICP, except those with irreversible problems or advanced neurologic disease, usually undergo ICP monitoring in an ICU. Multiple methods and devices are available to monitor ICP in various sites (Fig. 57-6).

The gold standard for monitoring ICP is the *ventriculostomy,* in which a specialized catheter is inserted into the lateral ventricle and coupled to an external transducer (Figs. 57-7 and 57-8). This technique directly measures the pressure within the ventricles, facilitates removal and/or sampling of CSF, and allows for intraventricular drug administration. In this system the transducer is external, and it is important to ensure that the transducer of the ventriculostomy is level with the foramen of Monro (interventricular foramen). The ventriculostomy system must also be at the ideal height (Fig. 57-9, *A*). A reference point

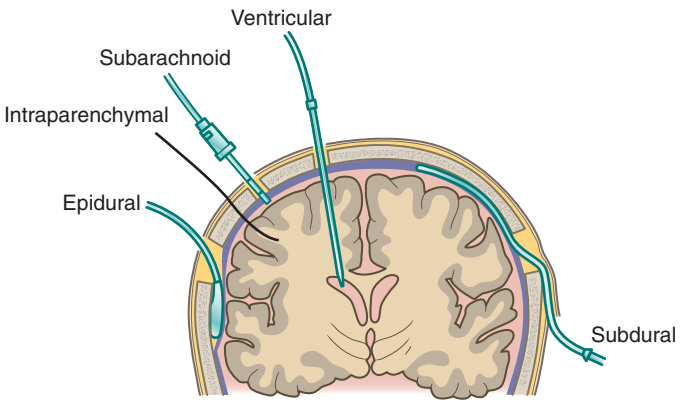

FIG. 57-6 Coronal section of brain showing potential sites for placement of intracranial pressure monitoring devices.

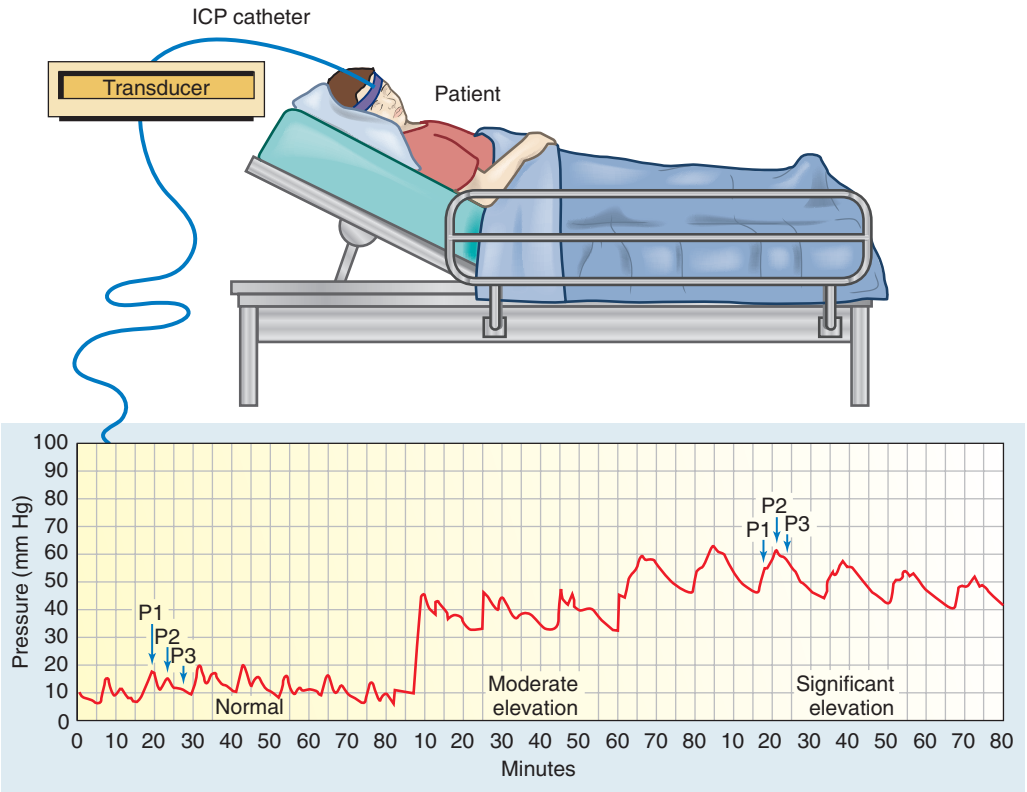

FIG. 57-7 Intracranial pressure *(ICP)* monitoring can be used to continuously measure ICP. The ICP tracing shows normal, elevated, and plateau waves. At high ICP the P2 peak is higher than the P1 peak, and the peaks become less distinct and plateau.

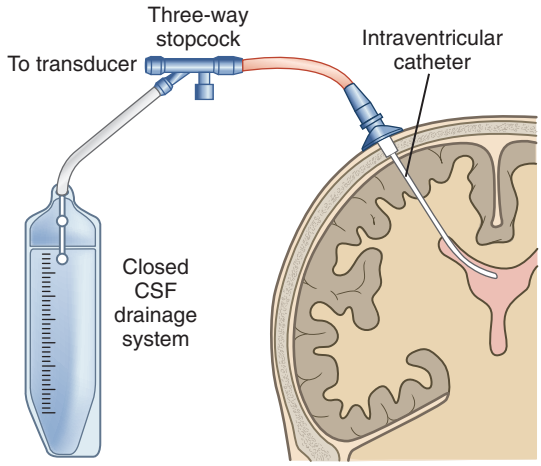

FIG. 57-8 Ventriculostomy in place. Cerebrospinal fluid *(CSF)* can be drained via a ventriculostomy when intracranial pressure (ICP) exceeds the upper pressure parameter set by the physician. Intermittent drainage involves opening the three-way stopcock to allow CSF to flow into the drainage bag for brief periods (30 to 120 seconds) until the pressure is below the upper pressure parameters.

TABLE 57-4 NORMAL INTRACRANIAL PRESSURE WAVEFORMS*

Waveform	Meaning
P1 Percussion wave	Represents arterial pulsations. Normally the highest of the three waveforms.
P2 Rebound wave or tidal wave	Reflects intracranial compliance or relative brain volume. When P2 is higher than P1, intracranial compliance is compromised.
P3 Dicrotic wave	Follows dicrotic notch. Represents venous pulsations. Normally the lowest waveform.

*See Fig. 57-7.

for this foramen is the tragus of the ear. Every time the patient is repositioned, the system needs assessed to ensure it is level.

The *fiberoptic catheter,* an alternative technology, uses a sensor transducer located within the catheter tip. The sensor tip is placed within the ventricle or the brain tissue and provides a direct measurement of brain pressure.

The *subarachnoid bolt* or *screw* is another method of monitoring ICP. It is placed just through the skull between the arachnoid membrane and the cerebral cortex. It does not allow for CSF drainage but is ideal for patients with mild or moderate head injury. It can easily be converted into a ventriculostomy if the patient decompensates.

Infection is a serious complication with ICP monitoring. Factors that contribute to the development of infection include ICP monitoring more than 5 days, use of a ventriculostomy, a CSF leak, and a concurrent systemic infection. Routinely assessing the insertion site, using aseptic technique, and monitoring the CSF for a change in drainage color or clarity are important nursing interventions.

ICP should be measured as a mean pressure. If a CSF drainage device is in place, the drain must be closed for at least 6 minutes to ensure an accurate reading. Record the waveform strip along with other pressure monitoring waveforms. The normal ICP waveform has three phases (see Fig. 57-7 and Table 57-4). It is important to monitor the ICP waveform, as well as

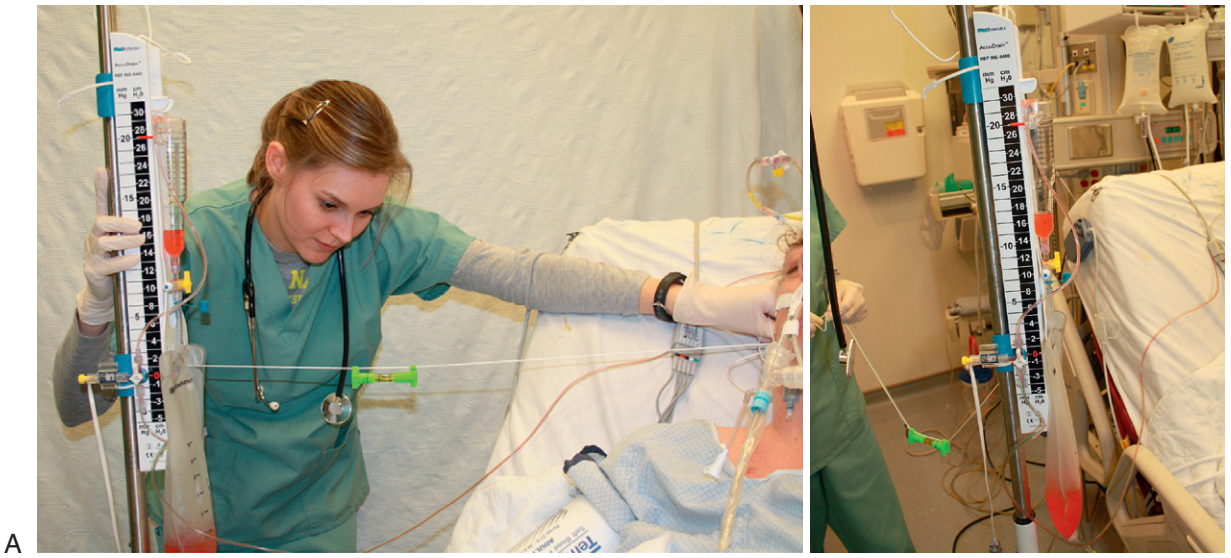

FIG. 57-9 **A,** Leveling a ventriculostomy. **B,** Cerebrospinal fluid is drained into a drainage system.

the mean CPP. When ICP is normal, P1, P2, and P3 resemble a staircase.[6] As ICP increases, P2 rises above P1, indicating poor ventricular compliance (see Fig. 57-7). Consider the rate at which changes occur and the patient's clinical condition. Neurologic deterioration might not occur until ICP elevation is pronounced and sustained. Immediately report to the health care provider any ICP elevation, either as a mean increase in pressure or as an abnormal waveform configuration.

Inaccurate ICP readings can be caused by CSF leaks around the monitoring device, obstruction of the intraventricular catheter or bolt (from tissue or blood clot), a difference between the height of the bolt and the transducer, kinks in the tubing, and incorrect height of the drainage system relative to the patient's reference point. Bubbles or air in the tubing can also dampen the waveform.

Cerebrospinal Fluid Drainage. With the ventricular catheter, it is possible to control ICP by removing CSF (see Fig. 57-8). The physician typically orders a specific level at which to initiate drainage (e.g., if ICP is greater than 20 mm Hg) and the frequency of drainage (intermittent or continuous). When the ICP is above the indicated level, the ventriculostomy system is opened by turning a stopcock and allowing the drainage of CSF, thus relieving pressure inside the cranial vault (see Fig. 57-9, *B*).

The two options for CSF drainage are intermittent or continuous. If intermittent drainage is ordered, open the ventriculostomy system at the indicated ICP and allow CSF to drain for 2 to 3 minutes. Then close the stopcock to return the ventriculostomy to a closed system. If continuous ICP drainage is ordered, careful monitoring of the volume of CSF drained is essential, keeping in mind that normal CSF production is about 20 to 30 mL/hr, with a total CSF volume of 90 to 150 mL within the ventricles and subarachnoid space. It is also recommended that a sign be posted above the patient's bed to notify anyone before turning, moving, or suctioning the patient to prevent the removal of too much CSF, which can result in other complications.

Strict aseptic technique during dressing changes or sampling of CSF is imperative to prevent infection. The system must remain intact to ensure that the ICP readings are accurate because treatment is initiated based on the pressures.

Complications of this type of drainage system include ventricular collapse, infection, and herniation or subdural hematoma formation from rapid decompression. Although it is generally recognized that CSF removal decreases ICP and improves CPP, guidelines for CSF removal are not universally accepted, but are typically based on institution or physician preference.[7]

Cerebral Oxygenation Monitoring. Technology is available to measure cerebral oxygenation and assess perfusion. Two such devices used in ICU settings are the *LICOX brain tissue oxygenation catheter* and the *jugular venous bulb catheter.* The LICOX catheter, which measures brain oxygenation and temperature, is placed in viable (healthy) white matter of the brain (Fig. 57-10). The LICOX system provides continuous monitoring of the pressure of oxygen in brain tissue ($PbtO_2$). The normal range for $PbtO_2$ is 20 to 40 mm Hg. A lower than normal $PbtO_2$ level is indicative of ischemia. Another advantage of the LICOX catheter is the ability to measure brain temperature. A cooler brain temperature (96.8° F [36° C]) may produce better outcomes.[8]

The jugular venous bulb catheter is placed in the internal jugular vein and positioned so that the catheter tip is located in the jugular bulb. Placement is verified by an x-ray. This catheter provides a measurement of jugular venous oxygen saturation ($SjvO_2$), which indicates total venous brain tissue extraction of oxygen. This is a measure of cerebral oxygen supply and demand. The normal $SjvO_2$ range is 55% to 75%. Values less than 50% demonstrate impaired cerebral oxygenation.

Collaborative Care

The goals of collaborative care (see Table 57-3) are to identify and treat the underlying cause of increased ICP and to support brain function. The earlier the condition is recognized and treated, the better the patient outcome. A careful history is an important diagnostic aid in the search for the underlying cause. The underlying cause of increased ICP is usually an increase in blood (hemorrhage), brain tissue (tumor or edema), or CSF (hydrocephalus) in the brain.

For any patient with increased ICP, it is important to maintain adequate oxygenation to support brain function. An endo-

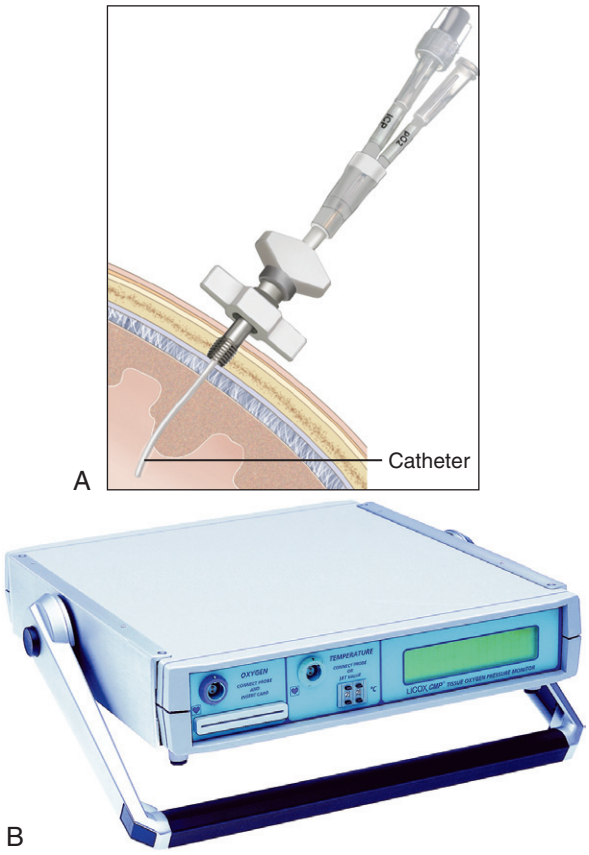

FIG. 57-10 A, The LICOX brain tissue oxygen system involves a catheter inserted through an intracranial bolt. **B,** The system measures oxygen in the brain ($PbtO_2$), brain tissue temperature, and intracranial pressure. (**B,** Permission granted by Integra LifeSciences Corporation, Plainsboro, NJ.)

tracheal tube or tracheostomy may be necessary to maintain adequate ventilation. Arterial blood gas (ABG) analysis guides the oxygen therapy. The goal is to maintain the PaO_2 at greater than or equal to 100 mm Hg and to keep $PaCO_2$ in normal range at 35 to 45 mm Hg. The patient may need to be on a mechanical ventilator to ensure adequate oxygenation.

If increased ICP is caused by a mass lesion (e.g., tumor, hematoma), surgical removal of the mass is the best treatment (see the sections on brain tumors and cranial surgery later in this chapter). Nonsurgical intervention for the reduction of tissue volume related to cerebral tissue swelling and cerebral edema includes the use of diuretics and corticosteroids. In aggressive situations, a craniectomy (removal of part of skull) may be performed to reduce ICP and prevent herniation (see head injury section for further details).

Drug Therapy. Drug therapy plays an important part in the management of increased ICP. Mannitol (Osmitrol) (25%) is an osmotic diuretic given IV. Mannitol acts to decrease the ICP in two ways: plasma expansion and osmotic effect. The immediate plasma-expanding effect reduces the hematocrit and blood viscosity, thereby increasing CBF and cerebral oxygen delivery. A vascular osmotic gradient is created by mannitol. Thus fluid moves from the tissues into the blood vessels, reducing the ICP because of the decrease in the total brain fluid content. Monitor fluid and electrolyte status when osmotic diuretics are used. Mannitol may be contraindicated if renal disease is present and if serum osmolality is elevated.[5]

Hypertonic saline solution is another drug treatment used to manage increased ICP. It produces massive movement of water out of edematous swollen brain cells and into the blood vessels. This movement of water out of the brain can reduce swelling and improve cerebral blood flow. Hypertonic solution infusion requires frequent monitoring of blood pressure and serum sodium levels because intravascular fluid volume excess can occur. Hypertonic saline infusion has been shown to be just as effective as mannitol when treating increased ICP, and both are often used concurrently when caring for a patient with a severe head injury.[9]

Corticosteroids (e.g., dexamethasone [Decadron]) are used to treat vasogenic edema surrounding tumors and abscesses. However, these drugs are not recommended for head-injured patients. Corticosteroids stabilize the cell membrane and inhibit the synthesis of prostaglandins (see Fig. 12-2), thus preventing the formation of proinflammatory mediators. Corticosteroids also improve neuronal function by improving CBF and restoring autoregulation.

Complications associated with the use of corticosteroids include hyperglycemia, increased incidence of infections, and gastrointestinal (GI) bleeding. Regularly monitor fluid intake and sodium levels, and perform blood glucose monitoring at least every 6 hours until hyperglycemia is ruled out. Patients receiving corticosteroids should concurrently be given antacids or histamine (H_2)-receptor blockers (e.g., cimetidine [Tagamet], ranitidine [Zantac]) or proton pump inhibitors (e.g., omeprazole [Prilosec], pantoprazole [Protonix, Protonix IV]) to prevent GI ulcers and bleeding.

Metabolic demands such as fever (greater than 100.4° F [38° C]), agitation or shivering, pain, and seizures can also increase ICP. The health care team should plan to reduce these metabolic demands to lower the ICP in the at-risk patient. Monitor patients for seizure activity. They may need to be placed on prophylactic antiseizure medication. Fever should be well controlled to maintain a temperature of 96.8° to 98.6° F (36° to 37° C) by using antipyretics (e.g., acetaminophen), cool baths, cooling blankets, ice packs, or intravascular cooling devices as necessary. However, avoid letting the patient shiver or shake, since this increases the metabolic workload on the brain. If this occurs, sedatives may be needed or a different cooling method selected.

Manage pain while being careful not to oversedate or overmedicate. Finally, the patient should remain in a quiet, calm environment with minimal noise and interruptions. Observe the patient for signs of agitation, irritation, or frustration. Also teach the caregiver and the family about decreasing stimulation, and coordinate with the health care team to minimize procedures that may produce agitation.

Drug therapy for reducing cerebral metabolism may be an effective strategy to control ICP. Reducing the metabolic rate decreases the CBF and therefore the ICP. High doses of barbiturates (e.g., pentobarbital [Nembutal], thiopental [Pentothal]) are used in patients with increased ICP refractory to other treatments. Barbiturates decrease cerebral metabolism, causing a decrease in ICP and a reduction in cerebral edema.[5] When this treatment is used, monitor the patient's ICP, blood flow, and EEG. Barbiturate dosing is typically based on analysis of the bedside EEG tracing and the ICP. The physician orders the

barbiturate infusion at a rate that achieves a desired level of brain wave suppression as a means to control ICP. Total *burst suppression,* recognized by the absence of spikes showing brain activity on the EEG monitor, indicates that maximal therapeutic effect has been achieved.[5]

Nutritional Therapy. Patients must have their nutritional needs met, regardless of their state of consciousness. Because malnutrition promotes continued cerebral edema, maintenance of optimal nutrition is imperative. The patient with increased ICP is in a hypermetabolic and hypercatabolic state that increases the need for glucose as fuel for metabolism of the injured brain. If the patient cannot maintain an adequate oral intake, other means of meeting the nutritional requirements, such as enteral feedings or parenteral nutrition, should be initiated.

Early feeding after brain injury may improve patient outcome.[10] Nutritional replacement should begin within 3 days after injury to reach full nutritional replacement within 7 days after the injury is sustained.[10] (Nutritional therapy is discussed in Chapter 40.) Feedings or supplements should be guided by the patient's fluid and electrolyte status and metabolic needs. The patient should remain in a normovolemic fluid state. Continuously evaluate the patient based on clinical factors such as urine output, insensible fluid loss, serum and urine osmolality, and serum electrolytes.

IV 0.9% sodium chloride is the preferred solution for administration of piggyback medications. If 5% dextrose in water or 0.45% sodium chloride is used, serum osmolarity decreases and an increase in cerebral edema may occur.

NURSING MANAGEMENT INCREASED INTRACRANIAL PRESSURE

NURSING ASSESSMENT

Subjective data about the patient with increased ICP can be obtained from the patient, caregiver, or family who are familiar with the patient. Learn appropriate neurologic assessment techniques. Describe the LOC by noting the specific behaviors observed. When a deviation from the normal state of consciousness occurs, use a more structured method of observation. This type of systematic approach to nursing assessment is illustrated in eFig. 57-1 (available on the website for this chapter). Assess the LOC using the Glasgow Coma Scale (Table 57-5). Also assess body functions, especially circulation and respiration.

GLASGOW COMA SCALE. The **Glasgow Coma Scale (GCS)** is a quick, practical, and standardized system for assessing the LOC. The three areas assessed in the GCS are the patient's ability to (1) speak, (2) obey commands, and (3) open the eyes when a verbal or painful stimulus is applied. Specific assessments evaluate the patient's response to varying degrees of stimulus. Three indicators of response are evaluated: (1) opening of the eyes, (2) the best verbal response, and (3) the best motor response (see Table 57-5).

Specific behaviors observed as responses to the testing stimulus are given a numeric value. Your responsibility is to elicit the best response on each of the scales: the higher the scores, the higher the level of brain functioning. The subscale scores are particularly important if a patient is untestable in one area. For example, severe periorbital edema may make eye opening impossible.

TABLE 57-5 GLASGOW COMA SCALE

Appropriate Stimulus	Response	Score
Eyes Open		
• Approach to bedside • Verbal command • Pain	Spontaneous response.	4
	Opening of eyes to name or command.	3
	Lack of opening of eyes to previous stimuli but opening to pain.	2
	Lack of opening of eyes to any stimulus.	1
	Untestable.*	U
Best Verbal Response		
• Verbal questioning with maximum arousal	Appropriate orientation, conversant. Correct identification of self, place, yr, and mo.	5
	Confusion. Conversant, but disorientation in one or more spheres.	4
	Inappropriate or disorganized use of words (e.g., cursing), lack of sustained conversation.	3
	Incomprehensible words, sounds (e.g., moaning).	2
	Lack of sound, even with painful stimuli.	1
	Untestable.*	U
Best Motor Response		
• Verbal command (e.g., "raise your arm, hold up two fingers")	Obedience of command.	6
	Localization of pain, lack of obedience but presence of attempts to remove offending stimulus.	5
• Pain (pressure on proximal nail bed)	Flexion withdrawal,* flexion of arm in response to pain without abnormal flexion posture.	4
	Abnormal flexion, flexing of arm at elbow and pronation, making a fist.	3
	Abnormal extension, extension of arm at elbow usually with adduction and internal rotation of arm at shoulder.	2
	Lack of response.	1
	Untestable.*	U

*Added to the original scale by some centers.

The total GCS score is the sum of the numeric values assigned to each of the three areas evaluated. The highest GCS score is 15 for a fully alert person, and the lowest possible score is 3. A GCS score of 8 or less generally indicates coma. Plot the results of the GCS scores on a graph, which can be used to determine whether the patient is stable, improving, or deteriorating.

The GCS offers several advantages in the assessment of the unconscious patient. It allows different health care professionals to arrive at the same conclusion regarding the patient's status and can be used to discriminate between different or changing states.

Although the GCS is the gold standard assessment tool for LOC, other scales are also used in the clinical setting.[11] In cases of stroke or hemorrhage associated with increased ICP, use the NIH Stroke Scale (see Table 58-9). Other components of the neurologic assessment include cranial nerve assessment and motor and sensory testing.

NEUROLOGIC ASSESSMENT. Compare the pupils with one another for size, shape, movement, and reactivity (Fig. 57-11).

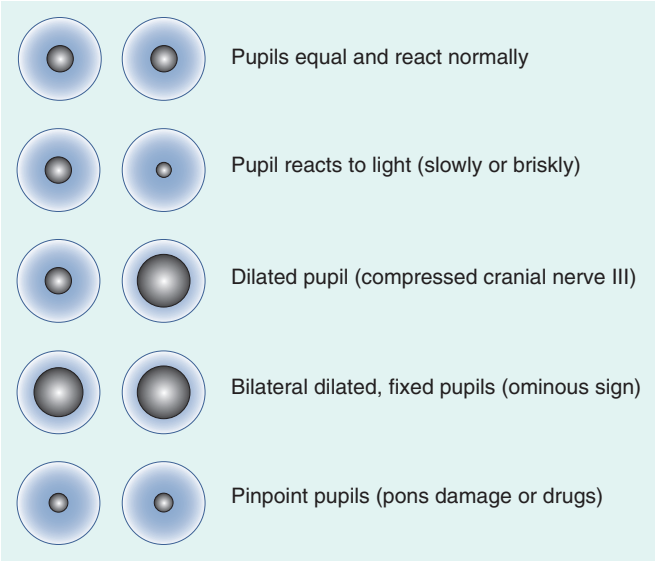

FIG. 57-11 Pupillary check for size and response.

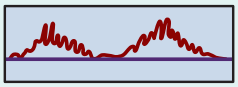

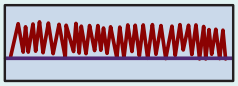

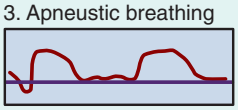

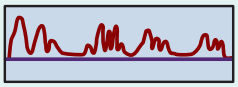

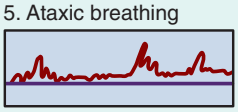

Pattern	Location of Lesion	Description
1. Cheyne-Stokes 	Bilateral hemispheric disease or metabolic brain dysfunction	Cycles of hyperventilation and apnea
2. Central neurogenic hyperventilation 	Brainstem between lower midbrain and upper pons	Sustained, regular rapid and deep breathing
3. Apneustic breathing 	Mid or lower pons	Prolonged inspiratory phase or pauses alternating with expiratory pauses
4. Cluster breathing 	Medulla or lower pons	Clusters of breaths follow each other with irregular pauses between
5. Ataxic breathing 	Reticular formation of the medulla	Completely irregular with some breaths deep and some shallow. Random, irregular pauses, slow rate

FIG. 57-12 Common abnormal respiratory patterns associated with coma.

If the oculomotor nerve (CN III) is compressed, the pupil on the affected side (ipsilateral) becomes larger until it fully dilates. If ICP continues to increase, both pupils dilate.

Test pupillary reaction with a penlight. The normal reaction is brisk constriction when the light is shone directly into the eye. Also note a consensual response (a slight constriction in the opposite pupil) at the same time. A sluggish reaction can indicate early pressure on CN III. A fixed pupil unresponsive to light stimulus usually indicates increased ICP. However, note that there are other causes of a fixed pupil, including direct injury to CN III, previous eye surgery, administration of atropine, and use of mydriatic eyedrops.

Evaluation of other cranial nerves can be included in the neurologic assessment. Eye movements controlled by CN III, IV, and VI can be examined in the patient who is awake and able to follow commands, and can be used to assess the function of the brainstem. Testing the corneal reflex gives information about the functioning of CN V and VII. If this reflex is absent, initiate routine eye care to prevent corneal abrasion (see Chapters 21 and 22).

Eye movements of the uncooperative or unconscious patient can be elicited by reflex with the use of head movements (oculocephalic) and caloric stimulation (oculovestibular) (see Chapters 21 and 22). To test the oculocephalic reflex (doll's eye reflex), turn the patient's head briskly to the left or right while holding the eyelids open. A normal response is movement of the eyes across the midline in the direction opposite that of the turning. Next, quickly flex and then extend the neck. Eye movement should be opposite to the direction of head movement—up when the neck is flexed and down when it is extended. Abnormal responses can help locate the intracranial lesion. This test should not be attempted if a cervical spine problem is suspected. (The oculovestibular reflex is discussed in Chapter 21.)

Test motor strength by asking the awake and cooperative patient to squeeze your hands to compare strength in the hands. The palmar drift test is an excellent measure of strength in the upper extremities. The patient raises the arms in front of the body with the palms facing upward. If there is any weakness in the upper extremity, the palmar surface turns downward and the arm drifts down. Asking the patient to raise the foot from the bed or to bend the knees up in bed is a good assessment of lower extremity strength. Test all four extremities for strength and for any asymmetry in strength or movement.

Assess the motor response of the unconscious or uncooperative patient by observation of spontaneous movement. If no spontaneous movement is possible, apply a pain stimulus to the patient, and note the response. Resistance to movement during passive range-of-motion exercises is another measure of strength. Do not include hand squeezing as part of the assessment of motor movement in the unconscious or uncooperative patient, since this is a reflex action and can misrepresent the patient's status.

Also record the vital signs, including BP, pulse, respiratory rate, and temperature. Be aware of Cushing's triad, which indicates severely increased ICP. Besides recording respiratory rate, also note the respiratory pattern. Specific respiratory patterns are associated with severely increased ICP (Fig. 57-12).

NURSING DIAGNOSES

Nursing diagnoses for the patient with increased ICP include, but are not limited to, the following:

- Decreased intracranial adaptive capacity *related to* decreased cerebral perfusion or increased ICP
- Risk for ineffective cerebral tissue perfusion *related to* reduction of venous and/or arterial blood flow and cerebral edema
- Risk for disuse syndrome *related to* altered LOC, immobility, and altered nutritional intake

Additional information on nursing diagnoses for patients with increased ICP is presented in eNursing Care Plan 57-1 (available on the website for this chapter).

PLANNING

The overall goals for the patient with increased ICP are to (1) maintain a patent airway; (2) have ICP within normal limits; (3) have normal fluid, electrolyte, and nutritional balance; and (4) prevent complications secondary to immobility and decreased LOC.

NURSING IMPLEMENTATION

ACUTE INTERVENTION

Respiratory Function. Maintaining a patent airway is critical in the patient with increased ICP and is a primary nursing responsibility. As the LOC decreases, the patient is at an increased risk of airway obstruction from the tongue dropping back and occluding the airway or from accumulation of secretions.

SAFETY ALERT

- Be alert to altered breathing patterns.
- Snoring sounds indicate obstruction and require immediate intervention.

Remove accumulated secretions by suctioning as needed. An oral airway facilitates breathing and provides an easier suctioning route in the comatose patient. In general, any patient with a GCS of 8 or less or an altered LOC who is unable to maintain a patent airway or effective ventilation needs intubation and mechanical ventilation.

Prevent hypoxia and hypercapnia to minimize secondary injury. Proper positioning of the head is important. Elevation of the head of the bed to 30 degrees enhances respiratory exchange and aids in decreasing cerebral edema. Suctioning and coughing cause transient decreases in the PaO_2 and increases in the ICP. Keep suctioning to a minimum and less than 10 seconds in duration, with administration of 100% oxygen before and after to prevent decreases in the PaO_2. To avoid cumulative increases in the ICP with suctioning, limit suctioning to two passes per suction procedure, if possible. Patients with elevated ICP are at risk for lower CPP during suctioning. CPP must be maintained above 60 mm Hg to preserve cerebral perfusion.

Try to prevent abdominal distention, since it can interfere with respiratory function. Insertion of a nasogastric tube to aspirate the stomach contents can prevent distention, vomiting, and possible aspiration. However, in patients with facial and skull fractures, a nasogastric tube is contraindicated unless a basilar skull fracture (at base of skull) has been ruled out, and oral insertion of a gastric tube is preferred.

Pain, anxiety, and fear related to the primary injury, therapeutic procedures, or noxious stimuli can increase ICP and BP, thus complicating the management and recovery of the brain-injured patient. The appropriate choice or combination of sedatives, paralytics, and analgesics for symptom management presents a challenge to the ICU team. Administration of these agents may alter the neurologic state, thus masking true neurologic changes. It may be necessary to temporarily suspend drug therapy to appropriately assess neurologic status. The choice, dose, and combination of agents may vary depending on the patient's history, neurologic state, and overall clinical presentation.

Opioids, such as morphine sulfate and fentanyl (Sublimaze), are rapid-onset analgesics with minimal effect on CBF or oxygen metabolism. The IV anesthetic sedative propofol (Diprivan) has gained popularity in the management of anxiety and agitation in the ICU because of its rapid onset and short half-life. An accurate neurologic assessment can be performed soon after turning off the infusion of propofol.[5] A side effect of this drug is hypotension.

Dexmedetomidine (Precedex), an α_2-adrenergic agonist, is used for continuous IV sedation of intubated and mechanically ventilated patients in the ICU setting for up to 24 hours. It is another ideal agent for neurologic patients because of the ease in obtaining a neurologic assessment without altering the dose because of its anxiolytic properties. When using continuous IV sedatives, be aware of the side effects of these drugs, especially hypotension, since this can result in a lower CPP value.

Nondepolarizing neuromuscular blocking agents (e.g., vecuronium [Norcuron], cisatracurium besylate [Nimbex]) are useful for achieving complete ventilatory control in the treatment of refractory intracranial hypertension. Because these agents paralyze muscles without blocking pain or noxious stimuli, they are used in combination with sedatives, analgesics, or benzodiazepines.

Benzodiazepines, although useful for sedation, are usually avoided in the management of the patient with increased ICP because of the hypotensive effect and long half-life, unless they are used as an adjunct to neuromuscular blocking agents.

Frequently monitor and evaluate the ABG values, and take measures to maintain the levels within prescribed or acceptable parameters (see Chapter 26). The appropriate ventilatory support can be ordered on the basis of the PaO_2 and $PaCO_2$ values.

Fluid and Electrolyte Balance. Fluid and electrolyte disturbances can have an adverse effect on ICP. Closely monitor IV fluids with the use of an accurate IV infusion control device or pump. Intake and output, with insensible losses and daily weights taken into account, are important parameters in the assessment of fluid balance.

Make electrolyte determinations daily, and discuss any abnormal values with the physician. It is especially important to monitor serum glucose, sodium, potassium, magnesium, and osmolality.

Monitor urine output to detect problems related to diabetes insipidus and SIADH. Diabetes insipidus is caused by a decrease in antidiuretic hormone (ADH). It results in increased urine output and hypernatremia. The usual treatment of diabetes insipidus is fluid replacement, vasopressin (Pitressin), or desmopressin acetate (DDAVP) (see Chapter 50). If it is not treated, severe dehydration will occur.

SIADH is caused by an excess secretion of ADH. SIADH results in decreased urine output and dilutional hyponatremia. It may result in cerebral edema, changes in LOC, seizures, and coma. (Treatment of SIADH is described in Chapter 50.)

Monitoring Intracranial Pressure. ICP monitoring is used in combination with other physiologic parameters to guide the care of the patient and assess the patient's response to treatment. Valsalva maneuver, coughing, sneezing, suctioning, hypoxemia, and arousal from sleep are factors that can increase ICP. Be alert to these factors and attempt to minimize them.

Body Position. Maintain the patient with increased ICP in the head-up position. Take care to prevent extreme neck flexion, which can cause venous obstruction and contribute to elevated ICP. Adjust the body position to decrease the ICP maximally and to improve the CPP. Elevation of the head of the bed promotes drainage from the head and decreases the vascular congestion that can produce cerebral edema. However, raising the head of the bed above 30 degrees may decrease the CPP by lowering systemic BP. Carefully evaluate the effects of elevation of the head of the bed on both the ICP and the CPP. Position

the bed so that it lowers the ICP while optimizing the CPP and other indices of cerebral oxygenation.

Take care to turn the patient with slow, gentle movements because rapid changes in position may increase the ICP. Prevent discomfort in turning and positioning the patient because pain or agitation also increases pressure. Increased intrathoracic pressure contributes to increased ICP by impeding the venous return. Thus coughing, straining, and the Valsalva maneuver should be avoided. Avoid extreme hip flexion to decrease the risk of raising the intraabdominal pressure, which increases ICP. Turn the patient at least every 2 hours.

Decorticate or decerebrate posturing is a reflex response in some patients with increased ICP. Turning, skin care, and even passive range of motion can elicit the posturing reflexes. Provide the physical care to minimize complications of immobility, such as atelectasis and contractures.

Protection From Injury. The patient with increased ICP and decreased LOC needs protection from self-injury. Confusion, agitation, and the possibility of seizures increase the risk for injury. Use restraints judiciously in the agitated patient. If restraints are absolutely necessary to keep the patient from removing tubes or falling out of bed, they should be secure enough to be effective, and the skin area under the restraints should be observed regularly for irritation. Agitation may increase with the use of restraints, which indicates the need for other measures to protect the patient from injury. Light sedation with agents such as midazolam (Versed) or lorazepam (Ativan) may be needed. Having a family member stay with the patient may have a calming effect.

For the patient with seizures or the patient at risk for such activity, institute seizure precautions. Seizures are most likely to occur in the first 7 days after traumatic injury, so prophylactic antiseizure therapy is usually used during this time.[12] Additional seizure precautions include padded side rails, an airway at the bedside, suction readily available, accurate and timely administration of antiseizure drugs, and close observation.

The patient can benefit from a quiet, nonstimulating environment. Always use a calm, reassuring approach. Touch and talk to the patient, even one who is in a coma.

Psychologic Considerations. In addition to carefully planned physical care, also be aware of the psychologic well-being of patients and their families. Anxiety over the diagnosis and the prognosis can be distressing to the patient, caregiver and family, and nursing staff. Your competent and assured manner in performing care is reassuring to everyone involved. Short, simple explanations are appropriate and allow the patient and caregiver to acquire the amount of information they desire. There is a need for support, information, and teaching of both patients and families. Assess the family members' desires to assist in providing care for the patient, and allow for their participation as appropriate. Encourage interdisciplinary management (social work, chaplain, etc.) of the patient and family in decision making as much as possible.

EVALUATION

The expected outcomes are that the patient with increased ICP will

- Maintain ICP and cerebral perfusion within normal parameters
- Experience no serious increases in ICP during or after care activities
- Experience no complications of immobility

Additional expected outcomes for the patient with increased ICP are addressed in eNursing Care Plan 57-1 (available on the website for this chapter).

HEAD INJURY

Head injury includes any injury or trauma to the scalp, skull, or brain. A serious form of head injury is *traumatic brain injury* (TBI). Statistics regarding the occurrence of head injuries are incomplete because many victims die at the injury scene or because the condition is considered minor and health care services are not sought. In U.S. hospital emergency departments, an estimated 1.7 million persons are treated and released with TBI. Fifty thousand people die and 275,000 persons are hospitalized with TBI. Of individuals hospitalized, 20% of the patients die.[13] At least 5.3 million Americans (2% of the U.S. population) currently live with disabilities resulting from TBI (*www.braintrauma.org*).

Motor vehicle collisions and falls are the most common causes of head injury. Other causes of head injury include firearms, assaults, sports-related trauma, recreational injuries, and war-related injuries.[14] Males are twice as likely to sustain a TBI as females.

Head trauma has a high potential for a poor outcome. Deaths from head trauma occur at three points after injury: immediately after the injury, within 2 hours after injury, and approximately 3 weeks after injury.[14] Factors that predict a poor outcome include an intracranial hematoma, older age of the patient, abnormal motor responses, impaired or absent eye movements or pupillary light reflexes, early sustained hypotension, hypoxemia or hypercapnia, and sustained ICP levels greater than 20 mm Hg.[15]

The GCS score on arrival at the hospital is also a strong predictor of survival. A GCS below 8 indicates a 30% to 70% chance of survival, and a score above 8 indicates a greater than 90% survival rate. The majority of deaths after a head injury occur immediately after the injury, either from the direct head trauma or from massive hemorrhage and shock. Deaths occurring within a few hours of the trauma are caused by progressive worsening of the head injury or internal bleeding. Immediate recognition of changes in neurologic status and rapid surgical intervention are critical in the prevention of deaths.[5]

Deaths occurring 3 weeks or more after the injury result from multisystem failure. Expert nursing care in the weeks after the injury is crucial in decreasing the mortality risk and in optimizing patient outcomes.

Types of Head Injuries

Scalp Lacerations. *Scalp lacerations* are an easily recognized type of external head trauma. Because the scalp contains many blood vessels with poor constrictive abilities, most scalp lacerations are associated with profuse bleeding. Even relatively small wounds can bleed significantly. The major complications associated with scalp laceration are blood loss and infection.

Skull Fractures. *Skull fractures* frequently occur with head trauma. Skull fractures can be described in several ways: (1) linear or depressed; (2) simple, comminuted, or compound; and (3) closed or open (Table 57-6). Fractures may be closed or open, depending on the presence of a scalp laceration or extension of the fracture into the air sinuses or dura. The type and severity of a skull fracture depend on the velocity, momentum,

TABLE 57-6 TYPES OF SKULL FRACTURES

Type	Description	Cause
Linear	Break in continuity of bone without alteration of relationship of parts	Low-velocity injuries
Depressed	Inward indentation of skull	Powerful blow
Simple	Linear or depressed skull fracture without fragmentation or communicating lacerations	Low to moderate impact
Comminuted	Multiple linear fractures with fragmentation of bone into many pieces	Direct, high-momentum impact
Compound	Depressed skull fracture and scalp laceration with communicating pathway to intracranial cavity	Severe head injury

TABLE 57-7 MANIFESTATIONS OF SKULL FRACTURES

Location	Manifestations
Frontal fracture	Exposure of brain to contaminants through frontal air sinus, possible association with air in forehead tissue, CSF rhinorrhea, or pneumocranium (air between the cranium and the dura mater)
Orbital fracture	Periorbital ecchymosis (raccoon eyes), optic nerve injury
Temporal fracture	Boggy temporal muscle because of extravasation of blood, oval-shaped bruise behind ear in mastoid region (Battle's sign), CSF otorrhea, middle meningeal artery disruption, epidural hematoma
Parietal fracture	Deafness, CSF or brain otorrhea, bulging of tympanic membrane caused by blood or CSF, facial paralysis, loss of taste, Battle's sign
Posterior fossa fracture	Occipital bruising resulting in cortical blindness, visual field defects, rare appearance of ataxia or other cerebellar signs
Basilar skull fracture	CSF or brain otorrhea, bulging of tympanic membrane caused by blood or CSF, Battle's sign, tinnitus or hearing difficulty, rhinorrhea, facial paralysis, conjugate deviation of gaze, vertigo

direction and shape (blunt or sharp) of the injuring agent, and site of impact.

The location of the fracture determines the clinical manifestations (Table 57-7). For example, a basilar skull fracture is a specialized type of linear fracture involving the base of the skull. Manifestations can evolve over the course of several hours; vary with the location and severity of fracture; and may include cranial nerve deficits, Battle's sign (postauricular ecchymosis), and periorbital ecchymosis (raccoon eyes) (Fig. 57-13). This fracture generally is associated with a tear in the dura and subsequent leakage of CSF. *Rhinorrhea* (CSF leakage from the nose) or *otorrhea* (CSF leakage from the ear) generally confirms that the fracture has traversed the dura (see Fig. 57-13). Rhinorrhea may also manifest as postnasal sinus drainage. The significance of rhinorrhea may be overlooked unless the patient is specifically assessed for this finding. The risk of meningitis is high with a CSF leak, and antibiotics should be administered as a preventive measure.

Two methods of testing can be used to determine whether the fluid leaking from the nose or ear is CSF. The first method

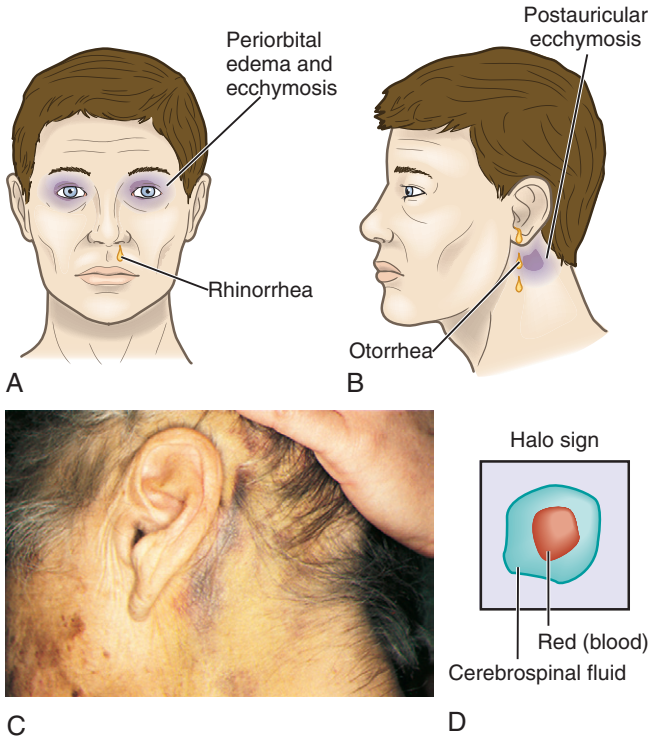

FIG. 57-13 **A,** Raccoon eyes and rhinorrhea. **B,** Battle's sign (postauricular ecchymosis) with otorrhea. **C,** Battle's sign. **D,** Halo or ring sign (see text).

is to test the leaking fluid with a Dextrostix or Tes-Tape strip to determine whether glucose is present. CSF gives a positive reading for glucose. If blood is present in the fluid, testing for glucose is unreliable because blood also contains glucose. In this event, look for the *halo* or *ring* sign (see Fig. 57-13, *D*). Allow the leaking fluid to drip onto a white gauze pad (4 × 4) or towel, and then observe the drainage. Within a few minutes, the blood coalesces into the center, and a yellowish ring encircles the blood if CSF is present. Note the color, appearance, and amount of leaking fluid because both tests can give false-positive results.

The major potential complications of skull fractures are intracranial infections, hematoma, and meningeal and brain tissue damage. Note that in cases where a basilar skull fracture is suspected, a nasogastric or oral gastric tube should be inserted under fluoroscopy.

Head Trauma. Brain injuries are categorized as diffuse (generalized) or focal (localized). In a *diffuse* injury (e.g., concussion, diffuse axonal injury), damage to the brain cannot be localized to one particular area. In a *focal injury* (e.g., contusion, hematoma), damage can be localized to a specific area of the brain. Brain injury can be classified as *minor* (GCS 13 to 15), *moderate* (GCS 9 to 12), and *severe* (GCS 3 to 8).

Diffuse Injury. **Concussion** (a sudden transient mechanical head injury with disruption of neural activity and a change in the LOC) is considered a minor diffuse head injury. The patient may or may not lose total consciousness with this injury.

Typical signs of concussion include a brief disruption in LOC, amnesia regarding the event (retrograde amnesia), and headache. The manifestations are generally of short duration. If the patient has not lost consciousness, or if the loss of consciousness lasts less than 5 minutes, the patient is usually discharged from the care facility with instructions to notify

the health care provider if symptoms persist or if behavioral changes are noted.

Postconcussion syndrome may develop in some patients, usually anywhere from 2 weeks to 2 months after the injury. Symptoms include persistent headache, lethargy, personality and behavioral changes, shortened attention span, decreased short-term memory, and changes in intellectual ability. This syndrome can significantly affect the patient's abilities to perform activities of daily living.

Although concussion is generally considered benign and usually resolves spontaneously, the symptoms may be the beginning of a more serious, progressive problem, especially in a patient with a history of prior concussion or head injury. At the time of discharge, it is important to give the patient and the caregiver instructions for observation and accurate reporting of symptoms or changes in neurologic status.

Diffuse Axonal Injury. **Diffuse axonal injury (DAI)** is widespread axonal damage occurring after a mild, moderate, or severe TBI. The damage occurs primarily around axons in the subcortical white matter of the cerebral hemispheres, basal ganglia, thalamus, and brainstem.[16] Initially, DAI was believed to occur from the tensile forces of trauma that sheared axons, resulting in axonal disconnection. There is increasing evidence that axonal damage is not preceded by an immediate tearing of the axon from the traumatic impact, but rather the trauma changes the function of the axon, resulting in axon swelling and disconnection. This process takes approximately 12 to 24 hours to develop and may persist longer.

The clinical signs of DAI are varied, but may include a decreased LOC, increased ICP, decortication or decerebration, and global cerebral edema. Approximately 90% of patients with DAI remain in a persistent vegetative state.[17] Patients with DAI who survive the initial event are rapidly triaged to an ICU, where they will be vigilantly watched for signs of increased ICP and treated accordingly (as previously discussed).

Focal Injury. Focal injury can be minor to severe and can be localized to an area of injury. Focal injury consists of lacerations, contusions, hematomas, and cranial nerve injuries.

Lacerations involve actual tearing of the brain tissue and often occur in association with depressed and open fractures and penetrating injuries. Tissue damage is severe, and surgical repair of the laceration is impossible because of the nature of brain tissue. Medical management consists of antibiotics until meningitis is ruled out, and prevention of secondary injury related to increased ICP. If bleeding is deep into the brain tissue, focal and generalized signs develop.

When major head trauma occurs, many delayed responses are seen, including hemorrhage, hematoma formation, seizures, and cerebral edema. Intracerebral hemorrhage is generally associated with cerebral laceration. This hemorrhage manifests as a space-occupying lesion accompanied by unconsciousness, hemiplegia on the contralateral side, and a dilated pupil on the ipsilateral side. As the hematoma expands, signs of increased ICP become more severe. Prognosis is generally poor for the patient with a large intracerebral hemorrhage. Subarachnoid hemorrhage and intraventricular hemorrhage can also occur secondary to head trauma.

A **contusion** is bruising of the brain tissue within a focal area. It is usually associated with a closed head injury. A contusion may contain areas of hemorrhage, infarction, necrosis, and edema, and it frequently occurs at a fracture site.

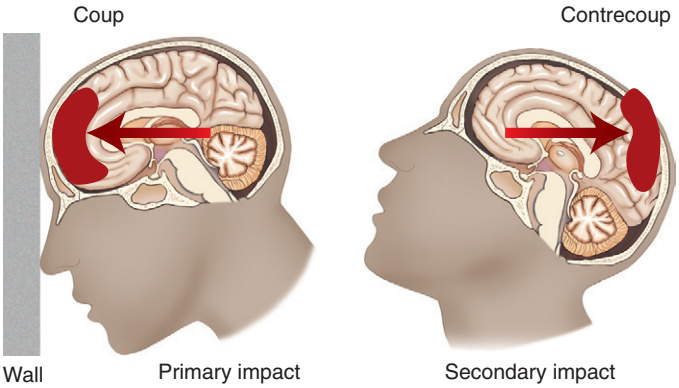

FIG. 57-14 Coup-contrecoup injury. After the head strikes the wall, a coup injury occurs as the brain strikes the skull (primary impact). The contrecoup injury (the secondary impact) occurs when the brain strikes the skull surface opposite the site of the original impact.

With contusion, the phenomenon of *coup-contrecoup injury* is often noted (Fig. 57-14), and injuries can range from minor to severe. Damage from coup-contrecoup injury occurs when the brain moves inside the skull due to high-energy or high-impact injury mechanisms. Contusions or lacerations occur both at the site of the direct impact of the brain on the skull *(coup)* and at a secondary area of damage on the opposite side away from injury *(contrecoup),* leading to multiple contused areas. *Contrecoup* injuries tend to be more severe, and overall patient prognosis depends on the amount of bleeding around the contusion site.

Contusions may continue to bleed or rebleed and appear to "blossom" on subsequent CT scans of the brain, which worsens the neurologic outcome. Neurologic assessment may demonstrate focal and generalized manifestation, depending on the contusion's size and location. Seizures are a common complication of brain contusion, especially in the first 7 days after injury.[12] Anticoagulant use and coagulopathy are associated with increased hemorrhage, more severe head injury, and a higher mortality rate.[18] This is especially important when considering older individuals who are taking warfarin (Coumadin) or aspirin at home. If they fall, their contusion is likely to be more severe due to the use of anticoagulants. Thus risk for falls should be assessed (see Table 63-1).

Complications

Epidural Hematoma. An **epidural hematoma** results from bleeding between the dura and the inner surface of the skull (Figs. 57-15 and 57-16). An epidural hematoma is a neurologic emergency and is usually associated with a linear fracture crossing a major artery in the dura, causing a tear. It can have a venous or an arterial origin. Venous epidural hematomas are associated with a tear of the dural venous sinus and develop slowly. With arterial hematomas, the middle meningeal artery lying under the temporal bone is often torn. Hemorrhage occurs into the epidural space, which lies between the dura and inner surface of the skull (see Fig. 57-15). Because this is an arterial hemorrhage, the hematoma develops rapidly.

Classic signs of an epidural hematoma include an initial period of unconsciousness at the scene, with a brief lucid interval followed by a decrease in LOC. Other manifestations may be a headache, nausea and vomiting, or focal findings. Rapid surgical intervention to evacuate the hematoma and prevent

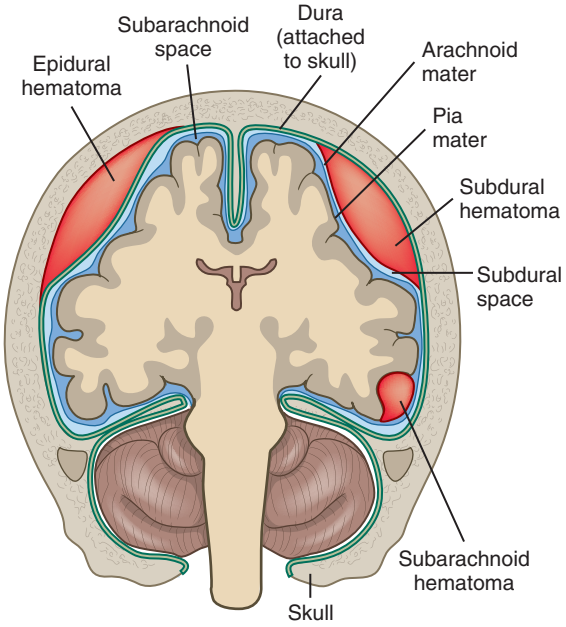

FIG. 57-15 Locations of epidural, subdural, and subarachnoid hematomas.

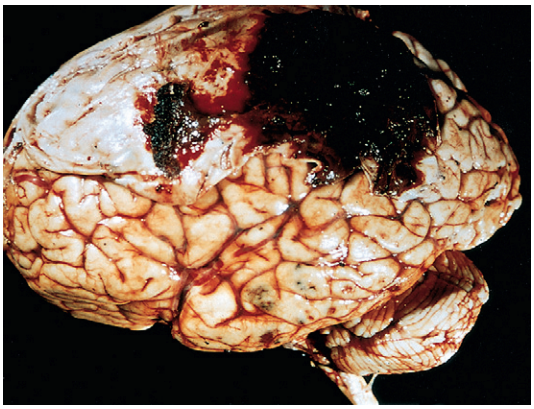

FIG. 57-16 Epidural hematoma covering a portion of the dura. Multiple small contusions are seen in the temporal lobe.

cerebral herniation, along with medical management for increasing ICP, can dramatically improve outcomes.

Subdural Hematoma. A **subdural hematoma** occurs from bleeding between the dura mater and the arachnoid layer of the meninges (see Fig. 57-15). A subdural hematoma usually results from injury to the brain tissue and its blood vessels. The veins that drain from the surface of the brain into the sagittal sinus are the source of most subdural hematomas. Because it is usually venous in origin, the subdural hematoma may be slower to develop. However, a subdural hematoma may be caused by an arterial hemorrhage, in which case it develops more rapidly.[19] Subdural hematomas may be acute, subacute, or chronic (Table 57-8).

An *acute subdural hematoma* manifests within 24 to 48 hours of the injury. The signs and symptoms are similar to those associated with brain tissue compression in increased ICP and include decreasing LOC and headache. The size of the hematoma determines the patient's clinical presentation and prognosis. The patient's appearance may range from drowsy and confused to unconscious. The ipsilateral pupil dilates and becomes fixed if ICP is significantly elevated. Blunt force injuries that produce acute subdural hematomas may also cause significant underlying brain injury, resulting in cerebral edema. The resulting increase in ICP from the cerebral edema can cause an increased morbidity and mortality risk despite surgical intervention to evacuate the hematoma.

TABLE 57-8 TYPES OF SUBDURAL HEMATOMAS

Occurrence After Injury	Progression of Symptoms	Treatment
Acute		
24-48 hr after severe trauma.	Immediate deterioration.	Craniotomy, evacuation and decompression.
Subacute		
48 hr–2 wk after severe trauma.	Alteration in mental status as hematoma develops. Progression dependent on size and location of hematoma.	Evacuation and decompression.
Chronic		
Weeks or months, usually >20 days after injury. Often injury seemed trivial or was forgotten by patient.	Nonspecific, nonlocalizing progression. Progressive alteration in LOC.	Evacuation and decompression, membranectomy.

LOC, Level of consciousness.

A *subacute subdural hematoma* usually occurs within 2 to 14 days of the injury. After the initial bleeding, a subdural hematoma may appear to enlarge over time as the breakdown products of the blood draw fluid into the subdural space.

A *chronic subdural hematoma* develops over weeks or months after a seemingly minor head injury. Chronic subdural hematomas are more common in older adults because of a potentially larger subdural space as a result of brain atrophy. With atrophy, the brain remains attached to the supportive structures, but tension is increased, and it is subject to tearing. Because the subdural space is larger, the presenting complaint is focal symptoms, rather than signs of increased ICP.[20] Chronic alcoholics are also prone to cerebral atrophy and subsequent development of subdural hematoma because of an increased incidence of falls.

Diagnosis of a subdural hematoma in the older adult may be delayed because symptoms mimic other health problems in this age-group, such as somnolence, confusion, lethargy, and memory loss. The manifestations of a subdural hematoma are often misinterpreted as vascular disease (stroke, transient ischemic attack [TIA]) and dementia.

Intracerebral Hematoma. **Intracerebral hematoma** occurs from bleeding within the brain tissue in approximately 16% of head injuries. It usually occurs within the frontal and temporal lobes, possibly from rupture of intracerebral vessels at the time of injury. The size and location of the hematoma are key determinants of the patient's outcome.

Diagnostic Studies and Collaborative Care

CT scan is the best diagnostic test to evaluate for head trauma because it allows rapid diagnosis and intervention in the acute care setting. MRI, PET, and evoked potential studies may also

TABLE 57-9 EMERGENCY MANAGEMENT

Head Injury

Etiology	Assessment Findings	Interventions
Blunt • Motor vehicle collision • Pedestrian event • Fall • Assault • Sports injury **Penetrating** • Gunshot wound • Arrow	**Surface Findings** • Scalp lacerations • Fracture or depressions in skull • Bruises or contusions on face, Battle's sign (bruising behind ears) • Raccoon eyes (dependent bruising around eyes) **Respiratory** • Central neurogenic hyperventilation • Cheyne-Stokes respirations • Decreased O_2 saturation • Pulmonary edema **Central Nervous System** • Unequal or dilated pupils • Asymmetric facial movements • Garbled speech, abusive speech • Confusion • Decreased level of consciousness • Combativeness • Involuntary movements • Seizures • Bowel and bladder incontinence • Flaccidity • Depressed or hyperactive reflexes • Decerebrate or decorticate posturing • GCS score <12 • CSF leaking from ears or nose	**Initial** • Ensure patent airway. • Stabilize cervical spine. • Administer O_2 via non-rebreather mask. • Establish IV access with two large-bore catheters to infuse normal saline or lactated Ringer's solution. • Intubate if GCS score <8. • Control external bleeding with sterile pressure dressing. • Remove patient's clothing. **Ongoing Monitoring** • Maintain patient warmth using blankets, warm IV fluids, overhead warming lights, warm humidified O_2. • Monitor vital signs, level of consciousness, O_2 saturation, cardiac rhythm, GCS score, pupil size and reactivity. • Anticipate need for intubation if gag reflex is impaired or absent. • Assume neck injury with head injury. • Assess for rhinorrhea, otorrhea, scalp wounds. • Administer fluids cautiously to prevent fluid overload and increasing ICP.

GCS, Glasgow Coma Scale, *ICP,* intracranial pressure.

be used in the diagnosis and differentiation of head injuries. An MRI scan is more sensitive than the CT scan in detecting small lesions. Transcranial Doppler studies allow for the measurement of CBF velocity. A cervical spine x-ray series, CT scan, or MRI of the spine may also be indicated, since cervical spine trauma often occurs at the same time as a head injury. In general, the diagnostic studies are similar to those used for a patient with increased ICP (see Table 57-3).

Emergency management of the patient with a head injury is presented in Table 57-9. In addition to measures to prevent secondary injury by treating cerebral edema and managing increased ICP, the principal treatment of head injuries is timely diagnosis and surgery (if necessary). For the patient with concussion and contusion, observation and management of increased ICP are the primary management strategies.

The treatment of skull fractures is usually conservative. For depressed fractures and fractures with loose fragments, a craniotomy is necessary to elevate the depressed bone and remove the free fragments. If large amounts of bone are destroyed, the bone may be removed (craniectomy), and a cranioplasty will be needed later (see the section on cranial surgery later in this chapter).

In cases of large acute subdural and epidural hematomas, or those associated with significant neurologic impairment, the blood must be removed through surgical evacuation. A craniotomy is generally performed to visualize and allow control of the bleeding vessels. Burr-hole openings may be used in an extreme emergency for a more rapid decompression, followed by a craniotomy. A drain may be placed postoperatively for several days to prevent reaccumulation of blood. In cases where extreme swelling is expected (e.g., DAI, hemorrhage), a craniectomy may be performed, which involves removing a piece of skull to reduce the pressure inside the cranial vault, thus reducing the risk of herniation.

NURSING MANAGEMENT HEAD INJURY

NURSING ASSESSMENT

A patient with a head injury always has the potential to develop increased ICP. Increased ICP is associated with higher mortality rates and poorer functional outcomes.[6] Objective data are obtained by applying the GCS (see Table 57-5), assessing and monitoring the neurologic status (see eFig. 57-1 on the website for this chapter), and determining whether a CSF leak has occurred. (Nursing assessment related to increased ICP is discussed on pp. 1365-1366.) Nursing assessment of the patient with a head injury is presented in Table 57-10.

NURSING DIAGNOSES

Nursing diagnoses and a potential complication for the patient who has sustained a head injury may include, but are not limited to, the following:

- Risk for ineffective cerebral tissue perfusion *related to* interruption of CBF associated with cerebral hemorrhage, hematoma, and edema
- Hyperthermia *related to* increased metabolism, infection, and hypothalamic injury

TABLE 57-10 NURSING ASSESSMENT

Head Injury

Subjective Data

Important Health Information

Past health history: Mechanism of injury: motor vehicle collision, sports injury, industrial incident, assault, falls

Medications: Anticoagulant medications

Functional Health Patterns

Health perception–health management: Alcohol or recreational drugs; risk-taking behaviors

Cognitive-perceptual: Headache, mood or behavioral change, mentation changes, aphasia, dysphasia, impaired judgment

Coping–stress tolerance: Fear, denial, anger, aggression, depression

Objective Data

General

Altered mental status

Integumentary

Lacerations, contusions, abrasions, hematoma, Battle's sign, periorbital edema and ecchymosis, otorrhea, exposed brain matter

Respiratory

Rhinorrhea, impaired gag reflex, inability to maintain a patent airway; impending herniation: altered/irregular respiratory rate and pattern

Cardiovascular

Impending herniation: Cushing's triad (systolic hypertension with widening pulse pressure, bradycardia with full and bounding pulse, irregular respirations)

Gastrointestinal

Vomiting, projectile vomiting, bowel incontinence

Urinary

Bladder incontinence

Reproductive

Uninhibited sexual expression

Neurologic

Altered level of consciousness, seizure activity, pupil dysfunction, cranial nerve deficit(s)

Musculoskeletal

Motor deficit/impairment, weakness, palmar drift, paralysis, spasticity, decorticate or decerebrate posturing, muscular rigidity or increased tone, flaccidity, ataxia

Possible Diagnostic Findings

Location and type of hematoma, edema, skull fracture, and/or foreign body on CT scan and/or MRI; abnormal EEG; positive toxicology screen or alcohol level, ↓ or ↑ blood glucose level; ↑ ICP

ICP, Intracranial pressure.

- Impaired physical mobility *related to* decreased LOC
- Anxiety *related to* abrupt change in health status, hospital environment, and uncertain future
- Potential complication: increased ICP *related to* cerebral edema and hemorrhage

PLANNING

The overall goals are that the patient with an acute head injury will (1) maintain adequate cerebral oxygenation and perfusion; (2) remain normothermic; (3) achieve control of pain and discomfort; (4) be free from infection; (5) have adequate nutrition; and (6) attain maximal cognitive, motor, and sensory function.

ETHICAL/LEGAL DILEMMAS

Brain Death

Situation

The emergency nurse receives a radio call from emergency medical service (EMS) personnel about R.G., a young man involved in a motorcycle crash. He was not wearing a helmet and has a large open skull fracture. Transport from the accident scene was delayed by 45 min as a result of a severe thunderstorm and traffic congestion. On the way to the hospital, R.G. exhibits fixed, dilated pupils and experiences cardiac arrest. Estimated arrival at the hospital is still an additional 45 min as a result of the severe weather. EMS personnel request permission to stop resuscitation efforts.

Ethical/Legal Points for Consideration

- Criteria for brain death include coma or unresponsiveness, absence of brainstem reflexes, and apnea (see Chapter 10).
- The definition of death has changed with the advent of new technology, monitoring devices, and interventions.
- These changes and their effect on the legal diagnosis of death will be accepted by the courts through expert witness testimony.
- Another circumstance that influences the manner in which a state of death is determined is the customary practice or best practice for the specific situation.
- In a situation where the professional responsible for determining a state of death is in remote contact with the patient, but the monitoring devices available provide virtual contact with the patient, a remote diagnosis of death may be legally acceptable.
- Brain death criteria do not address patients in a permanent vegetative state, since the brainstem activity in these patients is adequate to maintain heart and lung function.

Discussion Questions

1. What are your feelings about cessation of brain function vs. cessation of heart and lung function as the criteria for death of a patient?
2. What are your state's laws or practices about stopping cardiopulmonary resuscitation (CPR) efforts by EMS personnel in the field?
3. When brain death has occurred, what is your obligation for education of the family or significant other regarding organ donation?

NURSING IMPLEMENTATION

HEALTH PROMOTION. One of the best ways to prevent head injuries is to prevent car and motorcycle collisions. The use of helmets by cyclists has led to fewer TBIs. The use of car seat belts and child car seats is also associated with reduced TBI mortality rates.

Be active in campaigns that promote driving safety, and speak to driver education classes regarding the dangers of unsafe driving and of driving after drinking alcohol and using drugs. Wearing seat belts in cars and helmets for riding on motorcycles is the most effective measure for increasing survival after crashes. Protective helmets should also be worn by lumberjacks, construction workers, miners, horseback riders, bicycle riders, snowboarders, and skydivers. Additionally, individuals who are at risk for falls (e.g., older adults) should be evaluated for safety in the home, since falls are the second leading cause of head injuries.

ACUTE INTERVENTION. Management at the injury scene can have a significant impact on the outcome of the head injury. Emergency management of head injury is presented in Table 57-9. The general goal of nursing management of the head-

injured patient is to maintain cerebral oxygenation and perfusion and prevent secondary cerebral ischemia.

Surveillance or monitoring for changes in neurologic status is critically important because the patient's condition may deteriorate rapidly, necessitating emergency surgery. Appropriate preoperative and postoperative nursing interventions are initiated if surgery is anticipated. Because of the close association between hemodynamic status and cerebral perfusion, be aware of any coexisting injuries or conditions.

Explain the need for frequent neurologic assessments to both the patient and the caregiver. Behavioral manifestations associated with head injury can result in a frightened, disoriented patient who is combative and resists help. Your approach should be calm and gentle. A family member may be available to stay with the patient and thus decrease anxiety and fear. One of the most important needs for the caregiver and family members in the acute injury phase is information about the patient's diagnosis, treatment plan, and rationale for the interventions. Other teaching points are presented in Table 57-11.

Perform neurologic assessments at intervals based on the patient's condition. The GCS is useful in assessing the LOC (see Table 57-5). Indications of a deteriorating neurologic state, no matter how subtle, such as a decreasing LOC or decreasing motor strength, should be reported to the health care provider. Monitor the patient's condition closely.[21]

The major focus of nursing care for the brain-injured patient relates to increased ICP (see eNursing Care Plan 57-1). However, some problems may require specific nursing intervention.

Eye problems may include loss of the corneal reflex, periorbital ecchymosis and edema, and diplopia. Loss of the corneal reflex may necessitate administering lubricating eyedrops or taping the eyes shut to prevent abrasion. Periorbital ecchymosis and edema decrease with time, but cold and, later, warm compresses provide comfort and hasten the process. Diplopia can be relieved by use of an eye patch. Consider a consult with an ophthalmologist.

TABLE 57-11 PATIENT & CAREGIVER TEACHING GUIDE

Head Injury

Include the following instructions when teaching the patient and caregiver about care during the first 2 or 3 days after a head injury.

1. Notify your health care provider immediately if experiencing signs and symptoms that may indicate complications. These include the following:
   - Increased drowsiness (e.g., difficulty arousing, confusion)
   - Nausea or vomiting
   - Worsening headache or stiff neck
   - Seizures
   - Vision difficulties (e.g., blurring)
   - Behavioral changes (e.g., irritability, anger)
   - Motor problems (e.g., clumsiness, difficulty walking, slurred speech, weakness in arms or legs)
   - Sensory disturbances (e.g., numbness)
   - A heart rate <60 beats/min
2. Have someone stay with you.
3. Abstain from alcohol.
4. Check with your health care provider before taking drugs that may increase drowsiness, including muscle relaxants, tranquilizers, and opioid pain medications.
5. Avoid driving, using heavy machinery, playing contact sports, and taking hot baths.

Hyperthermia may occur from injury to or inflammation of the hypothalamus. Elevations in body temperature can result in increased CBF, cerebral blood volume, and ICP. Increased metabolism secondary to hyperthermia increases metabolic waste, which in turn produces further cerebral vasodilation. Avoid hyperthermia with a goal of a temperature of 96.8° to 98.6° F (36° to 37° C) as the standard of care. Use interventions to reduce temperature as previously discussed (see p. 1364) in conjunction with sedation as necessary to prevent shivering.

If CSF rhinorrhea or otorrhea occurs, inform the physician immediately. The head of the bed may be raised to decrease the CSF pressure so that a tear can seal. A loose collection pad may be placed under the nose or over the ear. Do not place a dressing in the nasal or ear cavities. Instruct the patient not to sneeze or blow the nose. Nasogastric tubes should not be used, and nasotracheal suctioning should not be performed on these patients because of the high risk of meningitis.

Nursing measures specific to the care of the immobilized patient, such as those related to bladder and bowel function, skin care, and infection, are also indicated. Nausea and vomiting may be a problem and can be alleviated by antiemetic drugs. Headache can usually be controlled with acetaminophen or small doses of codeine.

If the patient's condition deteriorates, intracranial surgery may be necessary (see the section on cranial surgery later in this chapter). A burr-hole opening or craniotomy may be indicated, depending on the underlying injury that is causing the symptoms. The emergency nature of the surgery may hasten the usual preoperative preparation. Consult with the neurosurgeon to determine specific preoperative nursing measures.

The patient is often unconscious before surgery, making it necessary for a family member to sign the consent form for surgery. This is a difficult and frightening time for the patient's caregiver and family and requires sensitive nursing management. The suddenness of the situation makes it especially difficult for the family to cope.

AMBULATORY AND HOME CARE. Once the condition has stabilized, the patient is usually transferred for acute rehabilitation management. There may be chronic problems related to motor and sensory deficits, communication, memory, and intellectual functioning. Many of the principles of nursing management of the patient with a stroke are appropriate for these patients (see Chapter 58).

Conditions that may require nursing and collaborative management include poor nutritional status, bowel and bladder management, spasticity, dysphagia, deep vein thrombosis, and hydrocephalus. The patient's outward appearance is not a good indicator of how well he or she will ultimately function in the home or work environment. The outward physical appearance does not necessarily reflect what has happened in the brain.

Seizure disorders are seen in approximately 5% of patients with a nonpenetrating head injury. Seizures are most likely to develop during the first week after the head injury,[12] but some patients may not develop a seizure disorder until years later. Antiseizure drugs may be used prophylactically to manage posttraumatic seizure activity.

The mental and emotional sequelae of brain trauma are often the most incapacitating problems. One of the consequences of TBI is that the person may not realize that a brain injury has occurred. Many of the patients with head injuries who have been comatose for more than 6 hours undergo some personality change. They may suffer loss of concentration and

memory and defective memory processing. Personal drive may decrease. Apathy may increase. Euphoria and mood swings, along with a seeming lack of awareness of the seriousness of the injury, may occur. The patient's behavior may indicate a loss of social restraint, judgment, tact, and emotional control.

Progressive recovery may continue for 6 months or more before a plateau is reached and a prognosis for recovery can be determined. Specific nursing management in the posttraumatic phase depends on specific residual deficits.

In all cases, the family must be given special consideration. They need to understand what is happening and be taught appropriate interaction patterns. Provide guidance and referrals for financial aid, child care, and other personal needs. Assist the family in involving the patient in family activities whenever possible. Help the patient and the family remain hopeful. The family often has unrealistic expectations of the patient as the coma begins to recede. The family expects full return to pretrauma status. In reality, the patient usually experiences a reduced awareness and ability to interpret environmental stimuli. Prepare the family for the patient's emergence from coma and explain that the process of awakening often takes several weeks. Arrange for social work and chaplain consultations for the family in addition to providing open visitation and frequent status updates.

When it is the time for discharge planning, the patient, caregiver, and family may benefit from specific posthospitalization instructions to avoid family-patient friction. Special "no" policies that may be appropriately suggested by the neurosurgeon, neuropsychologist, and nurse include no drinking of alcoholic beverages, no driving, no use of firearms, no working with hazardous implements and machinery, and no unsupervised smoking. Family members, particularly spouses, go through role transition as the role changes from that of spouse to that of caregiver. (The stresses and needs of family caregivers are discussed in Chapter 4.)

EVALUATION

The expected outcomes are that the patient with a head injury will

- Maintain normal CPP
- Achieve maximal cognitive, motor, and sensory function
- Experience no infection or hyperthermia

BRAIN TUMORS

The annual rate of newly diagnosed brain tumors in the United States is 22,910, with an estimated 13,700 deaths related to brain tumors. The brain is also a frequent site for metastasis from other sites. The 5-year survival rate for primary site brain tumors is approximately 36%.[22] Males have a slightly higher incidence of brain tumors than females. Brain tumors are more commonly seen in middle-aged persons, but they may occur at any age.

Types

Brain tumors can occur in any part of the brain or spinal cord. Tumors of the brain may be *primary,* arising from tissues within the brain, or *secondary,* resulting from a metastasis from a malignant neoplasm elsewhere in the body.[23] Metastatic brain tumors are the most common brain tumor. The cancers that most commonly metastasize to the brain are lung and breast.

Primary brain tumors are generally classified according to the tissue from which they arise (Table 57-12). Meningiomas represent 34% of all primary brain tumors, making them the most common primary brain tumor. Gliomas (e.g., astrocytoma, glioblastoma multiforme) account for 30% of all brain tumors and 80% of all malignant tumors. Glioblastoma multiforme is the most common form of glioma.

CULTURAL & ETHNIC HEALTH DISPARITIES

Brain Tumors

- Whites have a higher incidence of malignant brain tumors than African Americans.
- White males have the highest incidence of malignant brain tumors.
- African Americans have a higher incidence of benign brain tumors (e.g., meningiomas) than whites.

TABLE 57-12 TYPES OF BRAIN TUMORS

Type	Tissue of Origin	Characteristics
Gliomas		
• Astrocytoma	Supportive tissue, glial cells, and astrocytes	Can range from low-grade to moderate-grade malignancy.
• Glioblastoma multiforme	Primitive stem cell (glioblast)	Highly malignant and invasive. Among the most devastating of primary brain tumors.
• Oligodendroglioma	Oligodendrocytes	Benign (encapsulation and calcification).
• Ependymoma	Ependymal epithelium	Range from benign to highly malignant. Most are benign and encapsulated.
• Medulloblastoma	Primitive neuroectodermal cell	Highly malignant and invasive. Metastatic to spinal cord and remote areas of brain.
Meningioma	Meninges	Can be benign or malignant. Most are benign.
Acoustic neuroma (Schwannoma)	Cells that form myelin sheath around nerves Commonly affects cranial nerve VIII	Many grow on both sides of the brain. Usually benign or low-grade malignancy.
Pituitary adenoma	Pituitary gland	Usually benign.
Hemangioblastoma	Blood vessels of brain	Rare and benign. Surgery is curative.
Primary central nervous system lymphoma	Lymphocytes	Increased incidence in transplant recipients and acquired immunodeficiency syndrome (AIDS) patients.
Metastatic tumors	Lungs, breast	Malignant.

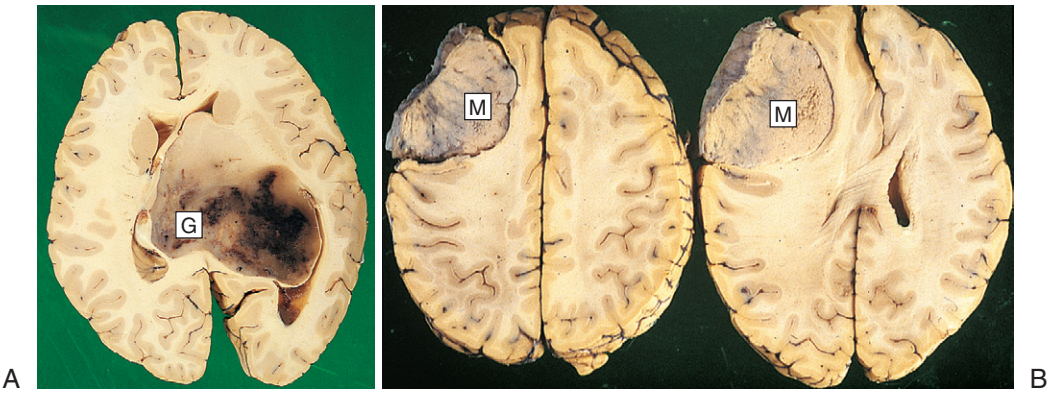

FIG. 57-17 **A,** A large glioblastoma *(G)* arises from one cerebral hemisphere and has grown to fill the ventricular system. **B,** Meningioma. These two different sections from different levels in the same brain show a meningioma *(M)* compressing the frontal lobe and distorting underlying brain.

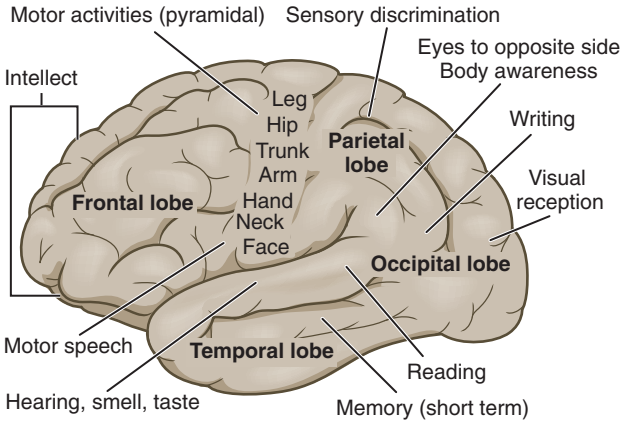

FIG. 57-18 Each area of the brain controls a particular activity.

More than half of brain tumors are malignant. They infiltrate the brain tissue and are not amenable to complete surgical removal. Other tumors may be histologically benign but are located such that complete removal is not possible.

Brain tumors rarely metastasize outside the central nervous system (CNS) because they are contained by structural (meninges) and physiologic (blood-brain) barriers. Table 57-12 compares the most common brain tumors. A glioblastoma and meningioma are shown in Fig. 57-17.

Clinical Manifestations and Complications

The clinical manifestations of brain tumors depend mainly on their location and size (Table 57-13). The rate of growth and the appearance of manifestations depend on the location, size, and mitotic rate of the cells of the tissue of origin. Fig. 57-18 illustrates the functional areas of the cerebral cortex and can be used as a guide to correlate the clinical manifestations with the location of the tumor, as indicated by an alteration in the function controlled by the affected area.

Wide ranges of possible clinical manifestations are associated with brain tumors. Headache is a common problem. Tumor-related headaches tend to be worse at night and may awaken the patient. The headaches are usually dull and constant but occasionally throbbing. Seizures are common in gliomas and brain metastases. Brain tumors can cause nausea and vomiting from increased ICP. Cognitive dysfunction, including memory problems and mood or personality changes, is another common manifestation, especially in patients with brain metastases. Muscle weakness, sensory losses, aphasia, and visual-spatial dysfunction are also manifestations of brain tumors.

If the tumor mass obstructs the ventricles or occludes the outlet, ventricular enlargement (hydrocephalus) can occur. As the brain tumor expands, it may also produce manifestations of increased ICP, cerebral edema, or obstruction of the CSF pathways. Unless treated, all brain tumors eventually cause death from increasing tumor volume leading to increased ICP.

TABLE 57-13 MANIFESTATIONS OF BRAIN TUMORS

Tumor Location	Manifestations
Cerebral hemisphere	
• Frontal lobe (unilateral)	Unilateral hemiplegia, seizures, memory deficit, personality and judgment changes, visual disturbances.
• Frontal lobe (bilateral)	Symptoms associated with unilateral frontal lobe tumors. Ataxic gait.
• Parietal lobe	Speech disturbance (if tumor is in the dominant hemisphere), inability to write, spatial disorders, unilateral neglect.
• Occipital lobe	Vision disturbances and seizures.
• Temporal lobe	Few symptoms. Seizures, dysphagia.
Subcortical	Hemiplegia. Other symptoms may depend on area of infiltration.
Meningeal tumors	Symptoms associated with compression of the brain and depend on tumor location.
Metastatic tumors	Headache, nausea, or vomiting because of ↑ ICP. Other symptoms depend on tumor location.
Thalamus and sellar tumors	Headache, nausea, vision disturbances, papilledema, and nystagmus occur from ↑ ICP. Diabetes insipidus may occur.
Fourth ventricle and cerebellar tumors	Headache, nausea, and papilledema from ↑ ICP. Ataxic gait and changes in coordination.
Cerebellopontine tumors	Tinnitus and vertigo, deafness.
Brainstem tumors	Headache on awakening, drowsiness, vomiting, ataxic gait, facial muscle weakness, hearing loss, dysphagia, dysarthria, "crossed eyes" or other visual changes, hemiparesis.

ICP, Intracranial pressure.

Diagnostic Studies

An extensive history and a comprehensive neurologic examination must be done in the workup of a patient with a suspected brain tumor. A careful history and physical examination may provide data with respect to location. New onset of seizures or adult-onset migraines may be indicative of a brain tumor and should be investigated. Diagnostic studies are similar to those used for a patient with increased ICP (see Table 57-3).

The sensitivity of techniques such as MRI and PET scans allows for detection of small tumors and may provide more reliable diagnostic information than a CT scan. CT and brain scanning are used to identify the lesion's location. Other tests include magnetic resonance spectroscopy, functional MRI, and single-photon emission computed tomography (SPECT). The EEG is useful for ruling out seizures, but is of less importance. A lumbar puncture is seldom diagnostic and carries with it the risk of cerebral herniation. Angiography can be used to determine blood flow to the tumor and further localize the tumor. Other studies are done to rule out a primary lesion elsewhere in the body. Endocrine studies are helpful when a pituitary adenoma is suspected (see Chapter 50).

The correct diagnosis of a brain tumor can be made by obtaining tissue for histologic study. In most patients, tissue is obtained at the time of surgery. Computer-guided stereotactic biopsy is also an option. A smear or frozen section can be performed in the operating room for a preliminary interpretation of the histologic type. With this information, the neurosurgeon can make a better decision about the extent of surgery. In some cases, immunohistochemical stains or electron microscopy may be necessary to ascertain the correct diagnosis. Determination of the MIB-1 index, a measure of mitotic rate, is often helpful in assessing the tumor's mitotic activity.

Collaborative Care

Treatment goals are aimed at (1) identifying the tumor type and location, (2) removing or decreasing tumor mass, and (3) preventing or managing increased ICP.

Surgical Therapy. Surgical removal is the preferred treatment for brain tumors (see the section on cranial surgery later in this chapter). Stereotactic surgical techniques are used with greater frequency to perform a biopsy and remove small brain tumors. The outcome of surgical therapy depends on the tumor's type, size, and location. Meningiomas and oligodendrogliomas can usually be completely removed, whereas the more invasive gliomas and medulloblastomas may only be partially removed. Computer-guided stereotactic biopsy, ultrasound, functional MRI, and cortical mapping can be used to localize brain tumors intraoperatively.

Complete surgical removal of brain tumors is not always possible because the tumor is not always accessible or may involve vital parts of the brain. Surgery can reduce tumor mass, which decreases ICP, provides relief of symptoms, and extends survival time.

Ventricular Shunts. Hydrocephalus can be treated with the placement of a ventricular shunt. A catheter with one-way valves is placed in the lateral ventricle and then tunneled through the skin to drain CSF into the jugular vein, peritoneum, or pelvis. Rapid decompression of ICP can cause total body collapse and weakness, including a headache that may be prevented by gradually introducing the patient to the upright position.

Manifestations of shunt malfunction, which are related to increased ICP, include decreasing LOC, restlessness, headache, blurred vision, or vomiting. This may necessitate shunt revision or replacement. Infection may also occur, as exhibited by high fever, persistent headache, and stiff neck. Antibiotics are used to treat the infection. In some situations the shunt must be replaced.

Radiation Therapy and Stereotactic Radiosurgery. Radiation therapy may be used as a follow-up measure after surgery. Radiation seeds can also be implanted into the brain. Cerebral edema and rapidly increasing ICP may be a complication of radiation therapy, but these problems can be managed with high doses of corticosteroids (dexamethasone, prednisone, or methylprednisolone [Solu-Medrol]). (Radiation therapy is discussed in Chapter 16.)

Stereotactic radiosurgery is a method of delivering a highly concentrated dose of radiation to a precise location within the brain. Stereotactic radiosurgery may be used when conventional surgery has failed or is not an option because of the tumor location. (Radiosurgery is discussed on p. 1379.)

Chemotherapy and Targeted Therapy. The effectiveness of chemotherapy has been limited by difficulty getting drugs across the blood-brain barrier, tumor cell heterogeneity, and tumor cell drug resistance. Chemotherapy drugs called nitrosoureas (e.g., carmustine [BCNU], lomustine [CCNU]) are used to treat brain tumors. Normally the blood-brain barrier prohibits the entry of most drugs into the brain. The most malignant tumors cause a breakdown of the blood-brain barrier in the area of the tumor, thus allowing chemotherapy agents to be used to treat the malignancy. Chemotherapy-laden biodegradable wafers (e.g., Gliadel wafer [polifeprosan with carmustine implant]) implanted at the time of surgery can deliver chemotherapy directly to the tumor site. Other drugs being used include methotrexate and procarbazine (Matulane). One method used to deliver chemotherapy drugs directly to the CNS is intrathecal administration via an Ommaya reservoir.

Temozolomide (Temodar) is the first oral chemotherapy agent found to cross the blood-brain barrier. In contrast with many traditional chemotherapy drugs, which require metabolic activation to exert their effects, temozolomide can convert spontaneously to a reactive agent that directly interferes with tumor growth. It does not interact with other drugs commonly taken by patients with brain tumors, such as antiseizure medications, corticosteroids, and antiemetics.

DRUG ALERT: Temozolomide (Temodar)

- Causes myelosuppression. Before using, it is recommended that absolute neutrophil count be ≥1500/μL and platelet count be ≥100,000/μL.
- To reduce nausea and vomiting, take on empty stomach.

Bevacizumab (Avastin) is used to treat patients with glioblastoma multiforme that continues to progress after standard therapy. Bevacizumab is a targeted therapy that inhibits the action of vascular endothelial growth factor, which helps form new blood vessels. These vessels can feed a tumor, helping it to grow, and can also provide a pathway for cancer cells to circulate in the body. (Targeted therapy is discussed in Chapter 16 and Table 16-13.)

Other Therapies. A medical device system, NovoTTF-100A System, is used to treat glioblastoma multiforme that recurs or progresses after receiving chemotherapy and radiation therapy. With this system, electrodes are placed on the surface of the

patient's scalp to deliver low-intensity, changing electrical fields called *tumor treatment fields* (TTFs) to the tumor site.

Many techniques to control and treat brain tumors are currently under investigation. Although progress in treatment has increased length and quality of life for patients with brain tumors, outcomes still remain poor for patients with gliomas.[24]

NURSING MANAGEMENT
BRAIN TUMORS

NURSING ASSESSMENT

Structure the initial assessment to provide baseline data of the patient's neurologic status. Use this information to design a realistic, individualized care plan. Assess the patient's LOC, motor abilities, sensory perception, integrated function (including bowel and bladder function), and balance and proprioception, and also assess the coping abilities of the patient, caregiver, and family. Watching a patient perform activities of daily living and listening to the patient's conversation can be part of the neurologic assessment. Having the patient or caregiver explain the problem can be helpful to determine the patient's limitations and obtain information about the patient's insight into the problems. Record all initial data to provide a baseline for comparison to determine whether the patient's condition is improving or deteriorating.

Interview data are as important as the actual physical assessment. Ask questions about the medical history, intellectual abilities and educational level, and history of nervous system infections and trauma. Determine the presence of seizures, syncope, nausea and vomiting, and headaches or other pain to help better plan care for the patient.

NURSING DIAGNOSES

Nursing diagnoses for the patient with a brain tumor may include, but are not limited to, the following:

- Risk for ineffective cerebral tissue perfusion *related to* cerebral edema
- Acute pain (headache) *related to* cerebral edema and increased ICP
- Anxiety *related to* diagnosis and treatment
- Potential complication: seizures *related to* abnormal electrical activity of the brain
- Potential complication: increased ICP *related to* tumor and failure of normal compensatory mechanisms

PLANNING

The overall goals are that the patient with a brain tumor will (1) maintain normal ICP, (2) maximize neurologic functioning, (3) achieve control of pain and discomfort, and (4) be aware of the long-term implications with respect to prognosis and cognitive and physical functioning.

NURSING IMPLEMENTATION

A primary or metastatic tumor of the frontal lobe can cause behavioral and personality changes. Loss of emotional control, confusion, disorientation, memory loss, impulsivity, and depression may be signs of a frontal lobe lesion. These behavioral changes are often not perceived by the patient but can be disturbing and even frightening to the caregiver and family. These changes can also cause a distancing to occur between the family and patient. Assist the caregiver and family in understanding what is happening to the patient, and support the family.

The confused patient with behavioral instability can be a challenge. Protecting the patient from self-harm is an important part of nursing care. Close supervision of activity, use of side rails, judicious use of restraints, appropriate sedative medications, padding of the rails and the area around the bed, and a calm reassuring approach are all essential techniques in the care of these patients.

Perceptual problems associated with frontal and parietal lobe tumors contribute to a patient's disorientation and confusion. Minimize environmental stimuli, create a routine, and use reality orientation for the confused patient.

Seizures, which often occur with brain tumors, are managed with antiseizure drugs. Also use seizure precautions for the patient's protection. Some behavioral changes seen in the patient with a brain tumor are a result of seizure disorders and can improve with adequate seizure control. Patients at risk for seizures may be unable to drive, so be aware of the extra resources needed and collaborate with the social worker and the family. (Seizure disorders are discussed in Chapter 59.)

Motor and sensory dysfunctions interfere with the activities of daily living.[25] Alterations in mobility must be managed. Encourage the patient to provide as much self-care as physically possible. Self-image often depends on the patient's ability to participate in care within the limitations of the physical deficits.

Language deficits can also occur in patients with brain tumors. Motor (expressive) or sensory (receptive) dysphasia may occur. The disturbance in communication can be frustrating for the patient and may interfere with your ability to meet the patient's needs. Make attempts to establish a communication system that can be used by both the patient and the staff.

Nutritional intake may be decreased because of the patient's inability to eat, loss of appetite, or loss of desire to eat. Assess the patient's nutritional status, and ensure adequate nutritional intake. Encourage the patient to eat. Some patients may need enteral or parenteral nutrition (see Chapter 40). The patient with a brain tumor who undergoes cranial surgery requires complex nursing care. This is discussed in the next section.

Although progress is continually being made in helping patients with brain tumors, the prognosis remains grim for those with highly invasive tumors.[24] Provide help and support during the adjustment phase and in long-range planning. Social work and home health nurses may be needed to assist the caregiver with discharge planning and to help the family adjust to role changes and psychosocial and socioeconomic factors. Issues related to palliative and end-of-life care need to be discussed with both the patient and the family (see Chapter 10).

EVALUATION

The expected outcomes are that the patient with a brain tumor will

- Achieve control of pain, vomiting, and other discomforts
- Maintain ICP within normal limits
- Demonstrate maximal neurologic function (cognitive, motor, sensory) given the location and extent of the tumor
- Maintain optimal nutritional status
- Accept the long-term consequences of the tumor and its treatment

TABLE 57-14 INDICATIONS FOR CRANIAL SURGERY

Indication	Cause	Surgical Procedure
Brain abscess	Bacteria that caused intracranial infection	Excision or drainage of abscess
Hydrocephalus	Overproduction of CSF, obstruction to flow, defective reabsorption	Placement of ventriculoatrial or ventriculoperitoneal shunt
Brain tumors	Benign or malignant cell growth	Excision or partial resection of tumor
Intracranial bleeding	Rupture of cerebral vessels because of trauma or stroke	Surgical evacuation through burr holes or craniotomy
Skull fractures	Trauma to skull	Debridement of fragments and necrotic tissue, elevation and realignment of bone fragments
Arteriovenous (AV) malformation	Congenital tangle of arteries and veins (frequently in middle cerebral artery)	Excision of malformation
Aneurysm repair	Dilation of weak area in arterial wall (usually near anterior portion of circle of Willis)	Dissection and clipping or coiling of aneurysm

CSF, Cerebrospinal fluid.

TABLE 57-15 TYPES OF CRANIAL SURGERY

Type	Description
Burr hole	Opening into the cranium with a drill. Used to remove localized fluid and blood beneath the dura.
Craniotomy	Opening into cranium with removal of bone flap and opening the dura to remove a lesion, repair a damaged area, drain blood, or relieve ↑ ICP.
Craniectomy	Excision into the cranium to cut away bone flap.
Cranioplasty	Repair of cranial defect resulting from trauma, malformation, or previous surgical procedure. Artificial material used to replace damaged or lost bone.
Stereotactic procedure	Precise localization of a specific area of the brain using a frame or a frameless system based on three-dimensional coordinates. Procedure is used for biopsy, radiosurgery, or dissection.
Shunt procedures	Alternate pathway to redirect cerebrospinal fluid from one area to another using a tube or implanted device. Examples include ventricular shunt and Ommaya reservoir.

ICP, Intracranial pressure.

CRANIAL SURGERY

The indication for cranial surgery may be related to a brain tumor, CNS infection (e.g., abscess), vascular abnormalities, craniocerebral trauma, seizure disorder, or intractable pain (Table 57-14).

Types

Various types of cranial surgical procedures are presented in Table 57-15.

Craniotomy. Depending on the location of the pathologic condition, a *craniotomy* may be frontal, parietal, occipital, temporal, suboccipital, or a combination of any of these. The surgeon drills a set of burr holes and uses a saw to connect the holes to remove the bone flap. Sometimes operating microscopes are used to magnify the site. After surgery, the bone flap is wired or sutured. Sometimes drains are placed to remove fluid and blood. Patients are usually cared for in an ICU until stable.

Stereotactic Radiosurgery. Stereotactic procedures use precision apparatus (often computer guided) to help the physician precisely target an area of the brain. Stereotactic biopsy can be performed to obtain tissue samples for histologic examination. CT scanning and MRI are used to image the targeted tissue. With the patient under general or local anesthesia, the surgeon drills a burr hole or creates a bone flap for an entry site and then introduces a probe and biopsy needle. Stereotactic procedures are used for removal of small brain tumors and abscesses, drainage of hematomas, ablative procedures for extrapyramidal diseases (e.g., Parkinson's disease), and repair of arteriovenous malformations. A major advantage of the stereotactic approach is a reduction in damage to surrounding tissue.

Stereotactic radiosurgery is not a form of surgery in the traditional sense. Instead, radiosurgery uses precisely focused radiation to destroy tumor cells and other abnormal growths in the brain. Computers create three-dimensional images of the brain, and these images are used to guide the focused radiation while the patient's head is held still in a stereotactic frame (Fig. 57-19). Radiosurgical techniques can use ionizing radiation generated by a linear accelerator, gamma knife, or CyberKnife. In these procedures, a high dose of cobalt radiation is delivered to precisely targeted tumor tissue. The dose of radiation is delivered in a single treatment lasting a few hours or in multiple sessions. Side effects of stereotactic radiosurgery may include fatigue, headache, and nausea.

In combination with stereotactic procedures to identify and localize tumor sites, surgical lasers can be used to destroy tumors. Three surgical lasers currently used are the carbon dioxide, argon, and neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers. All three work by creating thermal energy, which destroys the tissue on which it is focused. Laser therapy also provides the benefit of reducing damage to surrounding tissue.

NURSING MANAGEMENT CRANIAL SURGERY

NURSING IMPLEMENTATION

ACUTE INTERVENTION. The general preoperative and postoperative nursing care for the patient undergoing cranial surgery is similar regardless of the cause. Nursing management is similar to that for the patient with increased ICP (presented in eNursing Care Plan 57-1). The patient (if conscious and coherent), caregiver, and family will be concerned about the potential physical and emotional problems that can result from surgery. The uncertainty regarding prognosis and outcome requires compassionate nursing care in the preoperative period.

Preoperative teaching is important in allaying the fears of the patient, caregiver, and family, and also in preparing them for the postoperative period. Provide general information concerning the type of operation that will be performed and what can

FIG. 57-19 A, Patient in a stereotactic frame. **B,** Elekta's Fraxion head frame helps ensure accuracy and precision in stereotactic radiation therapy (SRT) of cancer targets in the brain and cranium. (Courtesy Elekta.)

be expected immediately after the operation. Explain that some hair may be shaved to allow for better exposure and to prevent contamination. The hair is usually removed in the operating room after induction of anesthesia. Also inform the family that the patient will be taken to an ICU or to a special care unit after surgery. The primary goal of care after cranial surgery is prevention of increased ICP. (Nursing management of the patient with increased ICP is presented on pp. 1356-1368.) Frequent assessment of the patient's neurologic status is essential during the first 48 hours. In addition to the neurologic functions, closely monitor fluid and electrolyte levels and serum osmolality to detect changes in sodium regulation, the onset of diabetes insipidus, or severe hypovolemia. Turning and positioning the patient may depend on the site of the operation.

Monitor the patient for pain and nausea. Although the brain itself does not possess pain receptors, patients often report headache caused by edema or pain at the incision site. Control pain with short-acting opioids and monitor neurologic status. Nausea and vomiting are common after surgery and are usually treated with antiemetics. The use of promethazine (Phenergan) is discouraged because it can increase somnolence, thus altering the accuracy of a neurologic assessment.

The surgical dressing is usually in place for a few days. With an incision over the skull in the anterior or middle fossa, the patient will return from the operating room with the head elevated at an angle of 30 to 45 degrees. The head of the bed should remain elevated at least 30 degrees unless the surgical approach is in the posterior fossa or a burr hole has been made. In these cases, the patient is generally kept flat or at a slight elevation (10 to 15 degrees) during the postoperative phase.

If a bone flap has been removed (craniectomy), do not position the patient on the operative side. Observe the dressing for color, odor, and amount of drainage. Notify the surgeon immediately of any excessive bleeding or clear drainage. Checking drains for placement and assessing the area around the dressing are also important. Scalp care should include meticulous care of the incision to prevent wound infection. Cleanse the area and treat it in accordance with hospital protocol or the neurosurgeon's orders. Once the dressing is removed, use an antiseptic soap for washing the scalp. The psychologic impact of hair removal can be alleviated by the use of a wig, turban, scarves, or cap after the incision has completely healed. For the patient who is receiving radiation, instruct the patient to use a sunblock and head covering if any exposure to the sun is anticipated.

AMBULATORY AND HOME CARE. The rehabilitative potential for a patient after cranial surgery depends on the reason for the surgery, the postoperative course, and the patient's general state of health. Base your nursing interventions on a realistic appraisal of these factors. An overall goal is to foster independence for as long as possible and to the highest degree possible.

Specific rehabilitation potential cannot be determined until cerebral edema and increased ICP subside postoperatively. Take care to maintain as much function as possible through measures such as careful positioning, meticulous skin and mouth care, regular range-of-motion exercises, bowel and bladder care, and adequate nutrition.

Referrals may be made to other specialists on the health care team. For example, the speech therapist may be helpful to the patient who has a speech problem, or the physical therapist may

ETHICAL/LEGAL DILEMMAS

Withholding Treatment

Situation

C.J., a 26-yr-old patient in a permanent vegetative state, is diagnosed with her fifteenth bladder infection. As her home care nurse, you must determine whether to seek antibiotics for this infection. The family members have expressed a concern that no heroic measures be used to extend the biologic life of their daughter and sister. However, they have been unwilling to withdraw the existing treatment, which is enteral nutrition through a gastrostomy tube. Should antibiotics be withheld?

Ethical/Legal Points for Consideration

- Patients in a persistent vegetative state do not recover.
- The primary legal issue here is who has the legal right to refuse or consent to treatment for this incapacitated patient. You would need to know if a guardian has been appointed by the court or if her parents retain a form of guardianship to make health care decisions for her.
- You also need to know when the vegetative state began; that is, did the patient ever have the right to consent having reached the age of majority as a competent adult, or did the vegetative state begin while she was a minor? If the patient did become a competent adult before the vegetative state, did she ever express any preference for quality-of-life and end-of-life decision making?
- The courts have widespread legal precedents for accepting the decision of the patient's guardian or parents or the patient's clearly expressed preferences for quality-of-life decision making.
- Some courts have made a distinction between medical treatment (antibiotics) and comfort care (enteral feeding tube). The antibiotics may be seen as medical treatment that could be legally refused.

Discussion Questions

1. How would you approach C.J.'s family?
2. What are your feelings about providing nutrition, hydration, and treatments that will prolong life in a patient for whom there is no hope of recovery?
3. What options are available to the family for the care of their daughter once a decision is made about withholding antibiotics?

TABLE 57-16 COMPARISON OF CEREBRAL INFLAMMATORY CONDITIONS

	Meningitis	Encephalitis	Brain Abscess
Cause	Bacteria (*Streptococcus pneumoniae, Neisseria meningitidis*, group B streptococci, viruses, fungi)	Bacteria, fungi, parasites, herpes simplex virus (HSV), other viruses (e.g., West Nile virus)	Streptococci, staphylococci through bloodstream
CSF (Reference Interval)			
• Pressure (70-150 mm H_2O)	Increased	Normal to slight increase	Increased
• WBC count (0-5 cells/μL)	*Bacterial:* >1000/μL (mainly neutrophils) *Viral:* 25-500/μL (mainly lymphocytes)	500/μL, neutrophils (early), lymphocytes (later)	25-300/μL (neutrophils)
• Protein (15-45 mg/dL [0.15-0.45 g/L])	*Bacterial:* >500 mg/dL *Viral:* 50-500 mg/dL	Slight increase	Normal
• Glucose (40-70 mg/dL [2.2-3.9 mmol/L])	*Bacterial:* Decreased *Viral:* Normal or low	Normal	Low or absent
• Appearance	*Bacterial:* Turbid, cloudy *Viral:* Clear or cloudy	Clear	Clear
Diagnostic Studies	CT scan, Gram stain, smear, culture, PCR*	CT scan, EEG, MRI, PET, PCR, IgM antibodies to virus in serum or CSF	CT scan
Treatment	Antibiotics, dexamethasone, supportive care, prevention of ↑ ICP	Supportive care, prevention of ↑ ICP, acyclovir (Zovirax) for HSV	Antibiotics, incision and drainage Supportive care

*PCR is used to detect viral RNA or DNA.
CSF, Cerebrospinal fluid; *ICP,* intracranial pressure; *PCR,* polymerase chain reaction.

provide an exercise plan to regain functional deficits. Address the needs and problems of each patient individually because many variables affect the plan. The patient's mental and physical deterioration, including seizures, personality disorganization, apathy, and wasting, is difficult for both family and health care professionals to watch. Cognitive and emotional residual deficits are often harder to accept than are motor and sensory losses.

INFLAMMATORY CONDITIONS OF THE BRAIN

Brain abscesses, meningitis, and encephalitis are the most common inflammatory conditions of the brain and spinal cord (Table 57-16). Inflammation can be caused by bacteria, viruses, fungi, and chemicals (e.g., contrast media used in diagnostic tests, blood in the subarachnoid space). CNS infections may occur via the bloodstream, by extension from a primary site, or along cranial and spinal nerves.

The mortality rate for inflammatory conditions of the brain is approximately 2% to 30% in the general population, with higher rates in older patients. Up to 40% of those who recover can have long-term neurologic deficits, including hearing loss.[26]

BRAIN ABSCESS

Brain abscess is an accumulation of pus within the brain tissue that can result from a local or systemic infection. Direct extension from an ear, tooth, mastoid, or sinus infection is the primary cause. Other causes for brain abscess formation include spread from a distant site (e.g., pulmonary infection, bacterial endocarditis), skull fracture, and prior brain trauma or surgery. Streptococci and *Staphylococcus aureus* are the primary infective organisms.

Manifestations of brain abscess, which are similar to those of meningitis and encephalitis, include headache, fever, and nausea and vomiting. Signs of increased ICP may include drowsiness, confusion, and seizures. Focal symptoms may reflect the local area of the abscess. For example, visual field defects or psychomotor seizures are common with a temporal lobe abscess, whereas an occipital abscess may be accompanied by visual impairment and hallucinations. CT and MRI are used to diagnose a brain abscess.

Antimicrobial therapy is the primary treatment for brain abscess. Other manifestations are treated symptomatically. If drug therapy is not effective, the abscess may need to be drained, or removed if it is encapsulated. In untreated cases the mortality rate approaches 100%.

Nursing measures are similar to those for management of meningitis or increased ICP. If surgical drainage or removal is the treatment of choice, nursing care is similar to that described under cranial surgery.

BACTERIAL MENINGITIS

Meningitis is an acute inflammation of the meningeal tissues surrounding the brain and spinal cord. Meningitis usually occurs in fall, winter, or early spring and is often secondary to viral respiratory disease. Older adults and persons who are debilitated are affected more frequently than the general population. College students living in dormitories and individuals living in institutions (e.g., prisoners) are also at a high risk for contracting meningitis.

Bacterial meningitis is considered a medical emergency. Untreated bacterial meningitis has a mortality rate near 100%.

Etiology and Pathophysiology

Streptococcus pneumoniae and *Neisseria meningitidis* are the leading causes of bacterial meningitis. *Haemophilus influenzae* was once the most common cause of bacterial meningitis. However, the use of *H. influenzae* vaccine has resulted in a significant decrease in meningitis related to this organism.

The organisms usually gain entry to the CNS through the upper respiratory tract or the bloodstream. However, they may enter by direct extension from penetrating wounds of the skull or through fractured sinuses in basilar skull fractures.

The inflammatory response to the infection tends to increase CSF production with a moderate increase in ICP. In bacterial meningitis the purulent secretions produced quickly spread to other areas of the brain through the CSF and cover the cranial nerves and other intracranial structures. If this process extends into the brain parenchyma or if concurrent encephalitis is present, cerebral edema and increased ICP become more of a problem. Closely observe all patients with meningitis for manifestations of increased ICP, which is thought to be a result of swelling around the dura and increased CSF volume.

Clinical Manifestations

Fever, severe headache, nausea, vomiting, and **nuchal rigidity** (neck stiffness) are key signs of meningitis. Photophobia, a decreased LOC, and signs of increased ICP may also be present. Coma is associated with a poor prognosis and occurs in 5% to 10% of patients with bacterial meningitis. Seizures occur in one third of all cases. The headache becomes progressively worse and may be accompanied by vomiting and irritability. If the infecting organism is a meningococcus, a skin rash is common and petechiae may be seen.

Complications

The most common acute complication of bacterial meningitis is increased ICP. Most patients have increased ICP, and it is the major cause of an altered mental status. Another complication of bacterial meningitis is residual neurologic dysfunction.

Dysfunction often occurs involving many cranial nerves. Cranial nerve irritation can have serious sequelae. The optic nerve (CN II) is compressed by increased ICP. Papilledema is often present, and blindness may occur. When the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves are irritated, ocular movements are affected. Ptosis, unequal pupils, and diplopia are common. Irritation of the trigeminal nerve (CN V) results in sensory losses and loss of the corneal reflex. Irritation of the facial nerve (CN VII) results in facial paresis. Irritation of the vestibulocochlear nerve (CN VIII) causes tinnitus, vertigo, and deafness. The dysfunction usually disappears within a few weeks. However, hearing loss may be permanent after bacterial meningitis.

Hemiparesis, dysphasia, and hemianopsia may also occur. These signs usually resolve over time. If they do not, a cerebral abscess, subdural empyema, subdural effusion, or persistent meningitis is suspected. Acute cerebral edema may cause seizures, CN III palsy, bradycardia, hypertensive coma, and death.

Headaches may occur for months after the diagnosis of meningitis until the irritation and inflammation have completely resolved. It is important to implement pain management for chronic headaches.

A noncommunicating hydrocephalus may occur if the exudate causes adhesions that prevent the normal flow of CSF from the ventricles. CSF reabsorption by the arachnoid villi may also be obstructed by the exudate. In this situation, surgical implantation of a shunt is the only treatment.

Waterhouse-Friderichsen syndrome is a complication of meningococcal meningitis. The syndrome is manifested by petechiae, disseminated intravascular coagulation (DIC), adrenal hemorrhage, and circulatory collapse. DIC and shock, which are some of the most serious complications of meningitis, are associated with meningococcemia. (DIC is discussed in detail in Chapter 31.)

Diagnostic Studies

When a patient has manifestations suggestive of bacterial meningitis, a blood culture and CT scan should be done. Diagnosis is usually verified by doing a lumbar puncture with analysis of the CSF. A lumbar puncture should be completed only after the CT scan has ruled out an obstruction in the foramen magnum in order to prevent a fluid shift resulting in herniation.

Specimens of the CSF, sputum, and nasopharyngeal secretions are taken for culture before the start of antibiotic therapy to identify the causative organism. A Gram stain is done to detect bacteria.

Variations in the CSF depend on the causative organism. Protein levels in the CSF are usually elevated and are higher in bacterial than in viral meningitis. The CSF glucose concentration is commonly decreased in bacterial meningitis but may be normal in viral meningitis. The CSF is purulent and turbid in bacterial meningitis. It may be the same or clear in viral meningitis. The predominant white blood cell type in the CSF during bacterial meningitis is neutrophils (see Table 57-16).

X-rays of the skull may demonstrate infected sinuses. CT scans and MRI may be normal in uncomplicated meningitis. In other cases, CT scans may reveal evidence of increased ICP or hydrocephalus.

Collaborative Care

Bacterial meningitis is a medical emergency. Rapid diagnosis based on history and physical examination is crucial because the patient is usually in a critical state when health care is sought. When meningitis is suspected, antibiotic therapy is instituted after the collection of specimens for cultures, even before the diagnosis is confirmed (Table 57-17).

Ampicillin, penicillin, vancomycin, cefuroxime (Ceftin), cefotaxime (Claforan), ceftriaxone (Rocephin), ceftizoxime (Cefizox), and ceftazidime (Ceptaz) are some commonly prescribed drugs for treating bacterial meningitis. Dexamethasone (a corticosteroid) may also be prescribed before or with the first

TABLE 57-17 COLLABORATIVE CARE

Bacterial Meningitis

Diagnostic
- History and physical examination
- Analysis of CSF for protein, glucose, WBC, Gram stain, and culture
- CBC, coagulation profile, electrolyte levels, glucose, platelet count

dose of antibiotics. Collaborate with the health care provider to manage the headache, fever, and nuchal rigidity often associated with meningitis.

NURSING MANAGEMENT BACTERIAL MENINGITIS

NURSING ASSESSMENT

Initial assessment should include vital signs, neurologic evaluation, fluid intake and output, and evaluation of the lungs and skin (see eFig. 57-1 available on the website for this chapter).

NURSING DIAGNOSES

Nursing diagnoses for the patient with bacterial meningitis may include, but are not limited to, the following:

- Decreased intracranial adaptive capacity *related to* decreased cerebral perfusion or increased ICP
- Risk for ineffective cerebral tissue perfusion *related to* reduction of blood flow and cerebral edema
- Hyperthermia *related to* infection
- Acute pain *related to* headache and muscle aches

Additional information on nursing diagnoses for the patient with bacterial meningitis is presented in eNursing Care Plan 57-2 (available on the website for this chapter).

PLANNING

The overall goals for the patient with bacterial meningitis are to (1) return to maximal neurologic functioning, (2) resolve the infection, and (3) control pain and discomfort.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Prevention of respiratory tract infections through vaccination programs for pneumococcal pneumonia and influenza is important. Two meningococcal vaccines are available in the United States: meningococcal polysaccharide vaccine (MPSV4) and meningococcal conjugate vaccine (MCV4). MPSV4 has been available since the 1970s. It is the only meningococcal vaccine licensed for people older than 55. MCV4 is the preferred vaccine for people 55 years of age and younger. Two doses of MCV4 are recommended for adolescents 11 through 18 years of age: the first dose at 11 or 12 years of age, with a booster dose at age 16.

Early and vigorous treatment of respiratory tract and ear infections is important. Persons who have close contact with anyone who has bacterial meningitis should be given prophylactic antibiotics.

ACUTE INTERVENTION. The patient with bacterial meningitis is usually acutely ill. The fever is high, and head pain is severe. Irritation of the cerebral cortex may result in seizures. The changes in mental status and LOC depend on the degree of increased ICP. Assess and record vital signs, neurologic status, fluid intake and output, skin, and lung fields at regular intervals based on the patient's condition.

Head and neck pain secondary to movement requires attention. Codeine provides some pain relief without undue sedation for most patients. Assist the patient to a position of comfort, often curled up with the head slightly extended. The head of the bed should be slightly elevated. A darkened room and a cool cloth over the eyes relieve the discomfort of photophobia.

For the delirious patient, additional low lighting may be necessary to decrease hallucinations. All patients suffer some degree of mental distortion and hypersensitivity, and they may be frightened and misinterpret the environment. Make every attempt to minimize environmental stimuli and prevent injury. A familiar person at the bedside may have a calming effect. Be efficient with care but also convey an attitude of caring and of unhurried gentleness. The use of touch and a soothing voice to give simple explanations of activities is helpful. If seizures occur, make appropriate observations and take protective measures. Administer antiseizure drugs such as phenytoin (Dilantin) or levetiracetam (Keppra) as ordered. Problems associated with increased ICP need to be managed (see the section on increased ICP earlier in this chapter).

Fever must be vigorously treated because it increases cerebral edema and the frequency of seizures. In addition, neurologic damage may result from an extremely high temperature over a prolonged time. Acetaminophen or aspirin may be used to reduce fever. However, if the fever is resistant to aspirin or acetaminophen, more vigorous means are necessary, such as a cooling blanket. Take care not to reduce the temperature too rapidly because shivering may result, causing a rebound effect and increasing the temperature. Wrap the extremities in soft towels or a blanket covered with a sheet to reduce shivering (which can raise ICP). If a cooling blanket is not available or desirable, tepid sponge baths with water may be effective in lowering the temperature. Protect the skin from excessive drying and injury and prevent breaks in the skin.

Because high fever greatly increases the metabolic rate and thus insensible fluid loss, assess the patient for dehydration and adequacy of fluid intake. Diaphoresis further increases fluid losses, which should be noted on the output record. Calculate replacement fluids as 800 mL/day for respiratory losses and 100 mL for each degree of temperature above 100.4°F (38°C). Supplemental feeding (e.g., enteral nutrition) to maintain adequate nutritional intake may be necessary. Follow the designated antibiotic schedule to maintain therapeutic blood levels.

Meningitis generally requires respiratory isolation until the cultures are negative. Meningococcal meningitis is highly contagious, whereas other causes of meningitis may pose minimal to no infection risk with patient contact. However, standard precautions are essential to protect the patient and the nurse.

AMBULATORY AND HOME CARE. After the acute period has passed, the patient requires several weeks of convalescence before resuming normal activities. In this period, stress the importance of adequate nutrition, with an emphasis on a high-protein, high-calorie diet in small, frequent feedings.

Muscle rigidity may persist in the neck and the backs of the legs. Progressive range-of-motion exercises and warm baths are useful. Have the patient gradually increase activity as tolerated, but encourage adequate rest and sleep.

Residual effects can result in sequelae such as dementia, seizures, deafness, hemiplegia, and hydrocephalus. Assess vision, hearing, cognitive skills, and motor and sensory abilities after recovery, with appropriate referrals as indicated. Throughout the acute and convalescent periods, be aware of the anxiety and stress experienced by the caregiver and other family members.

EVALUATION

The expected outcomes are that the patient with bacterial meningitis will

- Demonstrate appropriate cognitive function
- Be oriented to person, place, and time
- Maintain body temperature within normal range
- Report satisfaction with pain control

Additional information on expected outcomes for the patient with bacterial meningitis is addressed in eNursing Care Plan 57-2.

VIRAL MENINGITIS

The most common causes of viral meningitis are enteroviruses, arboviruses, human immunodeficiency virus, and herpes simplex virus (HSV). Enteroviruses are most often spread through direct contact with respiratory secretions. Viral meningitis usually manifests as a headache, fever, photophobia, and stiff neck.[26] The fever may be moderate or high.

The Xpert EV test is used to rapidly diagnose viral meningitis. A sample of CSF is used to determine if enterovirus is present, and results are available within hours of symptom onset.[27] An important diagnostic test is examination of the CSF via lumbar puncture. The CSF can be clear or cloudy, and the typical finding is lymphocytosis (see Table 57-16). Organisms are not seen on Gram stain or acid-fast smears. Polymerase chain reaction (PCR) used to detect viral-specific deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) is a highly sensitive method for diagnosing CNS viral infections.

Antibiotics should be administered after the lumbar puncture while awaiting the results of the CSF analysis. Antibiotics are the best defense for bacterial meningitis and can be easily discontinued if the meningitis is found to be viral.[26]

Viral meningitis is managed symptomatically because the disease is self-limiting. Full recovery from viral meningitis is expected. Rare sequelae include persistent headaches, mild mental impairment, and incoordination.

ENCEPHALITIS

Encephalitis, an acute inflammation of the brain, is a serious, and sometimes fatal, disease. In the United States, encephalitis is responsible for about 20,000 cases and 1400 deaths annually.[28]

Encephalitis is usually caused by a virus. Many different viruses have been implicated in encephalitis. Some of the viruses are associated with certain seasons of the year and endemic to certain geographic areas.

Ticks and mosquitoes transmit epidemic encephalitis. Examples include eastern equine encephalitis, La Crosse encephalitis, St. Louis encephalitis, West Nile encephalitis, and western equine encephalitis.[28] Nonepidemic encephalitis may occur as a complication of measles, chickenpox, or mumps. HSV encephalitis is the most common cause of acute nonepidemic viral encephalitis. Cytomegalovirus encephalitis is a common complication in patients with acquired immunodeficiency syndrome (AIDS).

Clinical Manifestations and Diagnostic Studies

The onset of infection is typically nonspecific, with fever, headache, nausea, and vomiting. Encephalitis can be acute or subacute. Signs of encephalitis appear on day 2 or 3 and may vary from minimal alterations in mental status to coma. Virtually any CNS abnormality can occur, including hemiparesis, tremors, seizures, cranial nerve palsies, personality changes, memory impairment, amnesia, and dysphasia.

Early diagnosis and treatment of viral encephalitis are essential for favorable outcomes. Diagnostic findings related to viral encephalitis are shown in Table 57-16. Brain imaging techniques include CT, MRI, and PET. PCR tests allow for early detection of HSV and West Nile encephalitis. West Nile virus should be strongly considered in adults over 50 years old who develop encephalitis or meningitis in summer or early fall. The best diagnostic test for West Nile virus is a blood test that detects viral RNA. This test is also used in screening blood, organs, cells, and tissues that have been donated.

NURSING AND COLLABORATIVE MANAGEMENT ENCEPHALITIS

Prevention of encephalitis requires mosquito control, including cleaning rain gutters, removing old tires, draining bird baths, and removing water where mosquitoes can breed. In addition, insect repellant should be used during mosquito season.

Collaborative and nursing management of encephalitis, including West Nile virus infection, is symptomatic and supportive. In the initial stages of encephalitis, many patients require intensive care.

Acyclovir (Zovirax) and vidarabine (Vira-A) are used to treat encephalitis caused by HSV infection. Acyclovir has fewer side effects than vidarabine and is often the preferred treatment. Use of these antiviral agents has been shown to reduce mortality rates, although neurologic complications may not be reduced. For maximal benefit, antiviral agents should be started before the onset of coma. Treat seizure disorders with antiseizure drugs. Prophylactic treatment with antiseizure drugs may be used in severe cases of encephalitis. Treatment of cytomegalovirus encephalitis in AIDS patients is discussed in Chapter 15.

RABIES

Although 30,000 to 70,000 people die each year from rabies worldwide, only one to three people die annually in the United States. The threat is much greater in developing countries. Rabies vaccine is encouraged for individuals who travel globally, since it remains a serious public health concern.

The etiology of rabies is an RNA virus that causes an acute, progressive viral encephalitis. Although rabies is generally transmitted via saliva from the bite of an infected animal, it can also be spread by scratches, mucous membrane contact with infected secretions, and inhalation of aerosolized virus into the respiratory tract. Any warm-blooded mammal, including livestock, can carry rabies. Throughout the world, rabid dogs are the most common disease vector. However, in developed countries, raccoons, skunks, bats, and foxes are the primary animal carriers.

The rabies virus spreads from the contact site through the CNS via peripheral nerve and possibly muscle fibers. During this time (2 to 14 days after exposure), patients experience flu-like symptoms, pain, paresthesias, or numbness. Then an acute neurologic syndrome occurs 2 to 7 days later and is manifested by agitation, hypersalivation, hydrophobia, dysarthria, vertigo, diplopia, hallucinations, and other neurologic sequelae (e.g., hyperactive reflexes, nuchal rigidity). Coma develops within 7 to 10 days of the neurologic syndrome. Patients experience flaccid paralysis, apnea, hydrophobia, and seizures. Death ensues as a result of respiratory and cardiovascular collapse within a few days after the onset of coma.

Because rabies is nearly always fatal, management efforts are directed at preventing the transmission and onset of the disease. Rabies postexposure prophylaxis is discussed in Chapter 69.

CASE STUDY

Traumatic Brain Injury

Comstock/Thinkstock

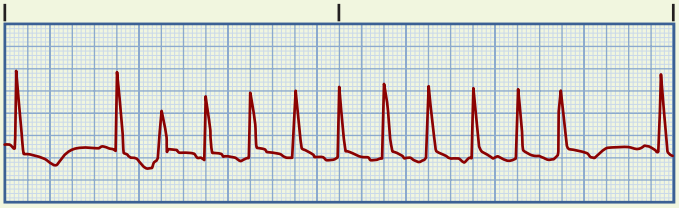
Patient Profile

C.G. is a 24-yr-old African American man who has just returned from a 15-mo Army deployment to Afghanistan. He comes to the outpatient clinic with a report of chronic headaches (pain rating of 8/10) and difficulty sleeping. His wife has noticed some personality changes since his return from deployment and is concerned that he has posttraumatic stress disorder (PTSD).

Subjective Data

- Reports that he has been depressed lately but attributes it to headache and difficulty returning home.
- Headache is worse in the morning or when he lies down.
- Uses tobacco and drinks coffee throughout the day.
- Has difficulty sleeping.
- Reports "incidents" of heavy combat and blasts with a loss of consciousness. Cannot remember how many times. Unable to obtain a more through history as he becomes quite agitated.

Objective Data



- During your assessment, you note that C.G. is looking around the room and jumps when the phone rings next door.
- Loss of short-term memory (remembers one of three items).
- Heart rate ranges from 100 to 130 beats/min.
- ECG strip is shown at right:
- Systolic BP ranges from 120 to 160 mm Hg.
- Right pupil, 3 mm sluggishly reactive; left pupil, 3 mm briskly reactive.

Diagnostic Studies

- CT of the head: negative for skull fracture, hematoma, or hemorrhage. Cerebral edema is noted with cingulate herniation on the right side.
- MRI performed following CT; mild diffuse axonal injury noted.

Discussion Questions

1. What could be the cause of C.G.'s hypertension, tachycardia, and ECG rhythm?
2. In addition to PTSD, what do his clinical manifestations suggest?
3. ***Priority Decision:*** What are the priority nursing interventions that should be implemented?
4. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
5. ***Evidence-Based Practice:*** What interventions and support can help his wife?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Vasogenic cerebral edema increases intracranial pressure by
   - **a.** shifting fluid in the gray matter.
   - **b.** altering the endothelial lining of cerebral capillaries.
   - **c.** leaking molecules from the intracellular fluid to the capillaries.
   - **d.** altering the osmotic gradient flow into the intravascular component.
2. A patient with intracranial pressure monitoring has a pressure of 12 mm Hg. The nurse understands that this pressure reflects
   - **a.** a severe decrease in cerebral perfusion pressure.
   - **b.** an alteration in the production of cerebrospinal fluid.
   - **c.** the loss of autoregulatory control of intracranial pressure.
   - **d.** a normal balance between brain tissue, blood, and cerebrospinal fluid.
3. A nurse plans care for the patient with increased intracranial pressure with the knowledge that the best way to position the patient is to
   - **a.** keep the head of the bed flat.
   - **b.** elevate the head of the bed to 30 degrees.
   - **c.** maintain patient on the left side with the head supported on a pillow.
   - **d.** use a continuous-rotation bed to continuously change patient position.
4. The nurse is alerted to a possible acute subdural hematoma in the patient who
   - **a.** has a linear skull fracture crossing a major artery.
   - **b.** has focal symptoms of brain damage with no recollection of a head injury.
   - **c.** develops decreased level of consciousness and a headache within 48 hours of a head injury.
   - **d.** has an immediate loss of consciousness with a brief lucid interval followed by decreasing level of consciousness.
5. During admission of a patient with a severe head injury to the emergency department, the nurse places the highest priority on assessment for
   - **a.** patency of airway.
   - **b.** presence of a neck injury.
   - **c.** neurologic status with the Glasgow Coma Scale.
   - **d.** cerebrospinal fluid leakage from the ears or nose.
6. A patient is suspected of having a brain tumor. The signs and symptoms include memory deficits, visual disturbances, weakness of right upper and lower extremities, and personality changes. The nurse recognizes that the tumor is most likely located in the
   - **a.** frontal lobe.
   - **b.** parietal lobe.
   - **c.** occipital lobe.
   - **d.** temporal lobe.

7. Nursing management of a patient with a brain tumor includes *(select all that apply)*
   - **a.** discussing with the patient methods to control inappropriate behavior.
   - **b.** using diversion techniques to keep the patient stimulated and motivated.
   - **c.** assisting and supporting the family in understanding any changes in behavior.
   - **d.** limiting self-care activities until the patient has regained maximum physical functioning.
   - **e.** planning for seizure precautions and teaching the patient and the caregiver about antiseizure drugs.
8. The nurse on the clinical unit is assigned to four patients. Which patient should she assess first?
   - **a.** Patient with a skull fracture whose nose is bleeding
   - **b.** Older patient with a stroke who is confused and whose daughter is present
   - **c.** Patient with meningitis who is suddenly agitated and reporting a headache of 10 on a 0-to-10 scale
   - **d.** Patient who had a craniotomy for a brain tumor who is now 3 days postoperative and has had continued vomiting
9. A nursing measure that is indicated to reduce the potential for seizures and increased intracranial pressure in the patient with bacterial meningitis is
   - **a.** administering codeine for relief of head and neck pain.
   - **b.** controlling fever with prescribed drugs and cooling techniques.
   - **c.** keeping the room dark and quiet to minimize environmental stimulation.
   - **d.** maintaining the patient on strict bed rest with the head of the bed slightly elevated.

1. b, 2. d, 3. b, 4. c, 5. a, 6. a, 7. c, e, 8. c, 9. b

LEARNING OUTCOMES

1. Describe the incidence of and risk factors for stroke.
2. Explain mechanisms that affect cerebral blood flow.
3. Compare and contrast the etiology and pathophysiology of ischemic and hemorrhagic strokes.
4. Correlate the clinical manifestations of stroke with the underlying pathophysiology.
5. Identify diagnostic studies performed for patients with strokes.
6. Differentiate among the collaborative care, drug therapy, and surgical therapy for patients with ischemic strokes and hemorrhagic strokes.
7. Describe the acute nursing management of a patient with a stroke.
8. Describe the rehabilitative nursing management of a patient with a stroke.
9. Explain the psychosocial impact of a stroke on the patient, caregiver, and family.

KEY TERMS

aneurysm, p. 1392
aphasia, p. 1394
brain attack, p. 1388
cerebrovascular accident (CVA), p. 1388
dysarthria, p. 1394
dysphasia, p. 1394
embolic stroke, p. 1392
hemorrhagic strokes, p. 1392
intracerebral hemorrhage, p. 1392
ischemic stroke, p. 1391
stroke, p. 1388
subarachnoid hemorrhage (SAH), p. 1392
thrombotic stroke, p. 1391
transient ischemic attack (TIA), p. 1391

Stroke occurs when there is (1) *ischemia* (inadequate blood flow) to a part of the brain or (2) hemorrhage into the brain that results in death of brain cells. Functions such as movement, sensation, or emotions that were controlled by the affected area of the brain are lost or impaired. The severity of the loss of function varies according to the location and extent of the brain damage.

The terms **brain attack** and **cerebrovascular accident (CVA)** are also used to describe stroke. The term *brain attack* communicates the urgency of recognizing the clinical manifestations of a stroke and treating this as a medical emergency, as would be done with a heart attack (Table 58-1). After the onset of a stroke, immediate medical attention is crucial to decrease disability and the risk of death.

Stroke is a major public health concern. An estimated 7 million people over the age of 20 in the United States have had a stroke, with 795,000 individuals affected annually.[1] With an aging population, a further increase in the incidence of stroke can be expected. However, stroke can occur at any age. About 28% of strokes occur in people younger than 65 years old.[2]

Stroke is the fourth most common cause of death in the United States, behind cancer, heart disease, and lung disease. More than 275,000 deaths occur annually from stroke. Women are more likely than men to die from a stroke because of the greater number of women over age 65.[1]

Stroke is the leading cause of serious, long-term disability. Of those who survive a stroke, 50% to 70% are functionally independent, and 15% to 30% live with permanent disability.

TABLE 58-1 PATIENT & CAREGIVER TEACHING GUIDE

Warning Signs of Stroke

Include the following information in the teaching plan for a patient at risk for stroke and the patient's caregiver.

- Call 911 and get medical help immediately if someone has one or more of the following symptoms or signs. Also, check the time so you will know when the first symptoms appeared. It is important to take immediate action.
  - Sudden numbness, weakness, paralysis of the face, arm, or leg, especially on one side of the body
  - Sudden confusion, trouble speaking or understanding
  - Slurred speech
  - Sudden trouble seeing in one or both eyes
  - Sudden trouble walking, dizziness, loss of balance or coordination
  - Sudden, severe headache with no known cause

Source: American Stroke Association: Learn to recognize a stroke, 2009. Retrieved from *www.strokeassociation.org/presenter.jhtml?identifier=1020*.

Twenty-six percent require long-term care after 3 months.[3] Common long-term disabilities include hemiparesis, inability to walk, complete or partial dependence for activities of daily living (ADLs), aphasia, and depression. In addition to the physical, cognitive, and emotional impact of the stroke on the stroke survivor, the stroke affects the lives of the stroke victim's caregiver and family.[4] A stroke is a lifelong change for both the stroke survivor and the family.

PATHOPHYSIOLOGY OF STROKE

Anatomy of Cerebral Circulation

Blood is supplied to the brain by two major pairs of arteries: the internal carotid arteries (anterior circulation) and the vertebral arteries (posterior circulation). The carotid arteries branch to supply most of the frontal, parietal, and temporal lobes; the basal ganglia; and part of the diencephalon (thalamus and hypothalamus). The major branches of the carotid arteries are the middle cerebral and anterior cerebral arteries. The vertebral arteries join to form the basilar artery, which branches to supply the middle and lower parts of the temporal lobes, occipital lobes, cerebellum, brainstem, and part of the diencephalon. The main branch of the basilar artery is the posterior cerebral artery. The anterior and posterior cerebral circulation is connected at the *circle of Willis* by the anterior and posterior communicating arteries (Fig. 58-1). (Fig. 56-9 illustrates the arteries at the base of the brain.) Genetic variations in this area are common, and all connecting vessels may not be present.

Regulation of Cerebral Blood Flow

The brain requires a continuous supply of blood to provide the oxygen and glucose that neurons need to function. Blood flow must be maintained at 750 to 1000 mL/min (55 mL/100 g of brain tissue), or 20% of the cardiac output, for optimal brain functioning. If blood flow to the brain is totally interrupted (e.g., cardiac arrest), neurologic metabolism is altered in 30 seconds, metabolism stops in 2 minutes, and cellular death occurs in 5 minutes.

The brain is normally well protected from changes in mean systemic arterial blood pressure (BP) over a range from 50 to 150 mm Hg by a mechanism known as *cerebral autoregulation*.

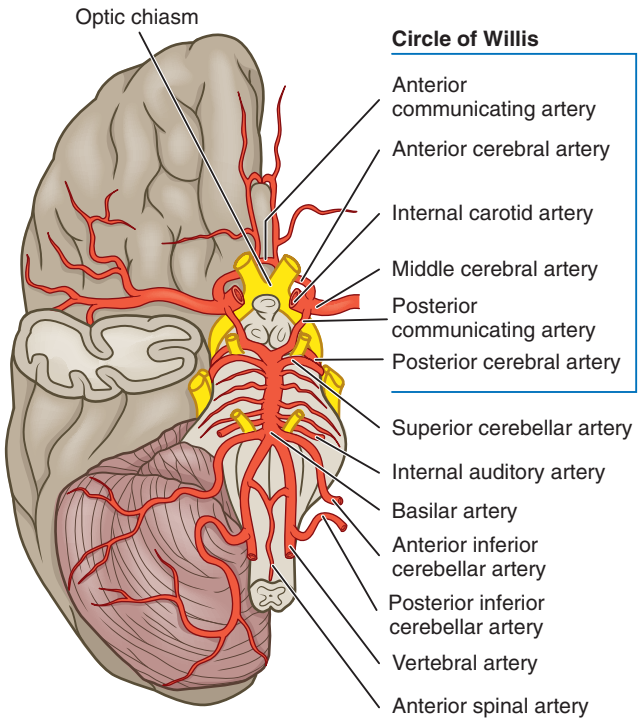

FIG. 58-1 Cerebral arteries and the circle of Willis. The top of the temporal lobe has been removed to show the course of the middle cerebral artery.

This involves changes in the diameter of cerebral blood vessels in response to changes in pressure so that the blood flow to the brain stays constant. When cerebral ischemia occurs, cerebral autoregulation may be impaired, and it is often dependent on changes in BP. Carbon dioxide is a potent cerebral vasodilator, and changes in arterial carbon dioxide levels have a dramatic effect on cerebral blood flow (increased carbon dioxide levels increase cerebral blood flow, and decreased carbon dioxide levels decrease cerebral blood flow). Very low arterial oxygen levels (partial pressure of arterial oxygen less than 50 mm Hg) or increases in hydrogen ion concentration also increase cerebral blood flow.

Factors that affect blood flow to the brain include systemic BP, cardiac output, and blood viscosity. During normal activity, oxygen requirements vary considerably, but changes in cardiac output, vasomotor tone, and distribution of blood flow normally maintain adequate blood flow to the head. Cardiac output has to be reduced by one third before cerebral blood flow is reduced. Changes in blood viscosity affect cerebral blood flow, with decreased viscosity increasing flow.

Collateral circulation may develop over time to compensate for a decrease in cerebral blood flow. An area of the brain can potentially receive blood supply from another blood vessel even if blood supply from the original vessel has been cut off (e.g., because of thrombosis). In other words, the vessels in the brain make an "alternate route" for blood flow to reach damaged areas. Individual differences in collateral circulation partly determine the degree of brain damage and functional loss when a stroke occurs. For example, the bloodstreams of the internal carotid system and the basilar system meet in the posterior communicating arteries. In normal situations the pressure of the arteries is equal and blood will not mix. However, if one of the vessels is blocked, blood will flow from the intact artery to the damaged one, preventing a CVA.

Intracranial pressure (ICP) also influences cerebral blood flow. Increased ICP causes brain compression and reduced cerebral blood flow. One of your major goals when caring for a stroke patient is to reduce secondary injury related to increased ICP (see Chapter 57).

RISK FACTORS FOR STROKE

The most effective way to decrease the burden of stroke is prevention and teaching, especially about risk factors. Risk factors can be divided into nonmodifiable and modifiable. Stroke risk increases with multiple risk factors.

Nonmodifiable Risk Factors

Nonmodifiable risk factors include age, gender, ethnicity or race, and family history or heredity. Stroke risk increases with age, doubling each decade after 55 years of age. Two thirds of all strokes occur in individuals older than 65 years, but stroke can occur at any age. Strokes are more common in men, but more women die from stroke than men. Because women tend to live longer than men, they have more opportunity to suffer a stroke.[1]

African Americans have a higher incidence of stroke and a higher death rate from stroke than whites. This may be related in part to a higher incidence of hypertension, obesity, and diabetes mellitus in African Americans.

Genetic risk factors are important in the development of all vascular diseases, including stroke. A person with a family history of stroke has an increased risk of having a stroke. Genes encoding products involved in lipid metabolism, thrombosis, and inflammation are believed to be potential genetic factors for stroke.

Modifiable Risk Factors

Modifiable risk factors are those that can potentially be altered through lifestyle changes and medical treatment, thus reducing the risk of stroke. Modifiable risk factors include hypertension, heart disease, diabetes mellitus, smoking, excessive alcohol consumption, obesity, sleep apnea, metabolic syndrome, lack of physical exercise, poor diet, and drug abuse.

Hypertension is the single most important modifiable risk factor, but it is still often undetected and inadequately treated. Increases in systolic and diastolic BP independently increase the risk of stroke. Stroke risk can be reduced by up to 50% with appropriate treatment of hypertension.[1-3]

Heart disease, including atrial fibrillation, myocardial infarction, cardiomyopathy, cardiac valve abnormalities, and cardiac congenital defects, is also a risk factor for stroke. Atrial fibrillation is responsible for about 20% of all strokes.[1] The incidence of atrial fibrillation increases with age.

Diabetes mellitus is a significant risk factor for stroke. The risk for stroke in people with diabetes mellitus is five times higher than in the general population.[1]

Increased serum cholesterol and smoking are risk factors for stroke. Smoking nearly doubles the risk of stroke. The risk associated with smoking decreases substantially over time after the smoker quits. After 5 to 10 years of no tobacco use, former smokers have the same risk of stroke as nonsmokers.[5]

The effect of alcohol on stroke risk appears to depend on the amount consumed. Women who drink more than one alcoholic drink per day and men who drink more than two alcoholic drinks per day are at higher risk for hypertension, which increases their chance of stroke. Illicit drug use, especially cocaine use, has been associated with stroke risk.[1]

Abdominal obesity increases ischemic stroke risk in all ethnic groups. In addition, obesity is also associated with hypertension, high blood glucose, and elevated blood lipid levels, all of which increase the risk of stroke.[1] An association of physical inactivity and increased stroke risk is present in both men and women, regardless of ethnicity. Benefits of physical activity can occur with even light to moderate regular activity and may be related to the beneficial impact of exercise on other risk factors. Nutrition teaching is important for the individual at risk for stroke, since a diet high in fat and low in fruits and vegetables may increase stroke risk.

The early forms of birth control pills that contained high levels of progestin and estrogen increased a woman's chance of experiencing a stroke, especially if the woman also smoked heavily. Newer, low-dose oral contraceptives have lower risks for stroke except in those individuals who are hypertensive and smoke.

Other conditions that may increase the risk for strokes include migraine headaches, inflammatory conditions, and hyperhomocysteinemia. Sickle cell disease is another known risk factor for stroke.

GENDER DIFFERENCES

Stroke

Men	Women
• Stroke is more common in men than in women. • In most age-groups, more men than women will have a stroke in a given year. • Men are more likely to have a thrombotic stroke. • Men are more likely to have an embolic stroke. • Men have a better chance of surviving a stroke than women do.	• At all ages, more women than men die from strokes. • Women are more likely to have a hemorrhagic stroke. • Women with atrial fibrillation have an increased risk for stroke. • Oral contraceptive use and pregnancy contribute to stroke risk. • tPA is used less frequently to treat women who have strokes.

tPA, Recombinant tissue plasminogen activator.

CULTURAL & ETHNIC HEALTH DISPARITIES

Stroke

African Americans
- Have a higher incidence of strokes than whites.
- The rate of first strokes is almost twice that of whites.
- Are three times more likely than whites to have an ischemic stroke and four times more likely to have a hemorrhagic stroke.
- High incidence of strokes may be related to their increased rates of hypertension, diabetes mellitus, and sickle cell anemia.
- Have a higher incidence of smoking and obesity than whites, which are two risk factors for stroke.
- Are twice as likely to die from a stroke as whites.

Other Ethnicities
- Hispanics, Native Americans, and Asian Americans have a higher incidence of strokes than whites.
- Diabetes (an important risk factor for strokes) is common among Hispanics.
- Native Americans are more likely than whites to have at least two risk factors for stroke.

Transient Ischemic Attack

Another risk factor associated with stroke is a past history of a **transient ischemic attack (TIA).** A TIA is a transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia, but without acute infarction of the brain. Clinical symptoms typically last less than 1 hour. In the past, TIAs were operationally defined as any focal cerebral ischemic event with symptoms lasting less than 24 hours. However, it is important to teach the patient to seek treatment for any stroke symptoms, since there is no way to predict if a TIA will resolve or if it is in fact the development of a stroke.[6] In general, one third of individuals who experience a TIA do not experience another event, one third have additional TIAs, and one third progress to stroke.[7]

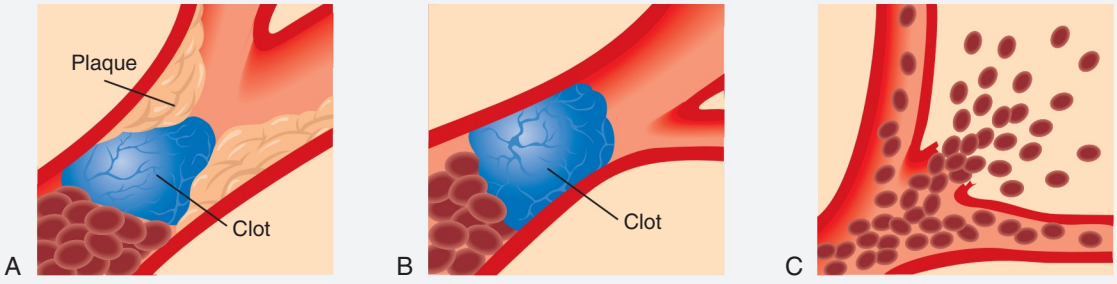
TIAs may be due to microemboli that temporarily block the blood flow. TIAs are a warning sign of progressive cerebrovascular disease. The signs and symptoms of a TIA depend on the blood vessel that is involved and the area of the brain that is ischemic. If the carotid system is involved, patients may have a temporary loss of vision in one eye *(amaurosis fugax),* transient hemiparesis, numbness or loss of sensation, or a sudden inability to speak. Signs of a TIA involving the vertebrobasilar system may include tinnitus, vertigo, darkened or blurred vision, diplopia, ptosis, dysarthria, dysphagia, ataxia, and unilateral or bilateral numbness or weakness.

TIAs should be treated as medical emergencies. Teach people at risk for TIA to seek medical attention immediately with any stroke-like symptom and to identify the time of symptom onset.[8]

TYPES OF STROKE

Unlike a TIA, where ischemia occurs without infarction, a stroke results in infarction and cell death. Strokes are classified as ischemic or hemorrhagic based on the cause and underlying pathophysiologic findings (Fig. 58-2 and Table 58-2).

Ischemic Stroke



An **ischemic stroke** results from inadequate blood flow to the brain from partial or complete occlusion of an artery. Nearly 80% of strokes are ischemic.[1] A TIA attack is usually a precursor to ischemic stroke. Ischemic strokes are further divided into thrombotic and embolic strokes.

Thrombotic Stroke. A **thrombotic stroke** occurs from injury to a blood vessel wall and formation of a blood clot (see Fig. 58-2, *A*). The lumen of the blood vessel becomes narrowed and, if it becomes occluded, infarction occurs. Thrombosis develops readily where atherosclerotic plaques have already narrowed blood vessels. Thrombotic stroke, which is the result of thrombosis or narrowing of the blood vessel, is the most common cause of stroke, accounting for about 60% of strokes.[1] Two thirds of thrombotic strokes are associated with hyperten-

TABLE 58-2 TYPES OF STROKE

Gender and Age	Warning and Onset	Prognosis
Ischemic		
Thrombotic		
Men more than women Oldest median age	*Warning:* TIA (30%-50% of cases) *Onset:* Often during or after sleep	Stepwise progression, signs and symptoms develop slowly, usually some improvement, recurrence in 20%-25% of survivors.
Embolic		
Men more than women	*Warning:* TIA (uncommon) *Onset:* Lack of relationship to activity, sudden onset	Single event, signs and symptoms develop quickly, usually some improvement, recurrence common without aggressive treatment of underlying disease.
Hemorrhagic		
Intracerebral		
Slightly higher in women	*Warning:* Headache (25% of cases) *Onset:* Activity (often)	Progression over 24 hr. Poor prognosis, fatality more likely with presence of coma.
Subarachnoid		
Slightly higher in women Youngest median age	*Warning:* Headache (common) *Onset:* Activity (often), sudden onset, most commonly related to head trauma	Usually single sudden event, fatality more likely with presence of coma.

TIA, Transient ischemic attack.

Thrombotic stroke. The process of clot formation (thrombosis) results in a narrowing of the lumen, which blocks the passage of the blood through the artery.

Embolic stroke. An embolus is a blood clot or other debris circulating in the blood. When it reaches an artery in the brain that is too narrow to pass through, it lodges there and blocks the flow of blood.

Hemorrhagic stroke. A burst blood vessel may allow blood to seep into and damage brain tissues until clotting shuts off the leak.

FIG. 58-2 Major types of stroke.

sion or diabetes mellitus, both of which accelerate atherosclerosis. In 30% to 50% of individuals, thrombotic strokes are preceded by a TIA.

The extent of the stroke depends on rapidity of onset, the size of the damaged area, and the presence of collateral circulation. Most patients with ischemic stroke do not have a decreased level of consciousness in the first 24 hours, unless it is due to a brainstem stroke or other conditions such as seizures, increased ICP, or hemorrhage. Ischemic stroke symptoms may progress in the first 72 hours as infarction and cerebral edema increase.

Embolic Stroke. **Embolic stroke** occurs when an embolus lodges in and occludes a cerebral artery, resulting in infarction and edema of the area supplied by the involved vessel (see Fig. 58-2, *B*). Embolism is the second most common cause of stroke, accounting for about 24% of strokes.[1] Most emboli originate in the endocardial (inside) layer of the heart, with plaque breaking off from the endocardium and entering the circulation. The embolus travels upward to the cerebral circulation and lodges where a vessel narrows or bifurcates (splits). Heart conditions associated with emboli include atrial fibrillation, myocardial infarction, infective endocarditis, rheumatic heart disease, valvular prostheses, and atrial septal defects. Less common causes of emboli include air and fat from long bone (e.g., femur) fractures.

The patient with an embolic stroke commonly has severe clinical symptoms that occur suddenly. Embolic strokes can affect any age-group. Rheumatic heart disease is one cause of embolic stroke in young to middle-aged adults. An embolus arising from an atherosclerotic plaque is more common in older adults.

Warning signs are less common with embolic than with thrombotic stroke. The embolic stroke often occurs rapidly, giving little time to accommodate by developing collateral circulation. The patient usually remains conscious, although he or she may have a headache. Prognosis is related to the amount of brain tissue deprived of its blood supply. The effects of the emboli are initially characterized by severe neurologic deficits, which can be temporary if the clot breaks up and allows blood to flow. Smaller emboli then continue to obstruct smaller vessels, which in turn involve smaller portions of the brain with fewer deficits noted. Recurrence of embolic stroke is common unless the underlying cause is aggressively treated.

Hemorrhagic Stroke

Hemorrhagic strokes account for approximately 15% of all strokes and result from bleeding into the brain tissue itself (intracerebral or intraparenchymal hemorrhage) or into the subarachnoid space or ventricles (subarachnoid hemorrhage or intraventricular hemorrhage).[1]

Intracerebral Hemorrhage. **Intracerebral hemorrhage** is bleeding within the brain caused by a rupture of a vessel and accounts for about 10% of all strokes (see Fig. 58-2, *C*). The prognosis of patients with intracerebral hemorrhage is poor, with the 30-day mortality rate at 40% to 80%. Fifty percent of the deaths occur within the first 48 hours.[1]

Hypertension is the most common cause of intracerebral hemorrhage (Fig. 58-3). Other causes include vascular malformations, coagulation disorders, anticoagulant and thrombolytic drugs, trauma, brain tumors, and ruptured aneurysms. Hemorrhage commonly occurs during periods of activity. Most often there is a sudden onset of symptoms, with progression over minutes to hours because of ongoing bleeding.

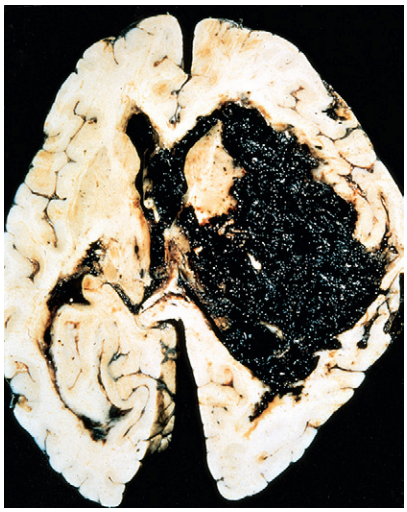


FIG. 58-3 Massive hypertensive hemorrhage rupturing into a lateral ventricle of the brain.

Manifestations include neurologic deficits, headache, nausea, vomiting, decreased level of consciousness (in about 50% of patients), and hypertension. The extent of the symptoms varies depending on the amount, location, and duration of the bleeding. A blood clot within the closed skull can result in a mass that causes pressure on brain tissue, displaces brain tissue, and decreases cerebral blood flow, leading to ischemia and infarction.

Approximately half of intracerebral hemorrhages occur in the putamen and internal capsule, central white matter, thalamus, cerebellar hemispheres, and pons. Initially, patients experience a severe headache with nausea and vomiting. Clinical manifestations of putaminal and internal capsule bleeding include weakness of one side (including the face, arm, and leg), slurred speech, and deviation of the eyes. Progression of symptoms related to a severe hemorrhage includes hemiplegia, fixed and dilated pupils, abnormal body posturing, and coma. Thalamic hemorrhage results in hemiplegia with more sensory than motor loss. Bleeding into the subthalamic areas of the brain leads to problems with vision and eye movement. Cerebellar hemorrhages are characterized by severe headache, vomiting, loss of ability to walk, dysphagia, dysarthria, and eye movement disturbances.

Hemorrhage in the pons is the most serious because basic life functions (e.g., respiration) are rapidly affected. Hemorrhage in the pons can be characterized by hemiplegia leading to complete paralysis, coma, abnormal body posturing, fixed pupils (small in size), hyperthermia, and death.

Subarachnoid Hemorrhage. **Subarachnoid hemorrhage (SAH)** occurs when there is intracranial bleeding into the cerebrospinal fluid–filled space between the arachnoid and pia mater membranes on the surface of the brain.[9] SAH is commonly caused by rupture of a cerebral **aneurysm** (congenital or acquired weakness and ballooning of vessels). Aneurysms may be saccular or berry aneurysms, ranging from a few millimeters to 20 to 30 mm in size, or fusiform atherosclerotic aneurysms. The majority of aneurysms are in the circle of Willis. Other causes of SAH include trauma and illicit drug (cocaine) abuse. About 40% of people who have a hemorrhagic stroke due to a ruptured aneurysm die during the first episode. Fifteen percent die from subsequent bleeding.[9] The incidence increases with age and is higher in women than men.

The patient may have warning symptoms if the ballooning artery applies pressure to brain tissue, or minor warning symptoms may result from leaking of an aneurysm before major rupture. In general, cerebral aneurysms are viewed as a "silent killer," since individuals do not have warning signs of an aneurysm until rupture has occurred.

SAFETY ALERT

- Sudden onset of a severe headache that is different from a previous headache and typically the "worst headache of one's life" is a characteristic symptom of a ruptured aneurysm.

Loss of consciousness may or may not occur. The patient's level of consciousness may range from alert to comatose, depending on the severity of the bleed. Other manifestations include focal neurologic deficits (including cranial nerve deficits), nausea, vomiting, seizures, and stiff neck. Despite improvements in surgical techniques and management, many patients with SAH die. Survivors may be left with significant morbidity, including cognitive difficulties.

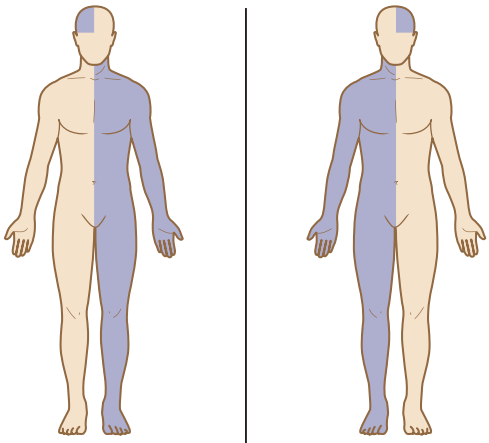
Complications of aneurysmal SAH include rebleeding before surgery or other therapy is initiated and cerebral vasospasm (narrowing of the blood vessels), which can result in cerebral infarction. Cerebral vasospasm is most likely due to an interaction between the metabolites of blood and the vascular smooth muscle. During the lysis of subarachnoid blood clots, metabolites are released. These metabolites can cause endothelial damage and vasoconstriction. In addition, release of endothelin (a potent vasoconstrictor) may play a major role in the induction of cerebral vasospasm after SAH. Patients with SAH who are at risk for vasospasm are often kept in the intensive care unit for 14 days until the threat of vasospasm is reduced. Peak time for vasospasm occurs 6 to 10 days after the initial bleed.

CLINICAL MANIFESTATIONS OF STROKE

The neurologic manifestations do not significantly differ between ischemic and hemorrhagic stroke. The reason for this is that destruction of neural tissue is the basis for neurologic dysfunction caused by both types of stroke. The clinical manifestations are related to the location of the stroke. Specific manifestations related to the type of stroke are discussed in the previous section. The general clinical manifestations of ischemic and hemorrhagic stroke are discussed together here.

A stroke can affect many body functions, including motor activity, bladder and bowel elimination, intellectual function, spatial-perceptual alterations, personality, affect, sensation, swallowing, and communication. The functions affected are directly related to the artery involved and area of the brain it supplies (Table 58-3). Manifestations related to right- and left-brain damage differ somewhat and are shown in Fig. 58-4.

An additional assessment question that you need to ask is the time of the onset of symptoms. This is important for all types of stroke, especially ischemic strokes, since the time can affect treatment decisions.



Motor Function

Motor deficits are the most obvious effect of stroke. Motor deficits include impairment of (1) mobility, (2) respiratory function, (3) swallowing and speech, (4) gag reflex, and (5) self-care abilities. Symptoms are caused by the destruction of motor neurons in the pyramidal pathway (nerve fibers from the brain that pass through the spinal cord to the motor cells). The characteristic motor deficits include loss of skilled voluntary movement *(akinesia),* impairment of integration of movements, alterations in muscle tone, and alterations in reflexes. The initial *hyporeflexia* (depressed reflexes) progresses to *hyperreflexia* (hyperactive reflexes) for most patients.

Motor deficits after a stroke follow certain specific patterns. Because the pyramidal pathway crosses at the level of the medulla, a lesion on one side of the brain affects motor function on the opposite side of the body (contralateral). The arms and legs of the affected side may be weakened or paralyzed to different degrees depending on which part of and to what extent the cerebral circulation was compromised. A stroke affecting the middle cerebral artery leads to a greater weakness in the upper extremity than the lower extremity. The affected shoulder

TABLE 58-3 STROKE MANIFESTATIONS RELATED TO ARTERY INVOLVEMENT

Artery	Deficit
Anterior cerebral	Motor and/or sensory deficit (contralateral), sucking or rooting reflex, rigidity, gait problems, loss of proprioception and fine touch
Middle cerebral	*Dominant side:* Aphasia, motor and sensory deficit, hemianopsia *Nondominant side:* Neglect, motor and sensory deficit, hemianopsia
Posterior cerebral	Hemianopsia, visual hallucination, spontaneous pain, motor deficit
Vertebral	Cranial nerve deficits, diplopia, dizziness, nausea, vomiting, dysarthria, dysphagia, and/or coma

Right-brain damage
(stroke on right side of the brain)

- Paralyzed left side: hemiplegia
- Left-sided neglect
- Spatial-perceptual deficits
- Tends to deny or minimize problems
- Rapid performance, short attention span
- Impulsive, safety problems
- Impaired judgment
- Impaired time concepts

Left-brain damage
(stroke on left side of the brain)

- Paralyzed right side: hemiplegia
- Impaired speech/language aphasias
- Impaired right/left discrimination
- Slow performance, cautious
- Aware of deficits: depression, anxiety
- Impaired comprehension related to language, math

FIG. 58-4 Manifestations of right-brain and left-brain stroke.

tends to rotate internally, and the hip rotates externally. The affected foot is plantar flexed and inverted. An initial period of flaccidity may last from days to several weeks and is related to nerve damage. Spasticity of the muscles, which follows the flaccid stage, is related to interruption of upper motor neuron influence.

Communication

The left hemisphere is dominant for language skills in right-handed persons and in most left-handed persons.[10] Language disorders involve expression and comprehension of written and spoken words. The patient may experience **aphasia,** which may be *receptive aphasia* (loss of comprehension), *expressive aphasia* (inability to produce language), or *global aphasia* (total inability to communicate). Aphasia occurs when a stroke damages the dominant hemisphere of the brain.

Dysphasia refers to impaired ability to communicate. However, in most settings the terms *aphasia* and *dysphasia* are used interchangeably, with aphasia often being the more common term used. (Dysphasia should not be confused with the similarly pronounced *dysphagia,* which is difficulty swallowing.)

Patterns of aphasia may differ, since the stroke affects different portions of the brain. Aphasia may be classified as *nonfluent* (minimal speech activity with slow speech that requires obvious effort) or *fluent* (speech is present but contains little meaningful communication) (Table 58-4). Most types of aphasia are mixed, with impairment in both expression and understanding. A massive stroke may result in global aphasia. Many stroke patients also experience **dysarthria,** a disturbance in the muscular control of speech. Impairment may involve pronunciation, articulation, and phonation. Dysarthria does not affect the meaning of communication or the comprehension of language, but it does affect the mechanics of speech. Some patients experience a combination of aphasia and dysarthria.

Affect

Patients who have had a stroke may have difficulty controlling their emotions. Emotional responses may be exaggerated or unpredictable. Depression and feelings associated with changes in body image and loss of function can make this worse.[11] Patients may also be frustrated by mobility and communication problems.

An example of unpredictable affect is as follows: a well-respected 63-year-old lawyer has returned home from the hospital after a stroke. During a meal with his family, he becomes frustrated and begins to cry because of the difficulty getting food into his mouth and chewing, something that he was able to do easily before his stroke. His family cannot understand why a previously very competent man is so emotional. As a nurse, it is important for you to help this patient and family understand that frustration and depression are common in the first year after a stroke.

Intellectual Function

Both memory and judgment may be impaired as a result of stroke. These impairments can occur with strokes affecting either side of the brain. A left-brain stroke is more likely to result in memory problems related to language. Patients with a left-brain stroke often are cautious in making judgments. The patient with a right-brain stroke tends to be impulsive and to move quickly.

TABLE 58-4 TYPES OF APHASIA

Type	Characteristics
Broca's	• A type of nonfluent aphasia. • Damage to frontal lobe of brain. • Frequently speak in short phrases that make sense but are produced with great effort. • Often omit small words such as "is," "and," and "the." • May say, "Walk dog," meaning, "I will take the dog for a walk," or "book book two table," for "There are two books on the table." • Typically understand speech of others fairly well. • Often aware of their difficulties and can become easily frustrated.
Wernicke's	• A type of fluent aphasia. • Damage occurs in left temporal lobe, although it can result from damage to right lobe. • May speak in long sentences that have no meaning, add unnecessary words, and even create made-up words. • May say, "You know that smoodle pinkered and that I want to get him round and take care of him like you want before." • Often difficult to follow what person is trying to say. • Usually have great difficulty understanding speech. • Often unaware of their mistakes.
Global	• A type of nonfluent aphasia. • Results from damage to extensive portions of language areas of brain. • Have severe communication difficulties. • May be extremely limited in ability to speak or comprehend language.
Other	• Results from damage to different language areas in brain. • Some people may have difficulty repeating words and sentences even though they can speak and they understand the meaning of the word or sentence. • Others may have difficulty naming objects even though they know what the object is and what its use is.

An example of behavior in people with right-brain stroke is that they try to rise quickly from a wheelchair without locking the wheels or raising the footrests. On the other hand, people with a left-brain stroke would move slowly and cautiously from the wheelchair. Patients with either type of stroke may have difficulty making generalizations, which interferes with their ability to learn.

Spatial-Perceptual Alterations

Individuals who have had a stroke on the right side of the brain are more likely to have problems with spatial-perceptual orientation. However, this can also occur in people with left-brain stroke.

Spatial-perceptual problems may be divided into four categories. The first is the result of damage of the parietal lobe and causes the patient to have an incorrect perception of self and illness. In this situation, patients may deny their illnesses or their own body parts. The second category occurs when the patient neglects all input from the affected side (erroneous perception of self in space). This may be worsened by *homonymous hemianopsia,* in which blindness occurs in the same half of the visual fields of both eyes. The patient also has difficulty with

spatial orientation, such as judging distances. The third spatial-perceptual deficit is *agnosia,* the inability to recognize an object by sight, touch, or hearing. The fourth deficit is *apraxia,* the inability to carry out learned sequential movements on command. Because patients may or may not be aware of their spatial-perceptual alterations, you need to assess for this potential problem, since it will affect rehabilitation and recovery.

Elimination

Most problems with urinary and bowel elimination occur initially and are temporary. When a stroke affects one hemisphere of the brain, the prognosis for normal bladder function is excellent. At least partial sensation for bladder filling remains, and voluntary urination is present. Initially, the patient may experience frequency, urgency, and incontinence. Although motor control of the bowel is usually not a problem, patients are frequently constipated. Constipation is associated with immobility, weak abdominal muscles, dehydration, and diminished response to the defecation reflex. Urinary and bowel elimination problems may also be related to inability to express needs and to manage clothing.

DIAGNOSTIC STUDIES FOR STROKE

When manifestations of a stroke occur, diagnostic studies are done to (1) confirm that it is a stroke and not another brain lesion and (2) identify the likely cause of the stroke (Table 58-5). Tests also guide decisions about therapy.

Important diagnostic tools for patients who have experienced a stroke are a noncontrast computed tomography (CT) scan or magnetic resonance imaging (MRI).[12] These tests can rapidly distinguish between ischemic and hemorrhagic stroke and help determine the size and location of the stroke. Serial CT scans may be used to assess the effectiveness of treatment and to evaluate recovery. Once the individual suspected of TIA or stroke arrives in the emergency department, it is important to rapidly assess and diagnose the patient (usually through a noncontrast head CT or MRI).[12] Rapid access to these diagnostic tools is important, since the results will determine treatment options for the patient.

CT angiography (CTA) provides visualization of cerebral blood vessels. It can be performed after or at the same time as the noncontrast CT scan. CTA can provide an estimate of perfusion and detect filling defects in the cerebral arteries. Magnetic resonance angiography (MRA) can detect vascular lesions and blockages, similar to CTA. CT/MRI perfusion and diffusion imaging may also be done.

Cardiac imaging is also recommended because many strokes are caused by blood clots from the heart. Angiography can identify cervical and cerebrovascular occlusion, atherosclerotic plaques, and malformation of vessels. Cerebral angiography is a definitive study to identify the source of SAH. Risks of angiography include dislodging an embolus, causing vasospasm, inducing further hemorrhage, and provoking an allergic reaction to contrast media.

Intraarterial digital subtraction angiography (DSA) reduces the dose of contrast material, uses smaller catheters, and shortens the length of the procedure compared with conventional angiography. DSA involves the injection of a contrast agent to visualize blood vessels in the neck and the large vessels of the circle of Willis. It is considered safer than cerebral angiography because less vascular manipulation is required.

Transcranial Doppler (TCD) ultrasonography is a noninvasive study that measures the velocity of blood flow in the major cerebral arteries. TCD is effective in detecting microemboli and vasospasm and is ideal for the patient suspected of having an SAH. Carotid duplex scanning is used not only to detect the cause of the stroke, but also to stratify patients for either medical management or carotid intervention if they have carotid stenoses.

A lumbar puncture may be done to look for evidence of red blood cells in the cerebrospinal fluid if an SAH is suspected but the CT does not show hemorrhage. A lumbar puncture is avoided if the patient is suspected of having an obstruction in the foramen magnum or other signs of increased ICP because of the danger of herniation of the brain downward, leading to pressure on cardiac and respiratory centers in the brainstem and potentially death.

If the suspected cause of the stroke includes emboli from the heart, diagnostic cardiac tests should be done. Blood tests are also done to help identify conditions contributing to stroke and to guide treatment (see Table 58-5).

The LICOX system may be used as a diagnostic tool to evaluate the progression of stroke. LICOX measures brain oxygenation and temperature (see discussion in Chapter 57 on p. 1365 and Fig. 57-10). Secondary brain injury adds significantly to mortality risk and poor functional outcome after a stroke.

TABLE 58-5 DIAGNOSTIC STUDIES

Stroke

Diagnosis of Stroke (Including Extent of Involvement)
- Computed tomography (CT) scan
- CT angiography (CTA)
- Magnetic resonance imaging (MRI)
- Magnetic resonance angiography (MRA)
- CT/MRI perfusion and diffusion imaging

Cerebral Blood Flow
- Cerebral angiography
- Carotid angiography
- Digital subtraction angiography
- Transcranial Doppler ultrasonography
- Carotid duplex scanning

Cardiac Assessment
- Electrocardiogram
- Chest x-ray
- Cardiac markers (troponin, creatine kinase-MB)
- Echocardiography (transthoracic, transesophageal)

Additional Studies
- Complete blood count, including platelets
- Coagulation studies: prothrombin time, activated partial thromboplastin time
- Electrolytes, blood glucose
- Renal and hepatic studies
- Lipid profile
- Cerebrospinal fluid analysis*

*A lumbar puncture to obtain cerebrospinal fluid is avoided if increased intracranial pressure is suspected.

COLLABORATIVE CARE FOR STROKE

Preventive Therapy

Primary prevention is a priority for decreasing morbidity and mortality risk from stroke (Table 58-6). The goals of stroke prevention include health promotion for a healthy lifestyle and management of modifiable risk factors to prevent a stroke. Health promotion focuses on (1) healthy diet, (2) weight control, (3) regular exercise, (4) no smoking, (5) limitation on alcohol consumption, and (6) routine health assessments. Patients with known risk factors such as diabetes mellitus, hypertension,

TABLE 58-6 COLLABORATIVE CARE

Stroke

Diagnostic (see Table 58-5)
- History and physical examination

Collaborative Therapy

Prevention
- Control of hypertension
- Control of diabetes mellitus
- Treatment of underlying cardiac problem
- No smoking
- Limiting alcohol intake

Drug Therapy
- Platelet inhibitors (e.g., aspirin)
- Anticoagulation therapy for patients with atrial fibrillation

Surgical Therapy
- Carotid endarterectomy
- Stenting of carotid artery
- Transluminal angioplasty
- Extracranial-intracranial bypass
- Surgical interventions for aneurysms at risk of bleeding

Acute Care
- Maintenance of airway
- Fluid therapy
- Treatment of cerebral edema
- Prevention of secondary injury

Ischemic Stroke
- Tissue plasminogen activator (tPA) IV or intraarterial
- Stent retrievers
- MERCI retriever

Hemorrhagic Stroke
- Surgical decompression if indicated
- Clipping or coiling of aneurysm

Rehabilitation
- Focus on helping patient achieve independence and functional recovery

MERCI, Mechanical embolus removal in cerebral ischemia.

HEALTHY PEOPLE

Prevention of Stroke

- Reduce salt and sodium intake.
- Maintain a normal body weight.
- Maintain a normal blood pressure.
- Increase level of physical exercise.
- Avoid cigarette smoking or tobacco products.
- Limit consumption of alcohol to moderate levels.
- Follow a diet that is low in saturated fat, total fat, and dietary cholesterol and high in fruits and vegetables.

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Can Mirror Therapy Improve Functioning After Stroke?

Clinical Question

For stroke patients (P), what is the effect of mirror therapy (I) versus control interventions (C) on motor function, activities of daily living (ADLs), and pain (O) at therapy completion and after 6 mo of therapy (T)?

Best Available Evidence

Randomized controlled trials (RCTs) and randomized crossover trials

Critical Appraisal and Synthesis of Evidence
- Fourteen trials (n = 567) of patients with stroke comparing mirror therapy to control interventions of no treatment, sham or placebo, or usual care.
- In mirror therapy, which is used to improve motor function after a stroke, a mirror is placed between a person's arms or legs so the image of the unaffected limb gives illusion of normal movement in the affected limb (see Fig. 63-24).
- Mirror therapy has a positive effect on motor function and ADLs in stroke patients, and on relieving pain in patients with complex regional pain syndrome, compared with control interventions.
- The effect of mirror therapy on motor function was stable at a 6-mo follow-up.

Conclusion
- Mirror therapy may improve motor function, ADLs, and pain compared with other interventions with effects lasting after 6 mo.

Implications for Nursing Practice
- Consult with rehabilitation care team if mirror therapy is available as an additional intervention for stroke patients.
- Motivate and encourage patients engaged in mirror therapy to practice as instructed.
- Mirror therapy may be helpful in osteoarthritis and with chronic and phantom limb pain.

Reference for Evidence

P, Patient population of interest; *I*, intervention or area of interest; *C*, comparison of interest or comparison group; *O*, outcomes of interest; *T*, timing (see p. 12).

obesity, high serum lipids, or cardiac dysfunction require close management.

Preventive Drug Therapy. Measures to prevent the development of a thrombus or an embolus are used in patients with TIAs, since they are at high risk for stroke. Antiplatelet drugs are usually the chosen treatment to prevent stroke in patients who have had a TIA. Aspirin is the most frequently used antiplatelet agent, commonly at a dose of 81 to 325 mg/day. Other drugs include ticlopidine (Ticlid), clopidogrel (Plavix), dipyridamole (Persantine), and combined dipyridamole and aspirin (Aggrenox).[13]

DRUG ALERT: Ticlopidine (Ticlid) and Clopidogrel (Plavix)
- All health care providers and dentists must be informed that the drug is being taken, especially before scheduling surgery or major dental procedures.
- Drug may need to be discontinued 10 to 14 days before surgery if antiplatelet effect is not desired.

For patients who have atrial fibrillation, oral anticoagulation can include warfarin (Coumadin), rivaroxaban (Xarelto), and dabigatran etexilate (Pradaxa). The primary advantage of rivaroxaban and dabigatran over warfarin is that these drugs do not need close monitoring or dosage adjustments. Statins (simvastatin [Zocor], lovastatin [Mevacor]) have also been shown to be effective in the prevention of stroke for individuals who have experienced a TIA in the past.[14]

Surgical Therapy for TIA and Stroke Prevention. Surgical interventions for the patient with TIAs due to carotid disease include carotid endarterectomy, transluminal angioplasty, stenting, and extracranial-intracranial (EC-IC) bypass. In a

carotid endarterectomy (CEA), the atheromatous lesion is removed from the carotid artery to improve blood flow (Fig. 58-5).

Transluminal angioplasty is the insertion of a balloon to open a stenosed artery in the brain and improve blood flow. The balloon is threaded up to the carotid artery via a catheter inserted in the femoral artery.

Stenting involves intravascular placement of a stent in an attempt to maintain patency of the artery (Fig. 58-6). The stent can be inserted during an angioplasty. Once in place, the system can be used with a tiny filter that opens like an umbrella. The filter catches and removes the debris that is stirred up during the stenting procedure before it floats to the brain, where it can trigger a stroke. Stenting is a less invasive strategy for revascularization in patients unable to withstand the CEA because of coexisting medical conditions. Initial research has shown the procedure to be as effective as the CEA.[15]

EC-IC bypass involves anastomosing (surgically connecting) a branch of an extracranial artery to an intracranial artery (most commonly, superficial temporal to middle cerebral artery) beyond an area of obstruction with the goal of increasing cerebral perfusion. This procedure is generally reserved for patients who do not benefit from other forms of therapy. Postoperatively nursing care for these patients consists of neurovascular assessment, BP management, assessment of stent occlusion or retroperitoneal hemorrhage as complications, and minimization of complications at the insertion site by keeping the patient's leg straight for the prescribed time.

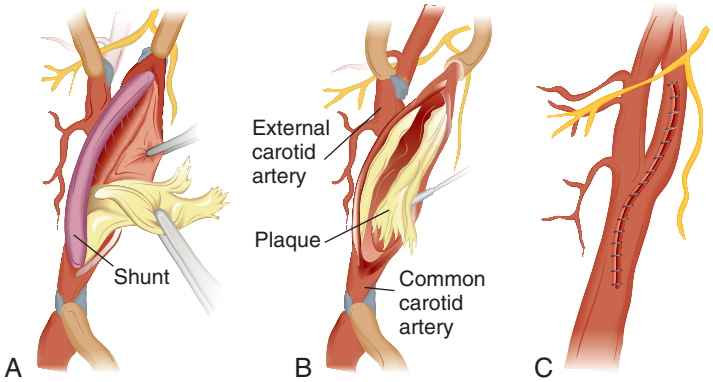

FIG. 58-5 Carotid endarterectomy is performed to prevent impending cerebral infarction. **A,** A tube is inserted above and below the blockage to reroute the blood flow. **B,** Atherosclerotic plaque in the common carotid artery is removed. **C,** Once the artery is stitched closed, the tube can be removed. A surgeon may also perform the technique without rerouting the blood flow.

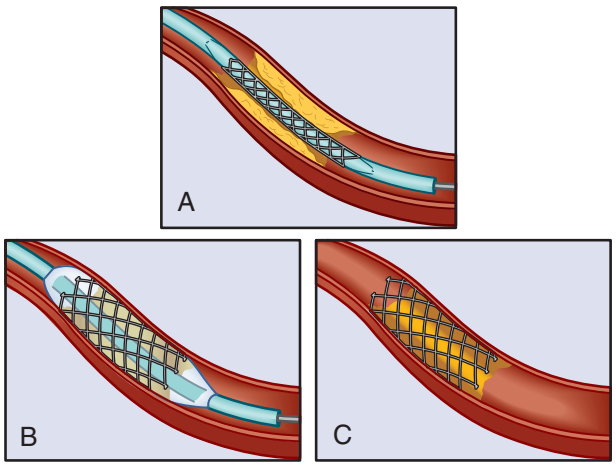

FIG. 58-6 Brain stent used to treat blockages in cerebral blood flow. **A,** A balloon catheter is used to implant the stent into an artery of the brain. **B,** The balloon catheter is moved to the blocked area of the artery and then inflated. The stent expands due to inflation of the balloon. **C,** The balloon is deflated and withdrawn, leaving the stent permanently in place holding the artery open and improving the flow of blood.

Acute Care for Ischemic Stroke

During initial evaluation, the single most important point in the patient's history is the time of onset of symptoms. The goals for collaborative care during the acute phase are preserving life, preventing further brain damage, and reducing disability.

Table 58-7 outlines the emergency management of the patient with a stroke. Acute care begins with managing circulation, airway, and breathing. Patients may have difficulty keeping an open and clear airway because of a decreased level of consciousness or decreased or absent gag and swallowing reflexes. Maintaining adequate oxygenation is important. Oxygen administration, artificial airway insertion, intubation, and mechanical ventilation may be required. Baseline neurologic assessment is carried out, and patients are monitored closely for signs of increasing neurologic deficit. About 25% of patients worsen in the first 24 to 48 hours.

For emergency care, patients should be transported to the closest certified stroke center or, when such an institution is not available, the closest facility offering emergency stroke care. The American Heart Association recommends that acute care facilities have stroke teams in place. The stroke team generally consists of the registered nurse, neurologist, radiologist, and CT technician.[16]

Elevated BP is common immediately after a stroke and may be a protective response to maintain cerebral perfusion. However, it can also be detrimental. Immediately after an ischemic stroke in those patients who do not receive fibrinolytic therapy (discussed below), the use of drugs to lower BP is recommended only if BP is markedly increased (systolic BP greater than 220 mm Hg or diastolic greater than 120 mm Hg). In a patient who is going to have fibrinolytic therapy, the BP needs to be less than 185/110 mm Hg and then maintained at or below 180/105 mm Hg for at least 24 hours after fibrinolytic therapy. In an acute stroke, IV antihypertensives such as labetalol (Normodyne) and nicardipine (Cardene) are preferred. Although low BP immediately after a stroke is uncommon, hypotension and hypovolemia should be corrected if present.

Fluid and electrolyte balance must be controlled carefully. Generally the goal is to keep the patient adequately hydrated to promote perfusion and decrease further brain injury. Overhydration may compromise perfusion by increasing cerebral edema. Adequate fluid intake during acute care via oral, IV, or tube feedings is a priority. Also monitor urine output to make sure the patient does not become dehydrated.

If secretion of antidiuretic hormone (ADH) increases in response to the stroke, urine output decreases and fluid is retained. Low serum sodium (hyponatremia) may occur. IV solutions with glucose and water are avoided because they are hypotonic and may further increase cerebral edema and ICP. In addition, hyperglycemia may be associated with further brain damage and should be treated. In general, decisions regarding individualized fluid and electrolyte replacement therapy are based on the extent of intracranial edema, symptoms of

TABLE 58-7 EMERGENCY MANAGEMENT

Stroke

Etiology	Assessment Findings	Interventions
• Sudden vascular compromise causing disruption of blood flow to brain • Thrombosis • Trauma • Aneurysm • Embolism • Hemorrhage • Arteriovenous malformation	• Altered level of consciousness • Weakness, numbness, or paralysis of portion of body • Speech or visual disturbances • Severe headache • Heart rate ↑ or ↓ • Respiratory distress • Unequal pupils • Hypertension • Facial drooping on affected side • Difficulty swallowing • Seizures • Bladder or bowel incontinence • Nausea and vomiting • Vertigo	**Initial** • Ensure patent airway. • Call stroke code or stroke team. • Remove dentures. • Perform pulse oximetry. • Maintain adequate oxygenation (SaO_2 >95%) with supplemental O_2, if necessary. • Establish IV access with normal saline. • Maintain BP according to guidelines (e.g., Cardiac Life Support).* • Remove clothing. • Obtain CT scan or MRI immediately. • Perform baseline laboratory tests (including blood glucose) immediately, and treat if hypoglycemic. • Position head in midline. • Elevate head of bed 30 degrees if no symptoms of shock or injury. • Institute seizure precautions. • Anticipate thrombolytic therapy for ischemic stroke. • Keep patient NPO until swallow reflex evaluated. **Ongoing Monitoring** • Monitor vital signs and neurologic status, including level of consciousness (NIH Stroke Scale), motor and sensory function, pupil size and reactivity, SaO_2, and cardiac rhythm. • Reassure patient and family.

*See Appendix A.
NIH, National Institutes of Health; *SaO_2,* arterial oxygen saturation.

increased ICP, central venous pressure levels, laboratory values for electrolytes, and intake and output.

Increased ICP is more likely to occur with hemorrhagic strokes but can occur with ischemic strokes. Increased ICP from cerebral edema usually peaks in 72 hours and may cause brain herniation. Management of increased ICP includes practices that improve venous drainage, such as elevating the head of the bed, maintaining head and neck in alignment, and avoiding hip flexion. Additional measures for reducing ICP include management of hyperthermia (goal temperature of 96.8° to 98.6° F [36° to 37° C]), drug therapy to prevent seizures, pain management, avoidance of hypervolemia, and management of constipation. Cerebrospinal fluid drainage may be used in some patients to reduce ICP. (The specific management of increased ICP is discussed in Chapter 57.)

Drug Therapy for Ischemic Stroke. Fibrinolytic therapy should not be delayed. Recombinant tissue plasminogen activator (tPA) is used to produce localized fibrinolysis by binding to the fibrin in the thrombi. The fibrinolytic action of tPA occurs as the plasminogen is converted to plasmin, whose enzymatic action then digests fibrin and fibrinogen, and thus lyses the clot. Other fibrinolytic agents cannot be substituted for tPA. (Fibrinolytic [thrombolytic] therapy is discussed in Chapter 34.)

tPA is administered IV to reestablish blood flow through a blocked artery to prevent cell death in patients with the acute onset of ischemic stroke. tPA must be administered within 3 to 4½ hours of the onset of clinical signs of ischemic stroke.[16,17] Patients are screened carefully before tPA can be given. Screening includes a noncontrast CT or MRI scan to rule out hemorrhagic stroke; blood tests for glucose level and coagulation disorders; and screening for recent history of gastrointestinal bleeding, stroke, or head trauma within the past 3 months, or major surgery within 14 days.[16,17] If tPA is expected as a treatment option, insert a urinary catheter, nasogastric tube, and multiple IVs before tPA administration. During infusion of the drug, closely monitor the patient's vital signs and neurologic status to assess for improvement or for potential deterioration related to intracerebral hemorrhage. Control of BP is critical during treatment and for 24 hours following.

Intraarterial infusion of tPA may also be used for patients with an ischemic stroke. Intraarterial tPA can be administered up to 6 hours after the onset of stroke symptoms. In the intraarterial tPA procedure, the neurovascular specialist inserts a thin, flexible catheter into an artery (usually the femoral artery) and guides the catheter to the area of the clot by angiogram. The tPA is administered through the catheter and immediately targets the clot. Less tPA is needed when it is delivered directly to the clot, which can reduce the possibility of intracranial hemorrhage.[17]

The use of anticoagulants (e.g., heparin) in the emergency phase after an ischemic stroke is generally not recommended because of the risk for intracranial hemorrhage. Acetylsalicylic acid (aspirin) at a dose of 325 mg may be initiated within 24 to 48 hours after the onset of an ischemic stroke. Complications of aspirin include gastrointestinal bleeding with higher doses. Aspirin should be administered cautiously if the patient has a history of peptic ulcer disease.[18]

After the patient has stabilized and to prevent further clot formation, patients with strokes caused by thrombi and emboli may be treated with anticoagulants and platelet inhibitors (see discussion on prevention of stroke on pp. 1396-1397). For patients who have atrial fibrillation, oral anticoagulants include warfarin, rivaroxaban, and dabigatran etexilate. Platelet inhibitors include aspirin, ticlopidine, clopidogrel, and dipyridamole. Additionally, the use of statins has been shown to be effective for the patient with an ischemic stroke.[14]

Surgical Therapy for Ischemic Stroke. Stent retrievers (e.g., Solitaire FR, Trevo) are a way of opening blocked arteries in the brain by using a removable stent system. During the procedure, a catheter is used to guide the small stent from the femoral artery in the groin area to the affected artery in the brain. The stent is guided into the part of the artery where a blood clot has

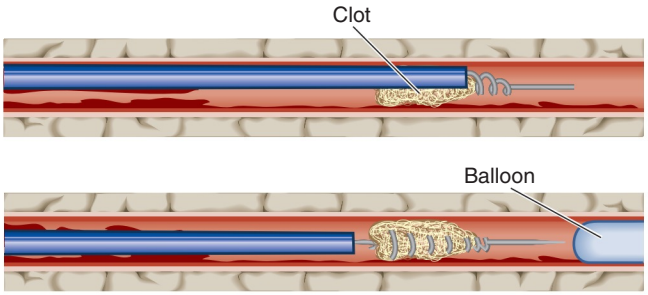

FIG. 58-7 The MERCI retriever removes blood clots in patients who are experiencing ischemic strokes. The retriever is a long, thin wire that is threaded through a catheter into the femoral artery. The wire is pushed through the end of the catheter up to the carotid artery. The wire reshapes itself into tiny loops that latch onto the clot, and the clot can then be pulled out. To prevent the clot from breaking off, a balloon at the end of the catheter inflates to stop blood flow through the artery. *MERCI*, Mechanical embolus removal in cerebral ischemia.

formed. The stent expands the interior walls of the artery and allows blood to get to the patient's brain immediately to prevent as much brain damage as possible. The clot seeps into the mesh of the stent. Then, after a few minutes the stent and clot are removed together.

Another surgical approach uses the mechanical embolus removal in cerebral ischemia (MERCI) retriever (Fig. 58-7), which allows the surgeon to go inside the blocked artery of a patient who is experiencing ischemic strokes. The MERCI retriever has a tiny, corkscrew-like device that uses a microcatheter inserted through a femoral artery balloon catheter. Once the corkscrew device reaches the clot in the brain, the device penetrates the clot, allowing it to be removed. A guidewire and the microcatheter are deployed through the balloon catheter and then placed just beyond the clot. The physician then deploys the MERCI retriever device to engage and ensnare the clot. Once the clot is captured, the balloon catheter is inflated to temporarily arrest forward flow while the clot is being withdrawn. The clot is pulled into the balloon catheter and completely out of the body. The balloon is then deflated and blood flow is restored. Research is also being conducted on other mechanical thrombectomy devices for the removal of clots, including acute balloon angioplasty and stenting, snare devices, and ultrasonic aspirators.[19]

Acute Care for Hemorrhagic Stroke

Drug Therapy for Hemorrhagic Stroke. Anticoagulants and platelet inhibitors are contraindicated in patients with hemorrhagic strokes. The main drug therapy for patients with hemorrhagic stroke is the management of hypertension. Oral and IV agents may be used to maintain BP within a normal to high-normal range (systolic BP less than 160 mm Hg). Seizure prophylaxis in the acute period after intracerebral and subarachnoid hemorrhages is situation specific and should be discussed with the collaborative care team.[20]

Surgical Therapy for Hemorrhagic Stroke. Surgical interventions for hemorrhagic stroke include immediate evacuation of aneurysm-induced hematomas or cerebellar hematomas larger than 3 cm. Individuals who have an arteriovenous malformation (AVM) may experience a hemorrhagic stroke if the AVM ruptures. The treatment of AVM is surgical resection and/or radiosurgery (i.e., gamma knife). Both may be preceded by interventional neuroradiology to embolize the blood vessels that supply the AVM.

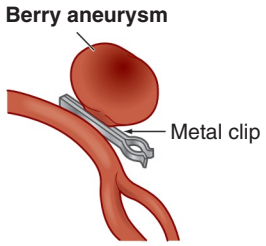

FIG. 58-8 Clipping of aneurysms.

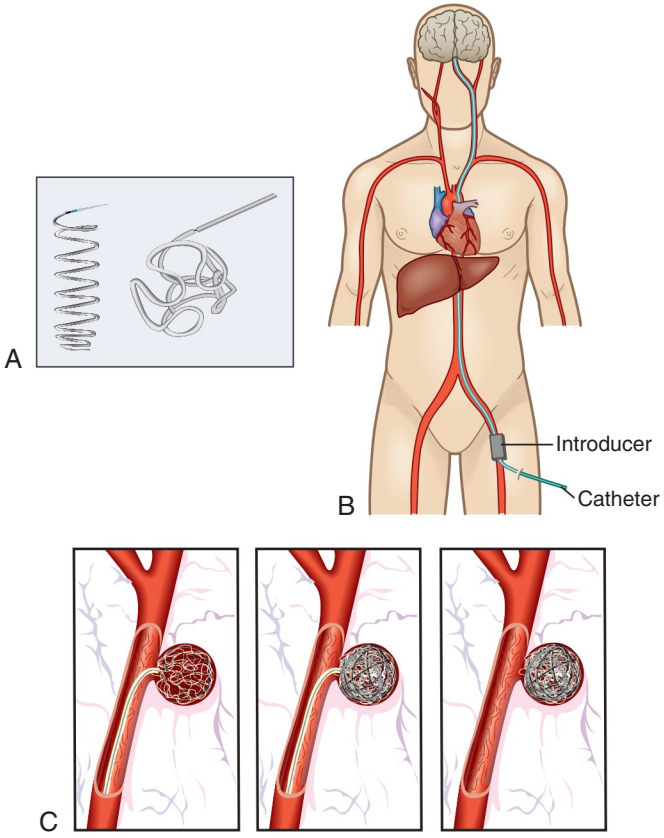

FIG. 58-9 Guglielmi detachable coil (GDC). **A,** A coil is used to occlude an aneurysm. Coils are made of soft, springlike platinum. The softness of the platinum allows the coil to assume the shape of irregularly shaped aneurysms while posing little threat of rupture of the aneurysm. **B,** A catheter is inserted through an introducer (small tube) in an artery in the leg. The catheter is threaded up to the cerebral blood vessels. **C,** Platinum coils attached to a thin wire are inserted into the catheter and then placed in the aneurysm until the aneurysm is filled with coils. Packing the aneurysm with coils prevents the blood from circulating through the aneurysm, reducing the risk of rupture.

SAH is usually caused by a ruptured aneurysm. Approximately 20% of patients have multiple aneurysms. Treatment of an aneurysm involves clipping or coiling the aneurysm to prevent rebleeding (Figs. 58-8 and 58-9). In *clipping* the aneurysm, the neurosurgeon places a metallic clip on the neck of the aneurysm to block blood flow and prevent rupture. The clip remains in place for life. In the procedure known as *coiling*, a metal coil is inserted into the lumen of the aneurysm via interventional neuroradiology (see Fig. 58-9). Guglielmi detachable coils (GDCs) provide immediate protection against hemorrhage by reducing the blood pulsations within the aneurysm. Eventually, a thrombus forms within the aneurysm and the aneurysm becomes sealed off from the parent vessel by the formation of an endothelialized layer of connective tissue.

Goals for managing ICP are the same for patients with SAH as they are for patients dealing with acute stroke. After aneurysmal occlusion via clipping or coiling, hyperdynamic therapy (hemodilution-induced hypertension using vasoconstricting agents such as phenylephrine or dopamine [Intropin] and hypervolemia) may be instituted in an effort to increase the mean arterial pressure and increase cerebral perfusion. Volume expansion is achieved via crystalloid or colloid solution.

Interventions to treat cerebral vasospasm either before or after aneurysm clipping or coiling include administration of the calcium channel blocker nimodipine (Nimotop), which is given to patients with SAH to decrease the effects of vasospasm and minimize cerebral damage. Nimodipine restricts the influx of calcium ions into cells by reducing the number of open calcium channels. Although nimodipine is a calcium channel blocker, its exact mechanism of action in reducing vasospasm is not well understood.

DRUG ALERT: Nimodipine (Nimotop)

- Assess BP and apical pulses before administration.
- If pulse is ≤60 beats/min or systolic BP is <90 mm Hg, hold medication and contact physician.

Subarachnoid and intracerebral hemorrhage can involve bleeding into the ventricles of the brain. This situation produces hydrocephalus, which further damages brain tissue from increased ICP. Insertion of a ventriculostomy for cerebrospinal fluid drainage can dramatically improve these situations.[21]

Rehabilitation Care

After the stroke patient has stabilized for 12 to 24 hours, collaborative care shifts from preserving life to lessening disability and attaining optimal function. Many of the interventions discussed in the acute phase are maintained during this phase. The patient may be evaluated by a physiatrist (a physician who specializes in physical medicine and rehabilitation). Remember that some aspects of rehabilitation actually begin in the acute care phase as soon as the patient is stabilized. Specific measures related to rehabilitation are discussed in the section on Ambulatory and Home Care on pp. 1408-1410.

NURSING MANAGEMENT
STROKE

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a person who has had a stroke are presented in Table 58-8. Primary assessment focuses on cardiac and respiratory status and neurologic assessment. If the patient is stable, the nursing history is obtained as follows: (1) description of the current illness with attention to initial symptoms, particularly symptom onset and duration, nature (intermittent or continuous), and changes; (2) history of similar symptoms previously experienced; (3) current medications; (4) history of risk factors and other illnesses such as hypertension; and (5) family history of stroke or cardiovascular diseases. This information is gained through an interview of the patient, family members, significant others, and/or caregiver.

Secondary assessment includes a comprehensive neurologic examination of the patient. This includes (1) level of consciousness, including assessment using the National Institutes of Health (NIH) Stroke Scale (Table 58-9); (2) cognition; (3) motor abilities; (4) cranial nerve function; (5) sensation; (6) proprioception; (7) cerebellar function; and (8) deep tendon reflexes.

TABLE 58-8 NURSING ASSESSMENT

Stroke

Subjective Data

Important Health Information

Past health history: Hypertension; previous stroke, TIA, aneurysm, cardiac disease (including recent myocardial infarction), dysrhythmias, heart failure, valvular disease, infective endocarditis; hyperlipidemia, polycythemia, diabetes, gout; previous head injury, family history of hypertension, diabetes, stroke, or coronary artery disease

Medications: Oral contraceptives; use of and compliance with antihypertensive and anticoagulant therapy; illegal substances and drug use (cocaine)

Functional Health Patterns

Health perception–health management: Positive family history of stroke; alcohol abuse, smoking, drug abuse

Nutritional-metabolic: Anorexia, nausea, vomiting; dysphagia, altered sense of taste and smell

Elimination: Change in bowel and bladder patterns

Activity-exercise: Loss of movement and sensation; syncope; weakness on one side; generalized weakness, easy fatigability

Cognitive-perceptual: Numbness, tingling of one side of the body; loss of memory; alteration in speech, language, problem-solving ability; pain; headache, possibly sudden and severe (hemorrhage); visual disturbances; denial of illness

Objective Data

General

Emotional lability, lethargy, apathy or combativeness, fever

Respiratory

Loss of cough reflex, labored or irregular respirations, tachypnea, rhonchi (aspiration), airway occlusion (tongue), apnea, coughing when eating or delayed coughing

Cardiovascular

Hypertension, tachycardia, carotid bruit

Gastrointestinal

Loss of gag reflex, bowel incontinence, decreased or absent bowel sounds, constipation

Urinary

Frequency, urgency, incontinence

Neurologic

Contralateral motor and sensory deficits, including weakness, paresis, paralysis, anesthesia; unequal pupils, hand grasps; akinesia, aphasia (expressive, receptive, global), dysarthria (slurred speech), agnosias, apraxia, visual deficits, perceptual or spatial disturbances, altered level of consciousness (drowsiness to deep coma) and Babinski's sign, ↓ followed by ↑ deep tendon reflexes, flaccidity followed by spasticity, amnesia, ataxia, personality change, nuchal rigidity, seizures

Possible Diagnostic Findings

Positive CT, CTA, MRI, MRA, or other neuroimaging scans showing size, location, and type of lesion; positive Doppler ultrasonography and angiography indicating stenosis

CTA, Computed tomographic angiography; *MRA,* magnetic resonance angiography; *TIA,* transient ischemic attack.

Clear documentation of initial and ongoing neurologic examinations is essential to note changes in the patient's status.

NURSING DIAGNOSES

Nursing diagnoses for the person with a stroke may include, but are not limited to, those presented in Nursing Care Plan 58-1.

TABLE 58-9 NATIONAL INSTITUTES OF HEALTH STROKE SCALE (NIHSS)

Description

The National Institutes of Health Stroke Scale (NIHSS) is a 15-item neurologic examination used to evaluate the effect of an acute stroke.

Procedure for Use

A trained observer rates the patient's ability to answer questions and perform activities. Ratings for each item are scored and there is an allowance for untestable (UN) items. If an item is left untested, a detailed explanation must be clearly written on the form. Training can be completed free at *www.nihstrokescale.org*.

Item	Scale Definition
Level of consciousness	0 = Alert 1 = Not alert, but arousable by minor stimulation 2 = Not alert, requires repeated stimulation to get attention 3 = Responds only with reflex motor or autonomic effects or totally unresponsive, flaccid, areflexic
Level of consciousness questions	0 = Answers both questions correctly 1 = Answers one question correctly 2 = Answers neither question correctly
Level of consciousness commands	0 = Performs both tasks correctly 1 = Performs one task correctly 2 = Performs neither task correctly
Best gaze	0 = Normal 1 = Partial gaze palsy 2 = Forced deviation, or total gaze paresis
Visual	0 = No visual loss 1 = Partial hemianopsia 2 = Complete hemianopsia 3 = Bilateral hemianopsia or blind
Facial palsy	0 = Normal symmetric movement 1 = Minor paralysis 2 = Partial paralysis 3 = Complete paralysis of one or both sides
Motor and drift (for each extremity)	0 = No drift 1 = Drift 2 = Some effort against gravity 3 = No effort against gravity, limb falls 4 = No movement UN = Amputation
Limb ataxia	0 = Absent 1 = Present in one limb 2 = Present in two limbs
Sensory	0 = Normal 1 = Mild to moderate sensory loss 2 = Severe to total sensory loss
Best language	0 = No aphasia, normal 1 = Mild to moderate aphasia 2 = Severe aphasia 3 = Mute, no usable speech or auditory comprehension
Dysarthria	0 = Normal 1 = Mild to moderate 2 = Severe UN = Intubated or other physical barrier
Extinction or inattention	0 = No abnormality 1 = Inattention or extinction to bilateral stimulation 2 = Does not recognize own hand
Distal motor function	0 = Normal (no flexion after 5 sec) 1 = At least some extension but not fully extended 2 = No voluntary extension after 5 sec

PLANNING

Together with the patient, caregiver, and family, establish the goals of nursing care. Typical goals are that the patient will (1) maintain a stable or improved level of consciousness, (2) attain maximum physical functioning, (3) attain maximum self-care abilities and skills, (4) maintain stable body functions (e.g., bladder control), (5) maximize communication abilities, (6) maintain adequate nutrition, (7) avoid complications of stroke, and (8) maintain effective personal and family coping.

NURSING IMPLEMENTATION

HEALTH PROMOTION. You have a major role in the promotion of a healthy lifestyle. Teaching should focus on stroke prevention, particularly for persons with known risk factors. Nursing measures to reduce risk factors for stroke are similar to those for coronary artery disease (see Chapter 34, Table 34-1) and are discussed earlier in this chapter on pp. 1394-1396.

Uncontrolled or undiagnosed hypertension is the primary cause of stroke. Therefore you need to be involved in BP screening and ensuring that patients adhere to the use of their antihypertensive medications. If a person is a diabetic, it is important that the diabetes is well controlled. If an individual has atrial fibrillation, an anticoagulant (see p. 1398) or aspirin may be used to reduce the risk of stroke. Because smoking is a major risk factor for stroke, you need to be actively involved in helping patients to stop smoking (see Chapter 11, Tables 11-4 to 11-6).

Another important aspect of health promotion is teaching patients and families about early symptoms associated with stroke or TIA. Table 58-1 presents information on when to seek health care for these symptoms.

ACUTE INTERVENTION

Respiratory System. During the acute phase after a stroke, management of the respiratory system is a nursing priority.[22] Stroke patients are particularly vulnerable to respiratory problems. Advancing age and immobility increase the risk for atelectasis and pneumonia.

Risk for aspiration pneumonia is high because of impaired consciousness or dysphagia. Dysphagia after stroke is common.[23] Airway obstruction can occur because of problems with chewing and swallowing, food pocketing (food remaining in the buccal cavity of the mouth), and the tongue falling back. Some stroke patients, especially those with brainstem or hemorrhagic stroke, may require endotracheal intubation and mechanical ventilation initially. Enteral tube feedings also place the patient at risk for aspiration pneumonia. All patients should be screened for their ability to swallow and kept on nothing-by-mouth (NPO) status until dysphagia has been ruled out.

Nursing interventions to support adequate respiratory function are individualized to meet the patient's needs. An oropharyngeal airway may be used in comatose patients to prevent the tongue from falling back and obstructing the airway and to provide access for suctioning. Alternatively, a nasopharyngeal airway may be used to provide airway protection and access. When an artificial airway is required for a prolonged time, a tracheostomy may be performed.

Nursing interventions include frequently assessing airway patency and function, providing oxygenation, suctioning, promoting patient mobility, positioning the patient to prevent aspiration, and encouraging deep breathing. In patients who are on mechanical ventilation, oral care at least every 2 hours reduces the occurrence of ventilator-assisted pneumonia.[24]

NURSING CARE PLAN 58-1

Patient With Stroke

NURSING DIAGNOSIS **Decreased intracranial adaptive capacity** *related to* decreased cerebral perfusion pressure of ≤50-60 mm Hg and sustained increase in ICP secondary to thrombus, embolus, or hemorrhage *as evidenced by* baseline ICP ≥15 mm Hg, elevated systolic blood pressure, bradycardia, widened pulse pressure, and increasing NIH Stroke Scale score

PATIENT GOAL Demonstrates signs of stable or improved cerebral perfusion

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Tissue Perfusion: Cerebral	***Cerebral Perfusion Promotion***
• Intracranial pressure _____ • Systolic blood pressure _____ • Diastolic blood pressure _____ **Measurement Scale** 1 = Severe deviation from normal range 2 = Substantial deviation from normal range 3 = Moderate deviation from normal range 4 = Mild deviation from normal range 5 = No deviation from normal range	• Consult with physician to determine hemodynamic parameters, and maintain hemodynamic parameters within this range. • Monitor neurologic status *to detect changes indicative of worsening or improving condition.* • Calculate and monitor cerebral perfusion pressure (CPP) *to detect change in condition.* • Monitor respiratory status (e.g., rate, rhythm, and depth of respirations; PaO_2, $PaCO_2$, pH, and bicarbonate levels) *because high $PaCO_2$ and a high hydrogen ion concentration (acidosis) are potent vasodilators that increase cerebral blood flow.* • Monitor patient's ICP and neurologic responses to care activities, *since changes in positioning and movement can increase ICP.* • Monitor determinants of tissue oxygen delivery (e.g., $PaCO_2$, SaO_2, hemoglobin levels, and cardiac output) *to ensure adequate cerebral oxygenation.* • Administer and titrate vasoactive drugs, as ordered, *to maintain hemodynamic parameters.* • Avoid neck flexion or extreme hip or knee flexion *to avoid obstruction of arterial and venous blood flow.*
• Restlessness _____ • Decreased level of consciousness _____ • Impaired cognition _____ • Impaired neurologic reflexes _____ **Measurement Scale** 1 = Severe 2 = Substantial 3 = Moderate 4 = Mild 5 = None	

NURSING DIAGNOSIS **Risk for aspiration** *related to* decreased level of consciousness and decreased or absent gag and swallowing reflexes

PATIENT GOALS
1. Demonstrates ability to swallow oral foods without aspiration
2. Maintains a clear airway

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Respiratory Status: Airway Patency	***Aspiration Precautions***
• Depth of inspiration _____ • Ability to clear secretions _____ **Measurement Scale** 1 = Severe deviation from normal range 2 = Substantial deviation from normal range 3 = Moderate deviation from normal range 4 = Mild deviation from normal range 5 = No deviation from normal range	• Monitor level of consciousness, cough reflex, gag reflex, and swallowing ability *to determine patient's ability to swallow foods without aspiration.* • Avoid liquids or use thickening agent *to facilitate swallowing.* • Feed in small amounts until patient is no longer at risk for aspiration. • Offer foods or liquids that can be formed into a bolus before swallowing. ***Airway Management*** • Auscultate breath sounds, noting areas of decreased or absent ventilation and presence of adventitious sounds *to identify airway obstruction and accumulation of secretions.* • Remove secretions by encouraging coughing or by suctioning *to clear airway.* • Encourage slow, deep breathing; turning; and coughing *to increase airway clearance without increasing ICP.* • Assist with incentive spirometer *to open collapsed alveoli, promote deep breathing, and prevent atelectasis.* • Keep patient NPO until swallow evaluation completed *to prevent aspiration.*
• Adventitious breath sounds _____ • Accumulation of sputum _____ **Measurement Scale** 1 = Severe 2 = Substantial 3 = Moderate 4 = Mild 5 = None	

NURSING DIAGNOSIS **Impaired physical mobility** *related to* neuromuscular and cognitive impairment and decreased muscle strength and control *as evidenced by* limited ability to perform gross and fine motor skills, limited range of motion, and difficulty turning

PATIENT GOALS
1. Demonstrates increased muscle strength and ability to move
2. Uses adaptive equipment to increase mobility

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Mobility	***Exercise Therapy: Muscle Control***
• Balance _____ • Muscle movement _____ • Joint movement _____ • Transfer performance _____ • Walking _____ **Measurement Scale** 1 = Severely compromised 2 = Substantially compromised 3 = Moderately compromised 4 = Mildly compromised 5 = Not compromised	• Collaborate with physical, occupational, and recreational therapists in developing and executing exercise program *to determine extent of problem and plan appropriate interventions.* • Determine patient's readiness to engage in activity or exercise protocol *to assess expected level of participation.* • Apply splints to achieve stability of proximal joints involved with fine motor skills *to prevent contractures.* • Encourage patient to practice exercises independently *to promote patient's sense of control.* • Reinforce instructions provided to patient about the proper way to perform exercises *to minimize injury and maximize effectiveness.* • Provide restful environment for patient after periods of exercise *to facilitate recuperation.*

*Nursing diagnoses listed in order of priority.

NURSING CARE PLAN 58-1—cont'd

Patient With Stroke

NURSING DIAGNOSIS **Impaired verbal communication** *related to* aphasia *as evidenced by* refusal or inability to speak, difficulty forming words and sentences to express thoughts, and inappropriate verbalization

PATIENT GOALS
1. Uses effective oral and written communication techniques
2. Demonstrates congruency of verbal and nonverbal communication

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Communication	***Communication Enhancement: Speech Deficit***
• Use of spoken language _____ • Use of written language _____ • Use of nonverbal language _____ • Exchanges messages accurately with others _____	• Listen attentively *to convey the importance of patient's thoughts and to promote a positive environment for learning.* • Provide positive reinforcement and praise *to build self-esteem and confidence.* • Use simple words and short sentences *to avoid overwhelming patient with verbal stimuli.* • Perform prescriptive speech-language therapies during informal interactions with patient *to reinforce prescribed therapies.* • Provide verbal prompts and reminders *to help patient to express self.*
Measurement Scale 1 = Severely compromised 2 = Substantially compromised 3 = Moderately compromised 4 = Mildly compromised 5 = Not compromised	

NURSING DIAGNOSIS **Unilateral neglect** *related to* visual field cut and loss on one side of body (hemianopsia) and brain injury from cerebrovascular problems *as evidenced by* consistent inattention to stimuli on affected side

PATIENT GOALS
1. Cares for both sides of the body appropriately
2. Uses strategies to minimize unilateral neglect

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Heedfulness of Affected Side	***Unilateral Neglect Management***
• Acknowledges affected side as being integral to self _____ • Protects affected side when positioning _____ • Protects affected side when ambulating _____ • Performs activities of daily living to affected side _____ • Arranges environment to compensate for physical or sensory deficits _____ • Uses visual scanning as a compensatory strategy _____	• Monitor for abnormal responses to three types of stimuli: sensory, visual, and auditory *to determine the presence of and degree to which unilateral neglect exists (e.g., inability to see objects on affected side, leaving food on a plate that corresponds to affected side, lack of sensation on affected side).* • Instruct patient to scan from left to right *to visualize the entire environment.* • Position bed in room so that individuals approach and care for patient on unaffected side. • Rearrange the environment to use the right or left visual field; position personal items, television, or reading materials within view on unaffected side *to compensate for visual field deficits.* • Touch unaffected shoulder when initiating conversation *to attract patient's attention.* • Gradually move personal items and activity to affected side as patient demonstrates an ability to compensate for neglect. • Include caregivers in rehabilitation process *to support the patient's efforts and assist with care to promote reintegration with the whole body.*
Measurement Scale 1 = Never demonstrated 2 = Rarely demonstrated 3 = Sometimes demonstrated 4 = Often demonstrated 5 = Consistently demonstrated	

NURSING DIAGNOSIS **Impaired urinary elimination** *related to* impaired impulse to void or inability to reach toilet or manage tasks of voiding *as evidenced by* loss of urinary control and involuntary loss of urine at unpredictable times

PATIENT GOALS
1. Perceives impulse to void, removes clothing for toileting, and uses toilet
2. Demonstrates ability to urinate when the urge arises or with a timed schedule

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Urinary Continence	***Urinary Habit Training***
• Recognizes urge to void _____ • Maintains predictable pattern of voiding _____ • Responds to urge in timely manner _____ • Starts and stops stream _____	• Keep a continence specification record for 3 days *to establish voiding pattern and plan appropriate interventions.* • Establish interval of initial toileting schedule (based on voiding pattern and usual routine) *to initiate process of improving bladder functioning and increased muscle tone.* • Assist patient to toilet and prompt to void at prescribed intervals *to assist patient in adapting to new toileting schedule.* • Teach patient to consciously hold urine until the scheduled toileting time *to improve muscle tone.* • Discuss daily record of continence with staff *to provide reinforcement and encourage compliance with toileting schedule.* • Give positive feedback or positive reinforcement to patient when he or she voids at scheduled toileting times, and make no comment when patient is incontinent, *to reinforce desired behavior.*
Measurement Scale 1 = Never demonstrated 2 = Rarely demonstrated 3 = Sometimes demonstrated 4 = Often demonstrated 5 = Consistently demonstrated	
• Urine leakage between voidings _____ • Wets clothing during the day _____ • Wets clothing or bedding during night _____

NURSING CARE PLAN 58-1—cont'd

Patient With Stroke

NURSING DIAGNOSIS **Impaired swallowing** *related to* weakness or paralysis of affected muscles *as evidenced by* drooling, difficulty in swallowing, choking

PATIENT GOAL Demonstrates effective swallowing without choking, coughing, or aspiration

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Swallowing Status	***Swallowing Therapy***
• Maintains food in mouth _____ • Handles oral secretions _____ • Ability to clear oral cavity _____ **Measurement Scale** 1 = Severely compromised 2 = Substantially compromised 3 = Moderately compromised 4 = Mildly compromised 5 = Not compromised	• Collaborate with other members of health care team (e.g., occupational therapist, speech pathologist, dietitian) *to provide continuity in patient's rehabilitative plan.* • Assist patient to sit in an erect position (as close to 90 degrees as possible) for feeding/exercise *to provide optimal position for chewing and swallowing without aspirating.* • Assist patient to position head in forward flexion in preparation for swallowing ("chin tuck"). • Assist patient to maintain sitting position for 30 min after completing meal *to prevent regurgitation of food.* • Instruct patient or caregiver on emergency measures for choking *to prevent complications in the home setting.* • Check mouth for pocketing of food after eating *to prevent collection and putrefaction of food and/or aspiration.* • Provide mouth care as needed *to promote comfort and oral health.* • Monitor body weight *to determine adequacy of nutritional intake.*
• Choking _____ • Coughing _____ • Gagging _____ **Measurement Scale** 1 = Severe 2 = Substantial 3 = Moderate 4 = Mild 5 = None	

NURSING DIAGNOSIS **Situational low self-esteem** *related to* actual or perceived loss of function and altered body image *as evidenced by* refusal to participate in self-care and expressions of helplessness and uselessness

PATIENT GOALS 1. Expresses positive feelings of self-worth
2. Participates in self-care of affected body parts

Outcomes (NOC)	Interventions (NIC) and *Rationales*
Self-Esteem	***Self-Esteem Enhancement***
• Verbalizations of self-acceptance _____ • Maintenance of grooming and hygiene _____ • Acceptance of self-limitations _____ • Description of self _____ • Feelings about self-worth _____ **Measurement Scale** 1 = Never positive 2 = Rarely positive 3 = Sometimes positive 4 = Often positive 5 = Consistently positive	• Monitor patient's statements of self-worth *to determine effect of stroke on self-esteem.* • Encourage patient to identify strengths *to facilitate patient's recognition of intrinsic value.* • Assist in setting realistic goals *to achieve higher self-esteem.* • Reward or praise patient's progress toward reaching goals. • Encourage increased responsibility for self *to promote sense of satisfaction, independence, and control, and to reduce frustrations.* • Monitor levels of self-esteem over time *to determine stressors or situations that trigger low self-esteem and to teach coping mechanisms.*

ICP, Intracranial pressure; *NIH,* National Institutes of Health; *$PaCO_2$,* partial pressure of carbon dioxide in arterial blood; *PaO_2,* partial pressure of oxygen in arterial blood; *SaO_2,* arterial oxygen saturation.

Patients who have an unclipped or uncoiled aneurysm may experience rebleeding and the possibility of increasing ICP further with coughing or suctioning, so nursing management is aimed at reducing these interventions while maintaining a proper airway.

Interventions related to maintenance of airway function are described in Nursing Care Plan 58-1.

Neurologic System. The primary clinical assessment tool to evaluate and document neurologic status in acute stroke patients is the NIH Stroke Scale (NIHSS),[25] which measures stroke severity (see Table 58-9). The NIHSS is a predictor of both short- and long-term outcomes of stroke patients. Additionally, it serves as a data collection tool for planning patient care and exchanging information among health care providers.

Additional neurologic assessment includes mental status, pupillary responses, and extremity movement and strength. Also closely monitor vital signs. A decreasing level of consciousness may indicate increasing ICP. Monitor ICP and cerebral perfusion pressure if the patient is in a critical care environment. Record your nursing assessment on flow sheets to communicate the patient's neurologic status to the stroke team.

Cardiovascular System. Nursing goals for the cardiovascular system are aimed at maintaining homeostasis. Many patients with stroke have decreased cardiac reserves secondary to cardiac disease. Cardiac efficiency may be further compromised by fluid retention, overhydration, dehydration, or BP variations. Central venous pressure, pulmonary artery pressure, or hemodynamic monitoring may be used as indicators of fluid balance or cardiac function in the critical care unit.

Nursing interventions include (1) monitoring vital signs frequently; (2) monitoring cardiac rhythms; (3) calculating intake and output, noting imbalances; (4) regulating IV infusions; (5) adjusting fluid intake to individual patient needs; (6) monitoring lung sounds for crackles and rhonchi indicating pulmonary congestion; and (7) monitoring heart sounds for murmurs or

for S_3 or S_4 heart sounds. Bedside monitors or telemetry may record cardiac rhythms.

Hypertension is sometimes seen after a stroke as the body attempts to increase cerebral blood flow. It is important to monitor for orthostatic hypotension before ambulating the patient for the first time. Neurologic changes can occur with a sudden decrease in BP.

After a stroke, the patient is at risk for venous thromboembolism (VTE), especially in the weak or paralyzed lower extremity. VTE is related to immobility, loss of venous tone, and decreased muscle pumping activity in the leg. The most effective prevention is to keep the patient moving. Teach the patient active range-of-motion exercises if the patient has voluntary movement in the affected extremity. For the patient with hemiplegia, perform passive range-of-motion exercises several times a day. Additional measures to prevent VTE include positioning to minimize the effects of dependent edema and using elastic compression gradient stockings or support hose. Sequential compression devices may be ordered for bedridden patients. VTE prophylaxis may include low-molecular-weight heparin (e.g., enoxaparin [Lovenox]). The nursing assessment for VTE includes measuring the calf and thigh daily, observing swelling of the lower extremities, noting unusual warmth of the leg, and asking the patient about pain in the calf.

Musculoskeletal System. The nursing goal for the musculoskeletal system is to maintain optimal function by preventing joint contractures and muscular atrophy. In the acute phase, range-of-motion exercises and positioning are important nursing interventions. Passive range-of-motion exercise is begun on the first day of hospitalization. Muscle atrophy secondary to lack of innervation and activity can develop after stroke, so exercise is an important intervention for rehabilitation and recovery.

The paralyzed or weak side needs special attention when the patient is positioned. Position each joint higher than the joint proximal to it to prevent dependent edema. Specific deformities on the weak or paralyzed side that may be present in patients with stroke include internal rotation of the shoulder; flexion contractures of the hand, wrist, and elbow; external rotation of the hip; and plantar flexion of the foot. Subluxation of the shoulder on the affected side is common. Careful positioning and moving of the affected arm may prevent development of a painful shoulder condition. Immobilization of the affected upper extremity may precipitate a painful shoulder-hand syndrome.

Nursing interventions to optimize musculoskeletal function include (1) trochanter roll at the hip to prevent external rotation; (2) hand cones (not rolled washcloths) to prevent hand contractures; (3) arm supports with slings and lap boards to prevent shoulder displacement; (4) avoidance of pulling the patient by the arm to avoid shoulder displacement; (5) posterior leg splints, footboards, or high-top tennis shoes to prevent footdrop; and (6) hand splints to reduce spasticity.

Use of a footboard for the patient with spasticity is controversial. Rather than preventing plantar flexion (footdrop), the sensory stimulation of a footboard against the bottom of the foot increases plantar flexion. Likewise, experts disagree on whether hand splints facilitate or diminish spasticity. The decision regarding the use of footboards or hand splints is made on an individual patient basis.

Integumentary System. The skin of the patient with stroke is particularly susceptible to breakdown related to loss of sensation, decreased circulation, and immobility. This is compounded by advanced age, poor nutrition, dehydration, edema, and incontinence.

DELEGATION DECISIONS

Caring for the Patient With an Acute Stroke

During the first 48 hr after an acute stroke, some nursing activities may be delegated to licensed practical/vocational nurses (LPNs/LVNs) and unlicensed assistive personnel (UAP). The registered nurse (RN) should communicate frequently with these staff members to rapidly intervene based on changes in the patient status.

Role of Registered Nurse (RN)

- Assess clinical manifestations of stroke and determine when clinical manifestations started.
- Screen patient for contraindications for tissue plasminogen activator (tPA) therapy.
- Infuse tPA for patients with ischemic stroke who meet the criteria for tPA administration.
- Assess respiratory status and initiate needed actions such as O_2, oropharyngeal or nasopharyngeal airways, suctioning, and patient positioning to prevent aspiration, obstruction, and atelectasis.
- Assess neurologic status, including intracranial pressure (ICP) if needed.
- Monitor cardiovascular status, including hemodynamic monitoring if needed.
- Assess patient's ability to swallow (in conjunction with the speech therapist).

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- Administer scheduled anticoagulant and antiplatelet medications.

Role of Unlicensed Assistive Personnel (UAP)

- Obtain vital signs frequently and report these to RN.
- Measure and record urine output.
- Assist with positioning patient and turning patient at least every 2 hr (as directed by RN).
- Perform passive and active range-of-motion exercises (after being trained and evaluated in these procedures).
- Place equipment needed for seizure precautions in patient room.

The nursing plan for prevention of skin breakdown includes (1) pressure relief by position changes, special mattresses, or wheelchair cushions; (2) good skin hygiene; (3) emollients applied to dry skin; and (4) early mobility. An example of a position change schedule is side-backside, with a maximum duration of 2 hours for any position. Position the patient on the weak or paralyzed side for only 30 minutes. If an area of redness develops and does not return to normal color within 15 minutes of pressure relief, the epidermis and dermis are damaged.

Do not massage the damaged area because this may cause additional damage. Control of pressure is the single most important factor in both the prevention and treatment of skin breakdown. Pillows can be used under lower extremities to reduce pressure on the heels. Vigilance and good nursing care are required to prevent pressure sores.

Gastrointestinal System. The most common bowel problem for the stroke patient is constipation. Patients may be prophylactically placed on stool softeners and/or fiber (psyllium [Metamucil]). If a patient has liquid stools, check for stool impaction. Fluid and fiber intake goals should be discussed with the stroke team and are based on the patient's nutritional and fluid status.

Physical activity also promotes bowel function. Laxatives, suppositories, or additional stool softeners may be ordered if the patient does not respond to increased fluid and fiber. Enemas are used only if suppositories and digital stimulation are ineffective because they cause vagal stimulation and increase ICP.

Bowel retraining may be needed and continues into the rehabilitation phase. A bowel management program consists of placing the patient on the bedpan or bedside commode or

taking the patient to the bathroom at a regular time daily to reestablish bowel regularity. A good time for the bowel program is 30 minutes after breakfast because eating stimulates the gastrocolic reflex and peristalsis, but timing may need to be adjusted, since individual bowel habits may vary.

Urinary System. In the acute stage of stroke the primary urinary problem is poor bladder control, resulting in incontinence. Take steps to promote normal bladder function and avoid the use of indwelling catheters. If an indwelling catheter must be used initially, remove it as soon as the patient is medically and neurologically stable. Long-term use of an indwelling catheter is associated with urinary tract infections and delayed bladder retraining.

An intermittent catheterization program may be used for patients with urinary retention because of the lower incidence of urinary infections. An alternative to intermittent catheterizations is the external catheter for male patients with urinary incontinence. External catheters do not alleviate the problem of urine retention. Avoid bladder overdistention.

Assist the patient with urinary difficulties or incontinence. Often the patient with stroke has functional incontinence, which is associated with communication difficulties, mobility problems, and dressing or undressing difficulties. A bladder retraining program consists of (1) adequate fluid intake with most of it given between 7:00 AM and 7:00 PM; (2) scheduled toileting every 2 hours using bedpan, commode, or bathroom while encouraging the usual position for urinating (standing for men and sitting for women); (3) observation for signs of restlessness, which may indicate the need for urination; and (4) assessment for bladder distention by palpation.

Assessment of postvoid residual volume is often done using bladder ultrasound. The ultrasound measures how much urine is in the bladder after voiding. If urine remains in the bladder, incomplete emptying is a problem and may cause urinary tract infections. A coordinated program by the entire nursing staff is needed to achieve urinary continence.

Nutrition. The patient's nutritional needs require quick assessment and treatment. The patient may initially receive IV infusions to maintain fluid and electrolyte balance and to administer drugs. Patients with severe impairment may require enteral or parenteral nutrition support. Patients should have their nutritional needs addressed in the first 72 hours of admission to the hospital because nutrition is important for recovery and healing.[26]

SAFETY ALERT

- The first oral feeding should be approached carefully because the gag reflex may be impaired due to dysphagia.

Speech therapists (if available) should perform a swallowing evaluation before patients are started on oral intake. The majority of patients experience dysphagia after a stroke.[23] Before initiating feeding, assess the gag reflex by gently stimulating the back of the throat with a tongue blade. If a gag reflex is present, the patient will gag spontaneously. If it is absent, defer the feeding, and begin exercises to stimulate swallowing. The speech therapist or occupational therapist is usually responsible for designing this program. However, you may be called on to develop the program in some clinical settings.

To assess swallowing ability, elevate the head of the bed to an upright position (unless contraindicated) and give the patient a small amount of crushed ice or ice water to swallow. If the gag reflex is present and the patient is able to swallow safely, you may proceed with feeding.

After careful assessment of swallowing, chewing, gag reflex, and pocketing, oral feedings can be initiated. Mouth care before feeding helps stimulate sensory awareness and salivation and can facilitate swallowing. The patient should remain in a high Fowler's position, preferably in a chair with the head flexed forward, for the feeding and for 30 minutes afterward.

The speech therapist may recommend various dietary items. Foods should be easy to swallow and provide enough texture, temperature (warm or cold), and flavor to stimulate a swallow reflex. Crushed ice can be used as a stimulant. Instruct the patient to swallow and then swallow again. Pureed foods are not usually the best choice because they are often bland and too smooth. Thin liquids are often difficult to swallow and may promote coughing. Thin liquids can be thickened with a commercially available thickening agent (e.g., Thick-It). Avoid milk products because they tend to increase the viscosity of mucus and increase salivation.

Place food on the unaffected side of the mouth. Feedings must be followed by scrupulous oral hygiene because food may collect on the affected side of the mouth. During the acute and rehabilitation phase of the stroke, a dietitian can assist in determining the appropriate daily caloric intake based on the patient's size, weight, and activity level. If the patient is unable to take in an adequate oral diet and dysphagia persists, a percutaneous endoscopic gastrostomy (PEG) tube (see Chapter 40, Fig. 40-7) may be used for nutritional support. Most commercially prepared formulas provide about 1 cal/mL. (Enteral feedings are described in Chapter 40.)

The inability to feed oneself can be frustrating and may result in malnutrition and dehydration. Interventions to promote self-feeding include using the unaffected upper extremity to eat; employing assistive devices such as rocker knives, plate guards, and nonslip pads for dishes (Fig. 58-10); removing unnecessary items from the tray or table, which can reduce spills; and providing a calm environment to decrease sensory overload and distraction. The effectiveness of the dietary program is evaluated in terms of maintenance of weight, adequate hydration, and patient satisfaction. Introduce these interventions in the acute care setting so that maximum rehabilitation can occur once the patient is discharged.

Communication. During the acute stage of stroke, your role in meeting the patient's psychologic needs is primarily supportive. Speech, comprehension, and language deficits are the most difficult problems for the patient and caregiver. Assess the patient for both the ability to speak and the ability to understand. The patient's response to simple questions can guide you in structuring explanations and instructions. If the patient cannot understand words, use gestures to support verbal cues. Collaborate with the speech therapist to assess and formulate a plan of care to enhance communication.

Nursing interventions that support communication include (1) communicating frequently and meaningfully; (2) allowing time for the patient to comprehend and answer; (3) using simple, short sentences; (4) using visual cues; (5) structuring conversation so that it permits simple answers by the patient; and (6) praising the patient honestly for improvements with speech.[27]

An alert patient is usually anxious because of lack of understanding about what has happened and because of difficulty with communication or inability to communicate. The stroke patient with aphasia may easily be overwhelmed by verbal stimuli. Give the patient extra time to comprehend and respond to communication. (Guidelines for communicating with a

FIG. 58-10 Assistive devices for eating. **A,** The curved fork fits over the hand. The rounded plate helps keep food on the plate. Special grips and swivel handles are helpful for some persons. **B,** Knives with rounded blades are rocked back and forth to cut food. The person does not need a fork in one hand and a knife in the other. **C,** Plate guards help keep food on the plate. **D,** Cup with special handle. (Courtesy Sammons Preston, Bolingbrook, Ill.)

patient who has aphasia are presented in Table 58-10.) A picture board may be helpful for communicating with the stroke patient. Further evaluation and treatment of language and communication deficits are often done by the speech therapist once the patient has stabilized.

Sensory-Perceptual Alterations. Patients who have had a stroke frequently have perceptual deficits. Patients with a stroke on the right side of the brain usually have difficulty judging position, distance, and rate of movement. These patients are often impulsive and impatient and tend to deny problems related to strokes. They may fail to correlate spatial-perceptual problems with the inability to perform activities, such as guiding a wheelchair through the doorway. The patient with a right-brain stroke (left hemiplegia) is at higher risk for injury because of mobility difficulties. Directions for activities are best given verbally for comprehension. Break the task down into simple steps for ease of understanding. Environmental control, such as removing clutter and obstacles and using good lighting, aids in concentration and safer mobility. Provide nonslip socks at all times. One-sided neglect is common for people with right-brain stroke, so you may assist or remind the patient to dress the weak or paralyzed side or shave the forgotten side of the face.

Patients with a left-brain stroke (right hemiplegia) commonly are slower in organization and performance of tasks. They tend to have impaired spatial discrimination. These patients usually admit to deficits and have a fearful, anxious response to a stroke. Their behaviors are slow and cautious. Nonverbal cues and instructions are helpful for comprehension with patients who have had a left-brain stroke.

Homonymous hemianopsia (blindness in the same half of each visual field) is a common problem after a stroke. Persistent disregard of objects in part of the visual field should alert you to this possibility. Initially, help the patient to compensate by arranging the environment within the patient's perceptual field, such as arranging the food tray so that all foods are on the right side or the left side to accommodate for field of vision (Fig. 58-11). Later, the patient learns to compensate for the visual

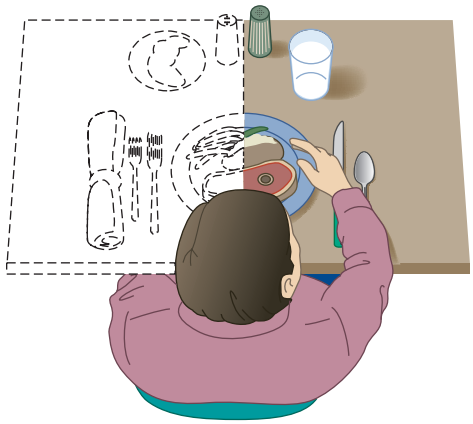

FIG. 58-11 Spatial and perceptual deficits in stroke. Perception of a patient with homonymous hemianopsia shows that food on the left side is not seen and thus is ignored.

TABLE 58-10 COMMUNICATION WITH A PATIENT WITH APHASIA

1. Decrease environmental stimuli that may be distracting and disrupting to communication efforts.
2. Treat the patient as an adult.
3. Speak with normal volume and tone.
4. Present one thought or idea at a time.
5. Keep questions simple or ask questions that can be answered with "yes" or "no."
6. Let the person speak. Do not interrupt. Allow time for the individual to complete thoughts.
7. Make use of gestures or demonstration as an acceptable alternative form of communication. Encourage this by saying, "Show me . . ." or "Point to what you want."
8. Do not pretend to understand the person if you do not. Calmly say you do not understand and encourage the use of nonverbal communication, or ask the person to write out what he or she wants.
9. Give the patient time to process information and generate a response before repeating a question or statement.
10. Allow body contact (e.g., the clasp of a hand, touching) as much as possible. Realize that touching may be the only way the patient can express feelings.
11. Organize the patient's day by preparing and following a schedule (the more familiar the routine, the easier it will be).
12. Do not push communication if the person is tired or upset. Aphasia worsens with fatigue and anxiety.

defect by consciously attending or by scanning the neglected side. The weak or paralyzed extremities are carefully checked for adequacy of dressing, for hygiene, and for trauma.

In the clinical situation, it is often difficult to distinguish between a visual field cut and a neglect syndrome. Both problems may occur with strokes affecting either the right or the left side of the brain. A person may be unfortunate enough to have both homonymous hemianopsia and a neglect syndrome, which increases the inattention to the weak or paralyzed side. A neglect syndrome results in decreased safety awareness and places the patient at high risk for injury. Immediately after the stroke, anticipate safety hazards and provide protection from injury. Safety measures can include closely observing the patient, elevating side rails, lowering the height of the bed, and using video monitors. Avoid the use of restraints and soft vests because this may agitate the patient.

Other visual problems may include *diplopia* (double vision), loss of the corneal reflex, and *ptosis* (drooping eyelid), especially if the stroke is in the vertebrobasilar distribution. Diplopia is

often treated with an eye patch. If the corneal reflex is absent, the patient is at risk for corneal abrasion and should be observed closely and protected against eye injuries. Corneal abrasion can be prevented with artificial tears or gel to keep the eyes moist and an eye shield (especially at night). Ptosis is generally not treated because it usually does not inhibit vision.

Coping. A stroke is usually a sudden, extremely stressful event for the patient, caregiver, family, and significant others. A stroke is often a family disease, affecting the family emotionally, socially, and financially and changing roles and responsibilities within the family.[28] An older couple may perceive the stroke as a threat to life and to accustomed lifestyle. Reactions to this threat vary considerably but may involve fear, apprehension, denial of the severity of stroke, depression, anger, and sorrow. During the acute phase of caring for the stroke patient and the family, nursing interventions designed to facilitate coping involve providing information and emotional support.

Explanations to the patient about what has happened and about diagnostic and therapeutic procedures should be clear and understandable. Decision making and upholding the patient's wishes during this challenging time are of upmost importance. Advance directives should be honored, and family meetings or updates should be held daily about feeding tube placement or tracheostomy.

Give the caregiver and family a careful, detailed explanation of what has happened to the patient. However, if the family is extremely anxious and upset during the acute phase, explanations may need to be repeated at a later time. Because family members usually have not had time to prepare for the illness, they may need assistance in arranging care for family members or pets and for transportation and finances. A social services referral is often helpful.

It is particularly challenging to keep the aphasic patient adequately informed. Tone, demeanor, and touch may also be used to convey support. When communicating with a patient who has a communication deficit, speak in a normal volume and tone, keep questions simple, and present one thought or idea at a time. To decrease frustration, always let the patient speak without interruption and make use of gestures. Do not forget to use writing and communication boards.[27]

AMBULATORY AND HOME CARE. The patient is usually discharged from the acute care setting to home, an intermediate or long-term care facility, or a rehabilitation facility. Ideally, discharge planning with the patient and the caregiver starts early in the hospitalization and promotes a smooth transition from one care setting to another. The stroke team provides guidance for the appropriate care necessary after discharge. If the patient requires a short- or long-term health care facility, the team can make appropriate referrals that allow time to select and arrange for care. A critical factor in discharge planning is the patient's level of independence in performing ADLs. If the patient is returning home, the team can make referrals for needed equipment and services in preparation for discharge.

You have an excellent opportunity to prepare the patient and caregiver for discharge through teaching, demonstration and return demonstration, practice, and evaluation of self-care skills. Total care is considered in discharge planning: medications, nutrition, mobility, exercises, hygiene, and toileting. Follow-up care is carefully planned to permit continuing nursing care; physical, occupational, and speech therapy; and medical care. Identify community resources to provide recreational activities, group support, spiritual assistance, respite care, adult day care, and home assistance based on the patient's needs.

Rehabilitation. *Rehabilitation* is the process of maximizing the patient's capabilities and resources to promote optimal functioning related to physical, mental, and social well-being. The goals of rehabilitation are to prevent deformity and maintain and improve function. Regardless of the care setting, ongoing rehabilitation is essential to maximize the patient's abilities. Most patients see the maximum benefit in the first year of recovery after a stroke.[29]

Rehabilitation requires a team approach so the patient and caregiver can benefit from the combined, expert care of a stroke team. The team must communicate and coordinate care to achieve the patient's goals. As a nurse, you are in a good position to facilitate this process and are often the key to successful rehabilitation efforts. The stroke team is composed of many members, including nurses, physicians, psychiatrist, physical therapist, occupational therapist, speech therapist, registered dietitian, respiratory therapist, vocational therapist, recreational therapist, social worker, psychologist, pharmacist, and chaplain. Physical therapy focuses on mobility, progressive ambulation, transfer techniques, and equipment needed for mobility. Occupational therapy emphasizes retraining for skills of daily living such as eating, dressing, hygiene, and cooking. Occupational therapists are also skilled in cognitive and perceptual evaluation and training. Speech therapy focuses on speech, communication, cognition, and eating abilities.

Many of the nursing interventions outlined in Nursing Care Plan 58-1 for the patient with a stroke are initiated in the acute phase of care and continue throughout rehabilitation. Some of the interventions are independent nursing actions, whereas others involve the entire rehabilitation team.

The rehabilitation nurse assesses the patient, caregiver, and family with attention to (1) the patient's rehabilitation potential, (2) physical status of all body systems, (3) complications caused by the stroke or other chronic conditions, (4) the patient's cognitive status, (5) family resources and support, and (6) expectations of the patient and caregiver related to the rehabilitation program.

Musculoskeletal Function. Initially emphasize the musculoskeletal functions of eating, toileting, and walking for rehabilitation of the patient. Initial assessment consists of determining the stage of recovery of muscle function. If the muscles are still flaccid several weeks after the stroke, the prognosis for regaining function is poor and care focuses on preventing additional loss (Fig. 58-12).

Most patients begin to show signs of spasticity with exaggerated reflexes within 48 hours after the stroke. Spasticity at this phase of stroke denotes progress toward recovery. As improvement continues, small voluntary movements of the hip or shoulder may be accompanied by involuntary movements in the rest of the extremity *(synergy)*. The final stage of recovery occurs when the patient has voluntary control of isolated muscle groups.

INFORMATICS IN PRACTICE

Video Games for Stroke Recovery

- Patients dealing with the effects of a stroke often have difficulty performing activities of daily living. Playing active video games, like Nintendo Wii or Xbox Kinect, brings some fun into stroke recovery and may get patients to spend more time in therapy.
- Gaming helps patients regain lost strength, improve motor skills, and improve problem solving and short- and long-term memory.
- Patients can play with their families, including children, making gaming a way to involve others in rehabilitation.

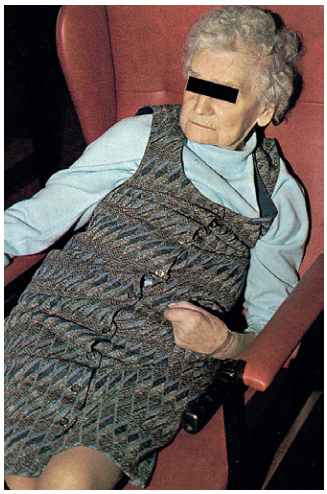

FIG. 58-12 Loss of postural stability is common after stroke. When the nondominant hemisphere is involved, walking apraxia and loss of postural control are usually apparent. The patient is unable to sit upright and tends to fall sideways. Provide appropriate support with pillows or cushions.

Interventions for the musculoskeletal system advance in a manner of progressive activity. Balance training is the initial step and begins with the patient sitting up in bed or dangling the legs over the edge of the bed. Evaluate tolerance by noting dizziness or syncope caused by vasomotor instability.

Also assess whether patients autocorrect their posture when sitting on the edge of the bed. If the patient can straighten his or her posture instead of leaning to the weaker side, the patient may be ready for the next step of transferring from bed to chair. Place the chair beside the bed so that the patient can lead with the stronger arm and leg. The patient sits on the side of the bed, stands, places the strong hand on the far wheelchair arm, and sits down. You may either supervise the transfer or provide minimal assistance by guiding the patient's strong hand to the wheelchair arm, standing in front of the patient while blocking the patient's knees with your knees to prevent knee buckling, and guiding the patient into a sitting position.

In some rehabilitation units the Bobath method is used as an approach to mobility (*http://ibita.org*). The goal of this approach is to help the patient gain control over patterns of spasticity by inhibiting abnormal reflex patterns. Therapists and nurses use the Bobath approach to encourage normal muscle tone, normal movement, and bilateral function of the body. An example is to have the patient transfer into the wheelchair using the weak or paralyzed side and the stronger side to facilitate more bilateral functioning.

Another approach to stroke rehabilitation is constraint-induced movement therapy (CIMT). CIMT encourages the patient to use the weakened extremity by restricting movement of the normal extremity. Complying with this approach can be challenging for patients and may limit its use. Movement training, skill acquisition, splinting, and exercise are additional therapies offered for rehabilitation of the stroke patient.[29]

Supportive or assistive equipment, such as canes, walkers, and leg braces, may be needed on a short- or long-term basis for mobility. The physical therapist usually selects the most appropriate supportive device(s) to meet individual needs and instructs the patient regarding use. Incorporate physical therapy activities into the patient's daily routine for additional practice and repetition of rehabilitation efforts.

Stroke Survivorship and Coping. Patients who have had strokes often exhibit emotional responses that are not appropriate or typical for the situation. Patients may appear apathetic, depressed, fearful, anxious, weepy, frustrated, and angry. Some patients, especially those with a stroke on the left side of the brain (right hemiplegia), have exaggerated mood swings. The patient may be unable to control emotions and may suddenly burst into tears or laughter. This behavior is out of context and often is unrelated to the patient's underlying emotional state. Nursing interventions for atypical emotional response are to (1) distract the patient who suddenly becomes emotional, (2) explain to the patient and family that emotional outbursts may occur after a stroke, (3) maintain a calm environment, and (4) avoid shaming or scolding the patient during emotional outbursts.

The patient with a stroke may experience many losses, including sensory, intellectual, communicative, functional, role behavior, emotional, social, and vocational losses. The patient, caregiver, and family often go through the process of grief and mourning associated with the losses. Some patients experience long-term depression with symptoms such as anxiety, weight loss, fatigue, poor appetite, and sleep disturbances. In addition, the time and energy required to perform previously simple tasks can result in anger and frustration.

The patient, caregiver, and family need help coping with the losses associated with stroke. Provide assistance by (1) supporting communication between the patient and family; (2) discussing lifestyle changes resulting from stroke deficits; (3) discussing changing roles and responsibilities within the family; (4) being an active listener to allow the expression of fear, frustration, and anxiety; (5) including the family and patient in short- and long-term goal planning and patient care; and (6) supporting family conferences.

Maladjusted dependence with inadequate coping occurs when the patient does not maintain optimal functioning for self-care, family responsibilities, decision making, or socialization. This situation can cause resentment from both the patient and family with a negative cycle of interpersonal dependency and control.[28] Caregivers and family members must cope with three aspects of the patient's behavior: (1) recognition of behavioral changes resulting from neurologic deficits that are not changeable, (2) responses to multiple losses by both the patient and the family, and (3) behaviors that may have been reinforced during the early stages of stroke as continued dependency.

The patient, caregiver, and family may express guilt over not living healthy lifestyles or not seeking professional help sooner. Family therapy is a helpful adjunct to rehabilitation. Open communication, information regarding the total effects of stroke, teaching regarding stroke treatment, and therapy are helpful. Stroke support groups in rehabilitation facilities and in the community are helpful in terms of mutual sharing, education, coping skills, and understanding.

Sexual Function. A patient who has had a stroke may be concerned about the loss of sexual function. Many patients are comfortable talking about their anxieties and fears regarding sexual function if you are comfortable and open to the topic. You may initiate the topic with the patient and spouse or significant other. Common concerns regarding sexual activity are impotence and the occurrence of another stroke during sex. Nursing interventions for sexual activity include teaching about (1) optional positioning of partners, (2) timing for peak energy times, and (3) patient and partner counseling.

Community Integration. Traditionally, successful community integration after stroke has been difficult for the patient because of persistent problems with cognition, coping, physical deficits,

and emotional lability that interfere with functioning. Older patients who have had a stroke often have more severe deficits and frequently experience multiple health problems. Failure to continue the rehabilitation regimen at home may result in deterioration and further complications.

Community resources can be an asset to patients and their families. The National Stroke Association provides information, resources, referral services, and quarterly newsletters on stroke. The American Stroke Association, a division of the American Heart Association, has information regarding stroke, hypertension, diet, exercise, and assistive devices. This association sponsors self-help groups in many areas. Easter Seals provides wheelchairs and other assistive devices for stroke patients. Local groups can offer more daily assistance such as meals and transportation. These resources can be identified by nurse case managers, home health nurses, discharge planners, and clinical nurse specialists. (Resources are listed at the end of the chapter.)

GERONTOLOGIC CONSIDERATIONS

STROKE

Stroke is a significant cause of death and disability. The highest incidence of stroke occurs among older adults. Stroke can result in a profound disruption in the life of an older person. The magnitude of disability and changes in total function can leave patients wondering if they can ever return to their "old self," and loss of independence may be a major concern. The ability to perform ADLs may require many adaptive changes because of physical, emotional, perceptual, and cognitive deficits. Home management may be a particular challenge if the patient has an older spouse caregiver who also has health problems. There may be limited family members (including adult children) living in close proximity to provide help.

The rehabilitative phase and helping the older patient deal with the residual deficits of stroke, as well as aging, can provide a challenging nursing experience. Patients may become fearful and depressed because they think they may have another stroke or die. The fear can become immobilizing and interfere with effective rehabilitation.

Changes may occur in the patient-spouse relationship. The dependency resulting from a stroke may threaten the relationship. The spouse may also have chronic medical problems that can affect the ability to take care of the stroke survivor. The patient may not want anyone other than the spouse to provide care, thus putting a significant burden on the spouse.

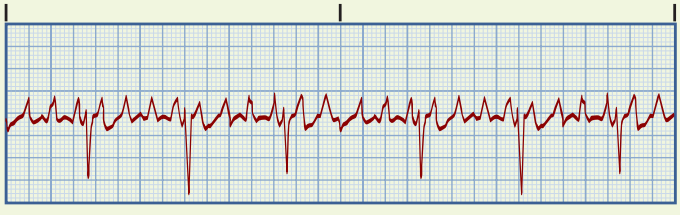
You have the opportunity to assist the patient and caregiver in the transition through acute hospitalization, rehabilitation, long-term care, and home care. The needs of the patient, the caregiver, and the family require ongoing nursing assessment and adaptation of interventions in response to changing needs to optimize quality of life for all of them.

CASE STUDY

Stroke

iStockphoto/Thinkstock

Patient Profile



A.J., a 66-yr-old white woman, awoke in the middle of the night and fell when she tried to get up and go to the bathroom (see Chapter 56 case study on p. 1344). She fell because she was not able to control her left leg. Her husband took her to the hospital, where she was diagnosed with an acute ischemic stroke. Because she had awakened with symptoms, the actual time of onset was unknown and she was not a candidate for tPA.

Subjective Data

- Left arm and leg are weak and feel numb
- Feeling depressed and fearful
- Requires help with ADLs
- Concerned about having another stroke
- Says she has not taken her medications for high cholesterol and high blood pressure for several weeks
- History of a brief episode of left-sided weakness and tingling of the face, arm, and hand 3 mo earlier, which totally resolved and for which she did not seek treatment

Objective Data

- BP 180/110 mm Hg
- ECG is as follows:

- Left-sided arm weakness (3/5) and leg weakness (4/5)
- Decreased sensation on the left side, particularly the hand
- Left homonymous hemianopsia
- Height 5 ft, 3 in, weight 160 lb
- Alert, oriented, and able to answer questions appropriately but mild slowness in responding

Past Medical History

- Migraines
- Hypertension
- Hyperlipidemia

Discussion Questions

1. How do A.J.'s prior health history and current findings put her at risk for another stroke?
2. How can you address A.J.'s concerns regarding having another stroke?
3. How can A.J. and her family address activity issues such as driving after the stroke?
4. What strategies can you use to help A.J. and her family cope with her depression?
5. ***Priority Decision:*** What are the priority lifestyle changes that A.J. should make to reduce the likelihood of another stroke?
6. How will homonymous hemianopsia affect A.J.'s hygiene, eating, driving, and community activities?
7. What factors should you assess for related to outpatient rehabilitation for A.J.?
8. ***Priority Decision:*** What are the priority nursing interventions for A.J.?
9. ***Priority Decision:*** Based on the assessment data provided, what are the priority nursing diagnoses? Are there any collaborative problems?
10. ***Delegation Decision:*** What nursing interventions for A.J. can the RN delegate to unlicensed assistive personnel (UAP)?
11. ***Evidence-Based Practice:*** A.J.'s family wants to know if her atrial flutter caused her stroke and, if so, what she can do to prevent additional problems with her atrial flutter.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Of the following patients, the nurse recognizes that the one with the highest risk for a stroke is a(n)
   a. obese 45-year-old Native American.
   b. 35-year-old Asian American woman who smokes.
   c. 32-year-old white woman taking oral contraceptives.
   d. 65-year-old African American man with hypertension.
2. The factor related to cerebral blood flow that most often determines the extent of cerebral damage from a stroke is the
   a. amount of cardiac output.
   b. oxygen content of the blood.
   c. degree of collateral circulation.
   d. level of carbon dioxide in the blood.
3. Information provided by the patient that would help differentiate a hemorrhagic stroke from a thrombotic stroke includes
   a. sensory disturbance.
   b. a history of hypertension.
   c. presence of motor weakness.
   d. sudden onset of severe headache.
4. A patient with right-sided hemiplegia and aphasia resulting from a stroke most likely has involvement of the
   a. brainstem.
   b. vertebral artery.
   c. left middle cerebral artery.
   d. right middle cerebral artery.
5. The nurse explains to the patient with a stroke who is scheduled for angiography that this test is used to determine the
   a. presence of increased ICP.
   b. site and size of the infarction.
   c. patency of the cerebral blood vessels.
   d. presence of blood in the cerebrospinal fluid.
6. A patient experiencing TIAs is scheduled for a carotid endarterectomy. The nurse explains that this procedure is done to
   a. decrease cerebral edema.
   b. reduce the brain damage that occurs during a stroke in evolution.
   c. prevent a stroke by removing atherosclerotic plaques blocking cerebral blood flow.
   d. provide a circulatory bypass around thrombotic plaques obstructing cranial circulation.
7. For a patient who is suspected of having a stroke, one of the most important pieces of information that the nurse can obtain is
   a. time of the patient's last meal.
   b. time at which stroke symptoms first appeared.
   c. patient's hypertension history and management.
   d. family history of stroke and other cardiovascular diseases.
8. Bladder training in a male patient who has urinary incontinence after a stroke includes
   a. limiting fluid intake.
   b. keeping a urinal in place at all times.
   c. assisting the patient to stand to void.
   d. catheterizing the patient every 4 hours.
9. Common psychosocial reactions of the stroke patient to the stroke include *(select all that apply)*
   a. depression.
   b. disassociation.
   c. intellectualization.
   d. sleep disturbances.
   e. denial of severity of stroke.

1. d, 2. c, 3. d, 4. c, 5. c, 6. c, 7. b, 8. c, 9. a, d, e

LEARNING OUTCOMES

1. Compare and contrast the etiology, clinical manifestations, collaborative care, and nursing management of tension-type, migraine, and cluster headaches.
2. Differentiate the etiology, clinical manifestations, diagnostic studies, collaborative care, and nursing management of seizure disorders, multiple sclerosis, Parkinson's disease, and myasthenia gravis.
3. Describe the clinical manifestations and nursing and collaborative management of restless legs syndrome, amyotrophic lateral sclerosis, and Huntington's disease.
4. Explain the potential impact of chronic neurologic disease on physical and psychologic well-being.
5. Outline the major goals of treatment for the patient with a chronic, progressive neurologic disease.

KEY TERMS

tension-type headache, p. 1414
tonic-clonic seizure, p. 1420

This chapter discusses headaches, chronic neurologic disorders, and degenerative neurologic disorders. Chronic neurologic disorders include seizure disorders and restless legs syndrome. Degenerative neurologic disorders include multiple sclerosis, Parkinson's disease, myasthenia gravis, amyotrophic lateral sclerosis, and Huntington's disease.

HEADACHES

Headache is probably the most common type of pain that humans experience. The majority of people have functional headaches, such as migraine or tension-type headaches. The others have organic headaches caused by intracranial or extracranial disease.

Headache pain can arise from both intracranial and extracranial sources. The pain-sensitive structures in the head include venous sinuses, dura, cranial blood vessels, three divisions of the trigeminal nerve (cranial nerve [CN] V), facial nerve (CN VII), glossopharyngeal nerve (CN IX), vagus nerve (CN X), and the first three cervical nerves.

Headaches are classified as primary or secondary headaches. *Primary headaches* are those not caused by a disease or another medical condition. Primary headache classifications include tension-type, migraine, and cluster headaches. The

TABLE 59-1 COMPARISON OF TYPES OF HEADACHES

Pattern	Tension-Type Headache	Migraine Headache	Cluster Headache
Site (see Fig. 59-1)	Bilateral, bandlike pressure at base of skull	Unilateral (in 60%), may switch sides, commonly anterior	Unilateral, radiating up or down from one eye
Quality	Constant, squeezing tightness	Throbbing, synchronous with pulse	Severe, bone-crushing
Frequency	Cycles for many years	Periodic, cycles of several months to years	May have months or years between attacks Attacks occur in clusters over a period of 2-12 wk
Duration	30 min–7 days	4-72 hr	5 min–3 hr
Time and mode of onset	Not related to time	May be preceded by prodrome Onset after awakening Gets better with sleep	Nocturnal, commonly awakens patient from sleep
Associated symptoms	Palpable neck and shoulder muscle tension, stiff neck, tenderness	Nausea, vomiting Irritability, sweating Photophobia Phonophobia Prodrome of sensory, motor, or psychic phenomena Family history (in 65%)	Facial flushing or pallor Unilateral lacrimation, ptosis, and rhinitis

type of primary headache is determined using the International Headache Society (IHS) guidelines based on characteristics of the headache (Table 59-1). *Secondary headaches* are caused by another condition or disorder, such as sinus infection, neck injury, and stroke. A patient may have more than one type of headache. The history and neurologic examination are diagnostic keys to determining the type of headache.

TENSION-TYPE HEADACHE

Tension-type headache, also called stress headache, is the most common type of headache. These headaches are characterized by their bilateral location and pressing or tightening quality. Tension-type headaches are usually of mild or moderate intensity and can last from minutes to days. Tension-type headaches are divided by frequency into episodic and chronic types.[1]

Etiology and Pathophysiology

Although the cause of tension-type headaches is not fully understood, the development of this type of headache is believed to be associated with neurovascular factors similar to those involved in migraine headaches. Many patients gradually progress over years from episodic to chronic headaches, with the increasing frequency associated with increasing intensity of the headache.[1]

Clinical Manifestations

Patients usually are initially seen with a bilateral frontal-occipital headache described as a constant, dull pressure, or bandlike headache associated with neck pain and increased tone in the cervical and neck muscles. The headache may involve sensitivity to light *(photophobia)* or sound *(phonophobia),* but does not involve nausea or vomiting. There is no *prodrome* (early manifestation of impending disease), and physical activity does not aggravate symptoms. The headaches may occur intermittently for weeks, months, or even years. Many patients can have a combination of migraine and tension-type headaches, with features of both occurring simultaneously. Patients with migraine headaches may experience tension-type headaches between migraine attacks. Fig. 59-1 shows the location of pain for common headache syndromes.

Diagnostic Studies

Careful history taking is probably the most important tool for diagnosing tension-type headache (Table 59-2). If tension-type headache is present during physical examination, increased

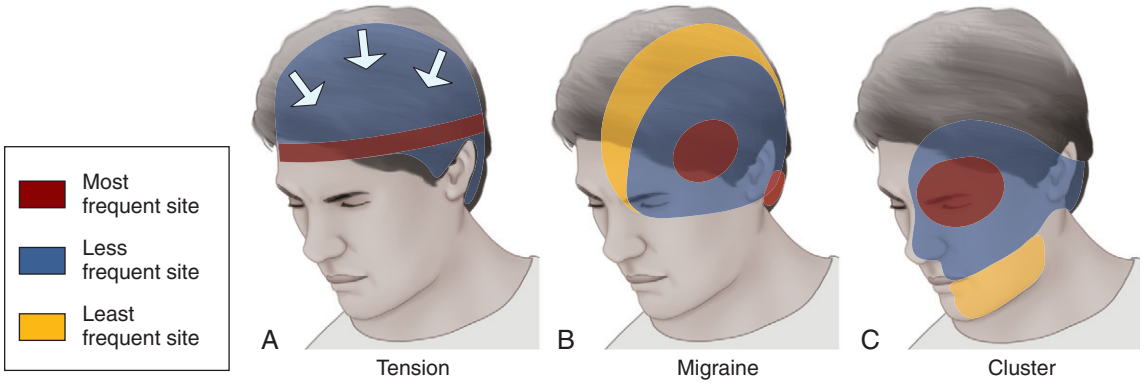

FIG. 59-1 Location of pain for common headache syndromes. **A,** Tension headache is often described as feeling of a weight in or on the head or a band squeezing the head. **B,** Migraine headache is described as an intense throbbing or pounding pain that involves one temple. The pain usually is unilateral (on one side of the head), although it can be bilateral. **C,** Cluster headache pain is focused in and around one eye and is often described as sharp, penetrating, or burning.

TABLE 59-2 DIAGNOSTIC STUDIES

Headaches

History and physical examination
- Neurologic examination (often negative)
- Inspection for local infections
- Palpation for tenderness, bony swellings
- Auscultation for bruits over major arteries

- Complete blood count (CBC)
- Electrolytes
- Urinalysis

Computed tomography (CT) scan of sinuses

Special studies (e.g., CT scan, angiography, EMG, EEG, MRI, MRA, lumbar puncture)

EEG, Electroencephalography; *EMG,* electromyography; *MRA,* magnetic resonance angiography.

GENDER DIFFERENCES

Headaches

Men	Women
• Cluster headaches are more common than in women (6:1). • Exercise-induced headaches are more common than in women.	• Migraine headaches are more common than in men (3:1). • Tension headaches are more common than in men.

resistance to passive movement of the head and tenderness of the head and neck may be present. Electromyography (EMG) may reveal sustained contraction of the neck, scalp, or facial muscles. However, many patients may not show increased muscle tension with this test, even when the test is done during the actual headache.

MIGRAINE HEADACHE

Migraine headache is a recurring headache characterized by unilateral (sometimes bilateral) throbbing pain, a triggering event or factor, and manifestations associated with neurologic and autonomic nervous system dysfunction. The most common age for onset of migraine is between 20 and 30 years. Migraine affects as many as 17% of females and 6% of males in the United States. Migraines are more common in women than men (see Gender Differences box). Risk factors for migraine include family history, low level of education, low socioeconomic status, high workload, and frequent tension-type headaches.[2]

The IHS subdivides migraines into categories. *Migraine without aura* (formerly called common migraine) is the most common type of migraine headache. *Migraine with aura* (formerly called classic migraine) occurs in only 10% of migraine headache episodes.

Etiology and Pathophysiology

Although many theories have addressed the cause of migraine headaches, the exact etiology is not known. The current theory is that a complex series of neurovascular events initiates a migraine headache.[3] People who have migraines have a state of neuronal hyperexcitability in the cerebral cortex, especially in the occipital cortex.

Approximately 70% of those with migraine have a first-degree relative who also had migraine headaches. Migraine is associated with seizure disorders, ischemic stroke, asthma, depression, anxiety, myocardial infarction, Raynaud's syndrome, and irritable bowel syndrome.[3]

In many cases, migraine headaches have no known precipitating events. However, for some patients, specific factors trigger or precipitate a headache. These include foods, menstruation, head trauma, physical exertion, fatigue, stress, missed meals, weather, and drugs. Food triggers include chocolate, cheese, oranges, tomatoes, onions, monosodium glutamate, aspartame, and alcohol (particularly red wine).

Clinical Manifestations

A prodrome and an aura may precede the headache phase by several hours or several days. The *prodrome* may include neurologic (e.g., photophobia), psychologic (e.g., hyperactivity, irritability), and other (e.g., food craving) manifestations. An **aura** is a complex of neurologic symptoms characterized by visual (e.g., bright lights, scotomas [patchy blindness], visual distortions, zigzag lines), sensory (voices or sounds that do not exist, strange smells), and/or motor (e.g., weakness, paralysis, feeling that limbs are moving) phenomena. The aura immediately precedes the headache and may last 10 to 30 minutes before the headache starts.

A migraine headache may last 4 to 72 hours. The headache is described as a steady, throbbing pain that is synchronous with the pulse. Although the headache is usually unilateral, it may switch to the opposite side in another episode. During the headache phase, some patients with migraine may tend to "hibernate." They seek shelter from noise, light, odors, people, and problems.

The presentation of migraine varies in severity. Not all migraine headaches are disabling, and many patients who have migraine headaches do not seek health care treatment for them. In some patients the symptoms of the migraine headaches may become worse over time.

Diagnostic Studies

The diagnosis of migraine headache is usually based on the patient history. The neurologic and other diagnostic examinations are often normal (see Table 59-2).

There is no specific laboratory or radiologic test for migraine headache. Neuroimaging techniques (e.g., head computed tomography [CT], with or without contrast, and magnetic resonance imaging [MRI]) are not recommended for routine evaluation of headache unless the neurologic examination reveals abnormal findings. If atypical features are present, then additional testing is done to rule out a secondary headache.

CLUSTER HEADACHE

Cluster headaches are a rare form of headache, affecting less than 0.1% of the population.[1] Cluster headaches involve repeated headaches that can occur for weeks to months at a time, followed by periods of remission.

Etiology and Pathophysiology

Neither the cause nor the pathophysiologic mechanism of cluster headache is fully known. The trigeminal nerve has a role in the production of pain, but cluster headaches also involve dysfunction of intracranial blood vessels, the sympathetic nervous system, and pain modulation systems. Imaging studies show hypothalamic activation at the onset of cluster headache.[3]

Alcohol is the only dietary trigger. Strong odors, weather changes, and napping are other triggers.[4]

Clinical Manifestations

The cluster headache is one of the most severe forms of headache, with intense pain lasting from a few minutes to 3 hours. The pain of cluster headache is sharp and stabbing, which is in contrast to the pulsing pain of the migraine headache. The pain is generally located around the eye, radiating to the temple, forehead, cheek, nose, or gums. Other manifestations may include swelling around the eye, lacrimation (tearing), facial flushing or pallor, nasal congestion, and constriction of the pupil. During the headache, the patient is often agitated and restless, unable to sit still or relax.

Cluster headaches can occur every other day and as often as eight times a day. The attacks occur in clusters. The clusters occur with regularity, usually at the same time each day, during the same seasons of the year. A cluster typically lasts 2 weeks to 3 months, and then the patient goes into remission for months to years.

Diagnostic Studies

The diagnosis of cluster headache is based on the patient history. Asking patients to keep a headache diary can be useful. CT scan, MRI, or magnetic resonance angiography (MRA) may rule out an aneurysm, a tumor, or an infection. A lumbar puncture may rule out other disorders that may cause similar symptoms.

OTHER TYPES OF HEADACHES

Although tension, migraine, and cluster headaches are by far the most common types of headaches, other types can occur. These headaches may be the first symptom of a more serious illness. Headache can accompany subarachnoid hemorrhage; brain tumors; other intracranial masses; vascular abnormalities; trigeminal neuralgia (tic douloureux); diseases of the eyes, nose, and teeth; and systemic illness (e.g., bacteremia, carbon monoxide poisoning, mountain sickness, polycythemia vera). The symptoms vary greatly. Because of the variety of causes of headache, clinical evaluation must be thorough. It should include an evaluation of personality, life adjustment, environment, and family situation, as well as a comprehensive evaluation of neurologic and physical status.

COLLABORATIVE CARE FOR HEADACHES

If no systemic underlying disease is the cause, the type of headache guides therapy. Table 59-2 outlines the general workup for a patient with headache to rule out any intracranial or extracranial disease. Table 59-3 summarizes the current therapies for prophylaxis and symptom relief of common headaches. These therapies include drugs, meditation, yoga, biofeedback, cognitive-behavioral therapy, and relaxation training.

Cognitive-behavioral therapy and relaxation therapy used alone or in conjunction with drug therapy may be beneficial to some patients. Biofeedback involves the use of physiologic monitoring equipment to give the patient information regarding muscle tension and peripheral blood flow (e.g., skin temperature of the fingers). The patient is trained to relax the muscles and raise the finger temperature, and is given reinforcement (operant conditioning) in accomplishing these changes. Acupuncture, acupressure, and hypnosis also work well in some patients with headaches. See Chapters 6 and 7 for further description of these therapies.

Drug Therapy

Tension-Type Headache. Drug treatment for tension-type headache usually involves aspirin, acetaminophen (Tylenol), or nonsteroidal antiinflammatory drugs (NSAIDs) used alone or in combination with a sedative, muscle relaxant, or tranquilizer. However, many of these drugs have serious side effects. Caution the patient about the long-term use of aspirin and aspirin-containing drugs because they can cause upper gastrointestinal (GI) bleeding and coagulation abnormalities in susceptible patients. Drugs containing acetaminophen can cause kidney damage with chronic use and liver damage when taking large doses or when combined with alcohol. To decrease the recurrence of tension-type headache, the patient may receive preventive therapy with a tricyclic antidepressant (e.g., amitriptyline [Elavil], nortriptyline) or topiramate (Topamax), divalproex (Depakote), or mirtazapine (Remeron).

Migraine Headache. The aim of drug treatment of an acute migraine attack is terminating or decreasing the symptoms. Many people with mild or moderate migraine can obtain relief with NSAIDs, aspirin, or caffeine-containing combination analgesics. For moderate to severe headaches, the triptans have become the first line of therapy. Triptans (e.g., sumatriptan [Imitrex]) affect selected serotonin receptors, thus reducing neurogenic inflammation of the cerebral blood vessels and producing vasoconstriction (see Table 59-3). They are most effective when taken at the onset of migraine headache or during the aura. Sumatriptan is available in various forms: oral, subcutaneous, nasal spray.

Some patients respond better to one triptan than to others, so health care providers need to be knowledgeable about all of them. Because these drugs cause vasoconstriction, patients with heart disease or stroke should avoid their use. The combination drug sumatriptan/naproxen (Treximet) combines a triptan with an antiinflammatory drug. Risk of serious cardiovascular events such as myocardial infarction, thromboembolic events, and stroke may increase over time with Treximet. When triptans are contraindicated, other drugs can be used (see Table 59-3).

DRUG ALERT: Sumatriptan (Imitrex)

- Should not be given to patients with the following:
  - History or manifestations of ischemic cardiac, cerebrovascular, or peripheral vascular problems
  - Uncontrolled hypertension, since it may increase blood pressure
- Excess dosage may produce tremor and decrease respirations.

Preventive treatment is important in the management of migraine headaches. The decision to initiate prophylactic treatment is individually determined based on frequency, severity, and any disability related to headaches. Several different classes of medications are used.

Topiramate, an antiseizure drug, taken daily is an effective therapy for migraine prevention. Common side effects include hypoglycemia, paresthesia, weight loss, and cognitive changes. Usually these side effects are mild to moderate and transient. Topiramate must be used for 2 to 3 months to determine its effectiveness. Not all patients will become pain free on this medication. Health care providers must provide adequate teaching regarding topiramate to promote patient adherence.

TABLE 59-3 COLLABORATIVE CARE

Headaches

Tension-Type Headache	Migraine Headache	Cluster Headache
Diagnostic		
History*	History*	History
Collaborative Therapy		
Abortive/Symptomatic Drugs		
Nonopioid analgesics: aspirin, acetaminophen, NSAIDs Analgesic combinations • butalbital/aspirin/caffeine (Fiorinal) • butalbital/acetaminophen/caffeine (Fioricet) • dichloralphenazone/acetaminophen/isometheptene (Midrin) Muscle relaxants	Nonopioid analgesics: aspirin, NSAIDs Serotonin receptor agonists • almotriptan (Axert) • eletriptan (Relpax) • frovatriptan (Frova) • naratriptan (Amerge) • rizatriptan (Maxalt) • sumatriptan (Imitrex) • zolmitriptan (Zomig) Combination • sumatriptan/naproxen (Treximet) α-Adrenergic blockers • ergotamine tartrate (Ergomar) • dihydroergotamine (DHE) Analgesic combinations • acetaminophen/caffeine/aspirin • acetaminophen/isometheptene/dichloralphenazone Corticosteroids • dexamethasone (Decadron)	α-Adrenergic blocker • ergotamine tartrate O_2 100% Serotonin receptor agonists • almotriptan • eletriptan • frovatriptan • naratriptan • rizatriptan • sumatriptan • zolmitriptan
Preventive/Prophylactic Drugs		
Tricyclic antidepressants • amitriptyline (Elavil) • nortriptyline (Pamelor) • doxepin (Sinequan) Selective serotonin reuptake inhibitors • fluoxetine (Prozac) • paroxetine (Paxil) β-Adrenergic blocker: • propranolol (Inderal) Other drugs • topiramate (Topamax) • divalproex (Depakote) • mirtazapine (Remeron) Biofeedback Psychotherapy Muscle relaxation training	β-Adrenergic blocker • propranolol Antidepressants • amitriptyline • imipramine (Tofranil) Antiseizure • valproic acid (Depakene) • divalproex • topiramate (Topamax) • gabapentin (Neurontin) Calcium channel blockers • verapamil (Calan) • flunarizine (Sibelium) Serotonin antagonist† • methysergide (Sansert) Botulinum toxin A (Botox) Biofeedback Relaxation therapy Cognitive-behavioral therapy	α-Adrenergic blocker • ergotamine tartrate Serotonin antagonist • methysergide Corticosteroid • prednisone Calcium channel blocker • verapamil Lithium Biofeedback

*Diagnostic imaging should be considered in nonacute headache patients with unexplained abnormal neurologic examination, atypical headache, headache features, or an additional risk factor such as immunodeficiency.
†Only for patients suffering from one or more severe headaches per week.

DRUG ALERT: Topiramate (Topamax)
- Instruct patient to do the following:
  - Not abruptly discontinue, since this may cause seizures.
  - Avoid tasks that require alertness until response to drug is established.
  - Take adequate fluids to decrease risk of renal stone development.

Botulinum toxin A (Botox) may be an effective prophylactic treatment for patients who have chronic migraines lasting for 4 hours or more at least 15 days each month, or migraines that do not respond to other medications. Botox is given by multiple injections around the head and neck. Its effects last 2 to 4 months; the injections are repeated every 3 months. The most common adverse reactions are neck pain and headache. There is a slight risk of the toxin migrating from the injection site to other areas of the face and neck, causing swallowing and breathing difficulties. Teach the patient to seek immediate medical attention if this occurs.[5]

Additional antiseizure drugs used in migraine prevention are divalproex and gabapentin (Neurontin). Antidepressants used in migraine prophylaxis include tricyclic antidepressants (e.g., amitriptyline) and selective serotonin reuptake inhibitors (e.g., fluoxetine [Prozac]). Other drugs used for migraine headache prevention are listed in Table 59-3.

Cluster Headache. Because cluster headaches occur suddenly, often at night, and do not last long, drug therapy is not as useful as it is for other types of headaches. Acute treatment of cluster headache is inhalation of 100% oxygen delivered at a rate of 6 to 8 L/min for 10 minutes, which may relieve headache by causing vasoconstriction and increasing synthesis of sero-

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Can Botulinum Toxin A Prevent Headaches?

Clinical Question

For adults with chronic headaches (P), does prophylactic botulinum toxin A (I) vs. placebo vs. medication (C) decrease headache frequency or severity (O)?

Best Available Evidence

Meta-analysis of randomized controlled trials (RCTs) and comparative effectiveness trials

Critical Appraisal and Synthesis of Evidence

- Twenty-seven RCTs (n = 5313) comparing botulinum toxin A (Botox) with placebo, and four trials comparing Botox with medication (amitriptyline [Elavil], topiramate [Topamax], valproic acid [Depakote]).
- Headaches assessed were migraine or tension, episodic (<15 headaches per month) or chronic (>15 headaches per month), and a chronic daily headache.
- Botox resulted in decreased frequency of chronic daily and chronic migraine headaches. It had no effect on episodic migraine or chronic tension-type headaches.
- Botox was not related to fewer migraine headaches when compared with valproic acid, topiramate, or amitriptyline.

Conclusion

- Botox is beneficial for chronic daily headaches and chronic migraine headaches.

Implications for Nursing Practice

- Inform patients that Botox can prevent some types of headaches.
- Advise patients of Botox side effects, including blepharoptosis, paresthesia, neck stiffness and pain, and muscle weakness.

Reference for Evidence

Jackson JL, Kuriyama A, Hayashino Y: Botulinum toxin A for prophylactic treatment of migraine and tension headaches in adults: a meta-analysis, *JAMA* 307:1736, 2012.

P, Patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcomes of interest (see p. 12).

tonin in the central nervous system. This can be repeated after a 5-minute rest. However, a drawback to this treatment is that the patient must have continuous access to the oxygen supply. The triptans (e.g., sumatriptan) are also effective in treating acute cluster headache. Intranasal administration of lidocaine is useful as an adjunctive therapy.[6]

Prophylactic drugs may include verapamil, lithium, ergotamine, divalproex, melatonin, or antiseizure medications. If the cluster headache recurs at a known time, prophylactic methysergide may be used. Options for patients with refractory cluster headaches include invasive nerve blocks, deep brain stimulation, and ablative neurosurgical procedures (e.g., percutaneous radiofrequency).

Other Headaches. Patients with frequent headaches may overuse analgesic drugs. *Medication overuse headache* (MOH) is the term used to describe an analgesic rebound headache. Drugs known to cause this problem are acetaminophen, aspirin, NSAIDs (e.g., ibuprofen), butalbital, sumatriptan, and opioids. Patients with daily headaches may complain of early awakening with decreased appetite, nausea, restlessness, decreased memory, and irritability. Treatment involves abrupt withdrawal of the offending drug (except for opioids, which need to be tapered) and initiation of alternative drugs such as amitriptyline.

TABLE 59-4 NURSING ASSESSMENT

Headaches

Subjective Data

Important Health Information

Past health history: Seizures, cancer, recent fall or trauma, cranial infection, stroke; asthma or allergies; mental illness; relationship of headache to overwork, stress, menstruation, exercise, food, sexual activity, travel, bright lights, or noxious environmental stimuli

Medications: Hydralazine (Apresoline), bromides, nitroglycerin, ergotamine (withdrawal), nonsteroidal antiinflammatory drugs (in high daily doses), estrogen preparations, oral contraceptives, over-the-counter or prescription remedies

Surgery or other treatments: Craniotomy, sinus surgery, facial surgery

Functional Health Patterns

Health perception–health management: Positive family history; malaise

Nutritional-metabolic: Ingestion of alcohol, caffeine, cheese, chocolate, monosodium glutamate, aspartame, lunch meats (nitrites in cured meats), sausage, hot dogs, onions, avocados; anorexia, nausea, vomiting (migraine prodrome); unilateral lacrimation (cluster)

Activity-exercise: Vertigo, fatigue, weakness, paralysis, fainting

Sleep-rest: Insomnia

Cognitive-perceptual

- *Migraine:* Aura; unilateral, severe, throbbing (possible switching of side) headache; visual disturbances; photophobia; phonophobia; dizziness; tingling or burning sensations
- *Cluster:* Unilateral and severe, nocturnal headache; nasal stuffiness
- *Tension-type:* Bilateral, bandlike, dull and persistent, base-of-skull headache, neck tenderness

Self-perception–self-concept: Depression

Coping–stress tolerance: Stress, anxiety, irritability, withdrawal

Objective Data

General

Anxiety, apprehension

Integumentary

Cluster: Forehead diaphoresis, pallor, unilateral facial flushing with cheek edema, conjunctivitis

Migraine: Generalized edema (prodrome), pallor, diaphoresis

Neurologic

Horner's syndrome, restlessness (cluster), hemiparesis (migraine)

Musculoskeletal

Resistance of head and neck movement, nuchal rigidity (meningeal, tension-type), palpable neck and shoulder muscle tension (tension-type)

Possible Diagnostic Findings

Evidence of disease, deformity, or infection on brain imaging (CT, MRI, MRA), cerebral angiogram, lumbar puncture, EEG, EMG; nonspecific brain imaging or laboratory tests

EMG, Electromyography; *MRA,* magnetic resonance angiography.

NURSING MANAGEMENT HEADACHES

NURSING ASSESSMENT

Table 59-4 outlines subjective and objective data you should obtain from a patient with headache. Because the history provides the key to assessment of headache, it should include specific details of the headache itself, such as the location and type of pain, onset, frequency, duration, relation to events (emotional, psychologic, physical), and time of day of the occurrence. Obtain information about previous illnesses, surgery, trauma, allergies, family history, and response to medication.

Suggest that the patient keep a diary of headache episodes with specific details. This type of record can be of great help in determining the type of headache and the precipitating events. If the patient has a history of migraine, tension-type, or cluster headaches, it is important to determine if the character, intensity, or location of the headache has changed. This may be an important clue as to the cause of the headache.

NURSING DIAGNOSES

Nursing diagnoses for the patient with headache may include, but are not limited to, the following:

- Acute pain *related to* headache
- Ineffective self-health management *related to* drug therapy and lifestyle adjustments

Additional information on nursing diagnoses is presented in eNursing Care Plan 59-1 for the patient with headache (available on the website for this chapter).

PLANNING

The overall goals are that the patient with a headache will (1) have reduced or no pain, (2) demonstrate understanding of triggering events and treatment strategies, (3) use positive coping strategies to deal with pain, and (4) experience increased quality of life and decreased disability.

NURSING IMPLEMENTATION

Patients with chronic headache present a great challenge to health care providers. Since an inability to cope with daily stresses can cause headaches, an effective therapy may be to help patients examine their lifestyle, recognize stressful situations, and learn to cope with them more appropriately. Help the patient identify precipitating factors and develop ways to avoid them. Encourage daily exercise, relaxation periods, and socialization because each can help decrease the recurrence of headache. Suggest alternative ways of handling headache pain through techniques such as relaxation, meditation, and yoga.

In addition to using analgesics and analgesic combinations for symptomatic relief of headache, encourage the migraine sufferer to seek a quiet, dimly lit environment. Massage and moist hot packs to the neck and head can help a patient with tension-type headaches. The patient should learn about the drugs prescribed for preventive/prophylactic and abortive/symptomatic treatment of headache and should be able to describe the purpose, action, dosage, and side effects of the drugs. To prevent accidental overdose, the patient should make a written note of each dose of drug or headache remedy.

For the patient with headaches triggered by food, provide dietary counseling. Encourage the patient to eliminate foods that may provoke headaches, such as chocolate, cheese, oranges, tomatoes, onions, monosodium glutamate, aspartame, alcohol (particularly red wine), excessive caffeine, and fermented or marinated foods. Active challenge and provocative testing with specific foods may be necessary to determine the specific causative agents. However, food triggers may change over time.

Teach patients to avoid smoking and exposure to triggers such as strong perfumes, volatile solvents, and gasoline fumes. Cluster headache attacks may occur at high altitudes with low oxygen levels during air travel. Ergotamine, taken before the plane takes off, may decrease the likelihood of these attacks. See Table 59-5 for a teaching guide for the patient with a headache.

TABLE 59-5 PATIENT & CAREGIVER TEACHING GUIDE

Headaches

Include the following instructions when teaching the patient with a headache and the patient's caregiver.

1. Keep a diary or calendar of headaches and possible precipitating events.
2. Avoid factors that can trigger a headache:
   - Foods containing amines (cheese, chocolate), nitrites (meats such as hot dogs), vinegar, onions, monosodium glutamate
   - Fermented or marinated foods
   - Caffeine
   - Oranges
   - Tomatoes
   - Aspartame
   - Nicotine
   - Ice cream
   - Alcohol (particularly red wine)
   - Emotional stress
   - Fatigue
   - Drugs such as ergot-containing preparations (ergotamine tartrate [Ergomar]) and monoamine oxidase inhibitors (e.g., rasagiline [Azilect])
3. Learn the purpose, action, dosage, and side effects of drugs taken.
4. Self-administer sumatriptan (Imitrex) subcutaneously if prescribed.
5. Use stress management techniques such as relaxation.
6. Participate in regular exercise.
7. Contact health care provider if any of the following occurs:
   - Symptoms become more severe, last longer than usual, or are resistant to medication.
   - Nausea and vomiting (if severe or not typical), change in vision, or fever occurs with the headache.
   - Problems occur with any drugs.

EVALUATION

Expected outcomes are that the patient with headache will

- Report satisfaction with pain relief
- Use drug and nondrug measures appropriately to manage pain

Additional information on expected outcomes for the patient with headache is presented in eNursing Care Plan 59-1 (available on the website for this chapter).

CHRONIC NEUROLOGIC DISORDERS

SEIZURE DISORDERS AND EPILEPSY

Seizure is a paroxysmal, uncontrolled electrical discharge of neurons in the brain that interrupts normal function. Seizures may accompany a variety of disorders, or they may occur spontaneously without any apparent cause. Seizures resulting from systemic and metabolic disturbances are not considered epilepsy if the seizures cease when the underlying problem is corrected. Metabolic disturbances that cause seizures include acidosis, electrolyte imbalances, hypoglycemia, hypoxia, alcohol and barbiturate withdrawal, dehydration, and water intoxication. Extracranial disorders that can cause seizures are heart, lung, liver, or kidney diseases; systemic lupus erythematosus; diabetes mellitus; hypertension; and septicemia.

Epilepsy is a condition in which a person has spontaneous recurring seizures caused by a chronic underlying condition. In the United States, it is estimated that more than 3 million people have active epilepsy, with 200,000 new cases diagnosed each year. National trends show that the incidence of epilepsy is

increasing in older adults. New cases of epilepsy are more common in African Americans and in socially disadvantaged populations. Males are slightly more likely to develop epilepsy than females. People at high risk for developing epilepsy include those with Alzheimer's disease or those who have had a stroke. The risk is also increased in the child of a person who has epilepsy.[7]

Etiology and Pathophysiology

Seizure disorders have many possible causes, with the most common causes varying by age. The most common causes of seizure disorder during the first 6 months of life are severe birth injury, congenital defects involving the central nervous system (CNS), infections, and inborn errors of metabolism. In people between 2 and 20 years of age, the primary causes are birth injury, infection, trauma, and genetic factors. In individuals between 20 and 30 years of age, seizure disorder usually occurs as the result of structural lesions, such as trauma, brain tumors, or vascular disease. After 50 years of age, the primary causes of seizure disorders are stroke and metastatic brain tumors. However, nearly 30% of all epilepsy cases are idiopathic, called *idiopathic generalized epilepsy (IGE),* meaning they are not attributable to a specific cause.

The etiology of recurring seizures (epilepsy) has long been attributed to a group of abnormal neurons *(seizure focus)* that seem to undergo spontaneous firing. This firing spreads by physiologic pathways to involve adjacent or distant areas of the brain. If this activity spreads to involve the whole brain, a generalized seizure occurs. The factor that causes this abnormal firing is not clear. Any stimulus that causes the cell membrane of the neuron to depolarize induces a tendency for spontaneous firing.

Scar tissue (gliosis) is often found in the area of the brain from which the epileptic activity arises. Scarring is believed to interfere with the normal chemical and structural environment of the brain neurons, making them more likely to fire abnormally.

In addition to neuronal alterations, changes in the function of astrocytes may play several key roles in recurring seizures. Activation of astrocytes by hyperactive neurons is one of the crucial factors that predispose neurons nearby to the generation of an epileptic discharge.

Genetic Link

Genetic abnormalities may be the most important factor contributing to IGE. Some types of epilepsy tend to run in families, suggesting a genetic influence. Other types of IGE are related to abnormalities in specific genes that control the flow of ions in and out of cells and regulate neuron signaling or are involved with protein and carbohydrate metabolism. Some researchers estimate that more than 500 genes could play a role in IGE.[8]

The role of genetics in the etiology of seizure disorders has been difficult to determine because of the problem of separating genetic from environmental or acquired influences. In some forms of epilepsy, families carry a predisposition to seizure disorders in the form of an inherently low threshold to seizure-producing stimuli, such as trauma, disease, and high fever.

Abnormal genes may influence the disorder in subtle ways. For example, a person with epilepsy may have an abnormally active version of a gene that increases resistance to drugs. This may help explain why antiseizure drugs do not work for some people.

TABLE 59-6 CLASSIFICATION OF SEIZURE DISORDERS

Generalized Seizures (Nonfocal Origin)	Focal Seizures (Focal Origin)
• Tonic-clonic seizures • Absence seizures • Typical • Atypical • Absence with special features • Myoclonic seizures • Tonic seizures • Atonic seizures (drop attacks) • Clonic seizures	• Simple focal seizures (no impairment of consciousness) • Complex focal seizures (impairment of consciousness) • Focal seizures evolving to secondary generalized seizures **Unknown**

Adapted from Berg AT, Berkovic SF, Brodie MJ, et al: Revised terminology and concepts for organization of seizures and epilepsies: report of the ILAE Commission on Classification and Terminology, 2005-2009, International League Against Epilepsy, *Epilepsia* 5:676, 2010.

Clinical Manifestations

The specific clinical manifestations of a seizure are determined by the site of the electrical disturbance.[9] The preferred method of classifying seizures is presented in Table 59-6. This system, which is based on the clinical and electroencephalographic manifestations of seizures, divides seizures into two major classes: *generalized* and *focal* (Fig. 59-2). Depending on the type, a seizure may progress through several phases: (1) the *prodromal phase,* with signs or activity that precede a seizure; (2) the *aural phase,* with a sensory warning; (3) the *ictal phase,* with full seizure; and (4) the *postictal phase,* the period of recovery after the seizure.

Generalized Seizures. **Generalized seizures** involve both sides of the brain and are characterized by bilateral synchronous epileptic discharges in the brain from the onset of the seizure. In most cases the patient loses consciousness for a few seconds to several minutes.

Tonic-Clonic Seizures. The most common generalized seizure is the generalized tonic-clonic (formerly known as *grand mal*) seizure. **Tonic-clonic seizure** is characterized by losing consciousness and falling to the ground if the patient is upright, followed by stiffening of the body (tonic phase) for 10 to 20 seconds and subsequent jerking of the extremities (clonic phase) for another 30 to 40 seconds. Cyanosis, excessive salivation, tongue or cheek biting, and incontinence may accompany the seizure.

In the postictal phase the patient usually has muscle soreness, is tired, and may sleep for several hours. Some patients may not feel normal for several hours or days after a seizure. The patient has no memory of the seizure.

Typical Absence Seizures. The **absence seizure** (formerly called petit mal) usually occurs only in children and rarely continues beyond adolescence. This type of seizure may cease altogether as the child matures, or it may evolve into another type of seizure. The typical clinical manifestation is a brief staring spell resembling "daydreaming" that lasts only a few seconds, so it often goes unnoticed. When untreated, the seizures may occur up to 100 times a day. The electroencephalogram (EEG) demonstrates a 3-Hz (cycles per second) spike-and-wave pattern that is unique to this type of seizure. Hyperventilation and flashing lights can precipitate absence seizures.

Atypical Absence Seizures. Another type of generalized seizure is *atypical absence seizure,* which is characterized by a

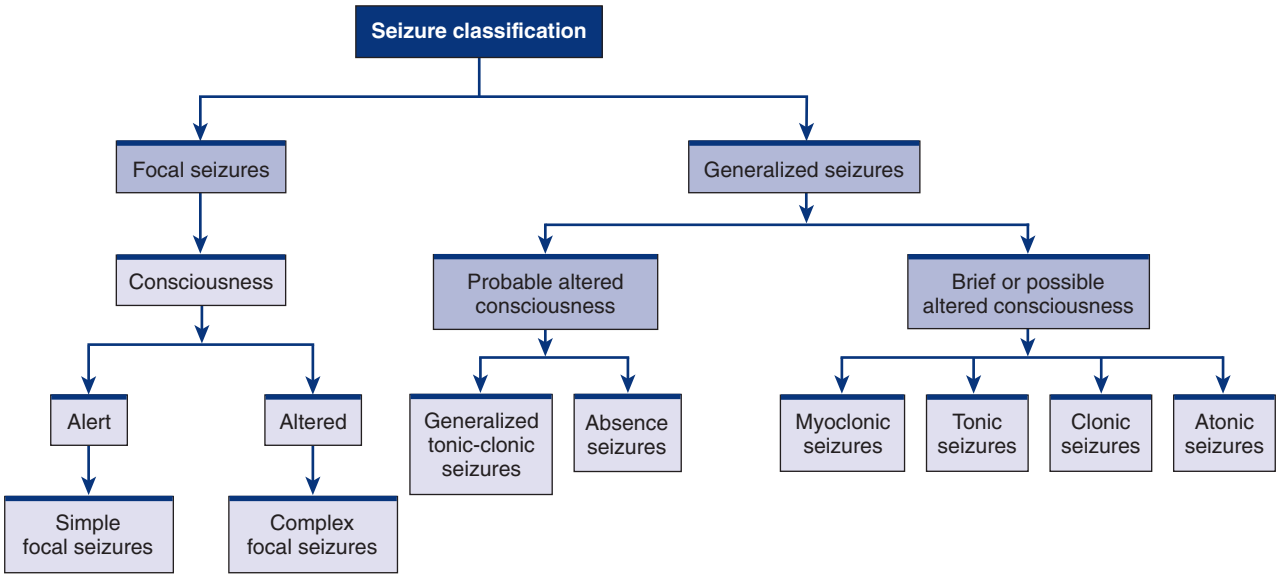

FIG. 59-2 Algorithm for classification of seizures.

staring spell accompanied by other signs and symptoms, including brief warnings, peculiar behavior during the seizure, or confusion after the seizure. It is longer lasting than a typical absence seizure and may be associated with loss of postural tone. The EEG demonstrates atypical spike-and-wave patterns, usually greater or less than 3 Hz.

Other Types of Generalized Seizures. Other generalized seizures are myoclonic, atonic, tonic, and clonic seizures. A *myoclonic seizure* is characterized by a sudden, excessive jerk of the body or extremities. The jerk may be forceful enough to hurl the person to the ground. These seizures are brief and may occur in clusters.

An *atonic* ("drop attack") seizure involves either a tonic episode or a paroxysmal loss of muscle tone and begins suddenly with the person falling to the ground. Consciousness usually returns by the time the person hits the ground, and normal activity can be resumed immediately. Patients with this type of seizure are at a great risk of head injury and often have to wear protective helmets.

A *tonic* seizure involves a sudden onset of maintained increased tone in the extensor muscles. These patients often fall.

Clonic seizures begin with loss of consciousness and sudden loss of muscle tone, followed by limb jerking that may or may not be symmetric.

Focal Seizures. **Focal seizures,** also called partial or partial focal seizures, are the other major class of seizures (see Table 59-6). Focal seizures begin in one hemisphere of the brain in a specific region of the cortex, as indicated by the EEG. They produce signs and symptoms related to the function of the area of the brain involved. For example, if the discharging focus is located in the medial aspect of the postcentral gyrus, the patient may experience paresthesias and tingling or numbness in the leg on the side opposite the focus. If the discharging focus is located in the part of the brain that governs a particular function, sensory, motor, cognitive, or emotional manifestations may occur.

Focal seizures are divided according to their clinical expression into (1) simple focal seizures (the person remains conscious) and (2) complex focal seizures (the person has a change or loss of consciousness).[8] In a *simple focal seizure,* patients remain conscious but experience unusual feelings or sensations that can take many forms. They may experience sudden and unexplainable feelings of joy, anger, sadness, or nausea. They also may hear, smell, taste, see, or feel things that are not real.

In a *complex focal seizure*, patients have a loss of consciousness or an alteration in their consciousness, producing a dreamlike experience. They display strange behavior such as lip smacking and *automatisms* (repetitive movements that may not be appropriate). Patients may continue an activity started before the seizure, such as counting out change or picking items from a grocery shelf, but after the seizure they do not remember the activity performed during the seizure. Other automatisms are less organized, such as picking at clothing, fumbling with objects (real or imaginary), or simply walking away. These seizures usually last just a few seconds.

Focal seizures may be confined to one side of the brain and remain focal (partial) in nature, or they may spread to involve the entire brain, culminating in a generalized tonic-clonic seizure. Any tonic-clonic seizure that is preceded by an aura or warning is a focal seizure that generalizes secondarily. Many tonic-clonic seizures that appear to be generalized from the outset may actually be secondary generalized seizures, but the preceding partial component may be so brief that it is undetected by the patient, by the observer, or even on the EEG. Unlike the primary generalized tonic-clonic seizure, the secondary generalized seizure may result in a transient residual neurologic deficit postictally. This is called *Todd's paralysis* (focal weakness), which resolves after varying lengths of time.

Psychogenic Seizures. Psychogenic seizures, also called pseudoseizures, are seizures that are psychiatric in origin. Since they closely resemble epileptic seizures, psychogenic seizures may be misdiagnosed as epilepsy. Proper diagnosis usually requires video-EEG monitoring to capture a typical episode. Patients with psychogenic seizures frequently have a history of emotional abuse, physical neglect, or a specific traumatic episode.[10]

Complications

Physical. **Status epilepticus** is a state of continuous seizure activity or a condition in which seizures recur in rapid succes-

sion without return to consciousness between seizures. It is the most serious complication of epilepsy and is a neurologic emergency. Status epilepticus can occur with any type of seizure. During repeated seizures the brain uses more energy than can be supplied. Neurons become exhausted and cease to function. Permanent brain damage may result. Tonic-clonic status epilepticus is the most dangerous because it can cause ventilatory insufficiency, hypoxemia, cardiac dysrhythmias, hyperthermia, and systemic acidosis, all of which can be fatal.

Subclinical seizures are a form of status epilepticus in which the sedated patient seizes but without external signs because of sedating medication. For example, a patient under sedation for ventilatory support in the intensive care unit (ICU) could experience a seizure without physical movements. The patient's health care providers could miss the seizure occurrence.

Another complication of seizures is severe injury and even death from trauma suffered during a seizure. Patients who lose consciousness during a seizure are at greatest risk.

Persons with epilepsy have a mortality rate that is two or three times the rate of the general population. Forty percent of these deaths are related to epilepsy because of accidents occurring during seizures, suicide, treatment-related death, death from an underlying disease, and sudden unexplained or unexpected death in epilepsy (SUDEP). SUDEP is higher in males, those on multiple antiseizure medications, and patients with long-standing epilepsy. The direct cause of SUDEP is unknown, but is thought to be related to respiratory dysfunction, cardiac dysrhythmias, or cerebral depression.[11]

Psychosocial. Perhaps the most common complication of seizure disorders is the effect it has on a patient's lifestyle. The patient may develop ineffective coping methods because of the psychosocial problems related to having a seizure disorder. Although attitudes have improved in recent years, epilepsy still carries a social stigma. The patient with epilepsy may experience discrimination in employment and educational opportunities. Transportation may be difficult because of legal sanctions against driving.

Diagnostic Studies

A diagnosis of epilepsy or seizure disorder has many socioeconomic, physical, and psychologic consequences for the patient. Therefore an accurate diagnosis is crucial. The most useful diagnostic tools are an accurate and comprehensive description of the seizures and the patient's health history (Table 59-7). The EEG is a useful diagnostic adjuvant to the history, but only if it shows abnormalities. Abnormal findings help determine the type of seizure and help pinpoint the seizure focus. Ideally, an EEG should be done within 24 hours of a suspected seizure. Unfortunately, only a small percentage of patients with seizure disorders have abnormal findings on the EEG the first time the test is done. Either repeated EEGs or continuous EEG monitoring may be needed to detect abnormalities. An EEG is not a definitive test because some patients who do not have seizure disorders have abnormal patterns on their EEGs, whereas many patients with seizure disorders have normal EEGs between seizures. If abnormal discharges do not occur during the 30 to 40 minutes of sampling during EEG, the test may not indicate an abnormality. Magnetoencephalography may be done in conjunction with the EEG. This test has greater sensitivity in detecting small magnetic fields generated by neuronal activity.

TABLE 59-7 COLLABORATIVE CARE

Seizure Disorders and Epilepsy

Diagnostic

History and Physical Examination

- Birth and developmental history
- Significant illnesses and injuries
- Family history
- Febrile seizures
- Comprehensive neurologic assessment

Seizure History

- Precipitating factors
- Antecedent events
- Seizure description (including onset, duration, frequency, postictal state)

Diagnostic Studies

- CBC, urinalysis, electrolytes, creatinine, fasting blood glucose
- Lumbar puncture for CSF analysis
- CT, MRI, MRA, MRS, PET scan
- Electroencephalography (EEG)

Collaborative Therapy

- Antiseizure drugs (see Table 59-9)
- Surgery (see Table 59-10)
- Vagal nerve stimulation
- Psychosocial counseling

MRA, Magnetic resonance angiography; *MRS,* magnetic resonance spectroscopy; *PET,* positron emission tomography.

A complete blood count, serum chemistries, studies of liver and kidney function, and a urinalysis should be done to rule out metabolic disorders. A CT scan or MRI should be done in any new-onset seizure to rule out a structural lesion. Cerebral angiography, single-photon emission computed tomography (SPECT), magnetic resonance spectroscopy (MRS), MRA, and positron emission tomography (PET) may be used in selected clinical situations.

If a patient is diagnosed with a seizure disorder, it is important to classify the seizure type correctly (see Fig. 59-2 and Table 59-6). The choice of treatment depends on the type of seizure.

Collaborative Care

Most seizures do not require professional emergency medical care because they are self-limiting and rarely cause bodily injury. However, if status epilepticus occurs, if significant bodily harm occurs, or if the event is a first-time seizure, medical care should be sought immediately. Table 59-8 summarizes emergency care of the patient with a generalized tonic-clonic seizure, the seizure most likely to warrant professional emergency medical care. Table 59-7 outlines the diagnostic studies and collaborative care of seizure disorders.

Drug Therapy. The primary treatment for seizure disorders is antiseizure drugs (Table 59-9). Because a cure is not possible, the goal of therapy is to prevent seizures with a minimum of toxic side effects from drug therapy. Medications control seizures in about 70% of the patients. Drugs generally act by stabilizing nerve cell membranes and preventing spread of the epileptic discharge. The principle of drug therapy is to begin with a single drug based on the patient's age and weight; type, frequency, and cause of seizure; and then increase the dosage until seizures are controlled or toxic side effects occur.

TABLE 59-8 EMERGENCY MANAGEMENT

Tonic-Clonic Seizures

Etiology

Head Trauma
- Epidural hematoma
- Subdural hematoma
- Intracranial hematoma
- Cerebral contusion
- Traumatic birth injury

Drug-Related Processes
- Overdose
- Withdrawal of alcohol, opioids, antiseizure drugs
- Ingestion, inhalation

Infectious Processes
- Meningitis
- Septicemia
- Encephalitis

Intracranial Events
- Brain tumor
- Subarachnoid hemorrhage
- Stroke
- Hypertensive crisis
- Increased ICP secondary to clogged shunt

Metabolic Imbalances
- Fluid and electrolyte imbalance
- Hypoglycemia

Medical Disorders
- Heart, liver, lung, or kidney disease
- Systemic lupus erythematosus

Other
- Cardiac arrest
- Idiopathic
- Psychiatric disorders
- High fever

Assessment Findings

- Aura (peculiar sensations that precede seizure)
- Loss of consciousness
- Bowel and bladder incontinence
- Tachycardia
- Diaphoresis
- Warm skin
- Pallor, flushing, or cyanosis
- *Tonic phase:* Continuous muscle contractions
- *Hypertonic phase:* Extreme muscular rigidity lasting 5–15 sec
- *Clonic phase:* Rigidity and relaxation alternating in rapid succession
- *Postictal phase:* Lethargy, altered level of consciousness
- Confusion and headache
- Repeated tonic-clonic seizures for several min

Interventions

Initial
- Ensure patent airway.
- Protect patient from injury during seizure. *Do not restrain.* Pad side rails.
- Remove or loosen tight clothing.
- Establish IV access.
- Stay with patient until seizure has passed.
- Anticipate administration of phenobarbital, phenytoin (Dilantin), or benzodiazepines (e.g., diazepam [Valium], midazolam [Versed], lorazepam [Ativan]) to control seizures.
- Suction as needed.
- Assist ventilations if patient does not breathe spontaneously after seizure. Anticipate need for intubation if gag reflex absent.

Ongoing Monitoring
- Monitor vital signs, level of consciousness, O_2 saturation, Glasgow Coma Scale results, pupil size and reactivity.
- Reassure and orient the patient after seizure.
- Never force an airway between a patient's clenched teeth.
- Give IV dextrose for hypoglycemia.

ICP, Intracranial pressure.

If seizure control is not achieved with a single drug, the drug dosage or timing of administration may be changed or a second drug may be added. About one third of patients require a combination regimen for adequate control.

The therapeutic range for each drug indicates the serum level above which most patients experience toxic side effects and below which most continue to have seizures. Therapeutic drug ranges are only guides for therapy. If the patient's seizures are well controlled with a subtherapeutic level, the drug dosage need not be increased. Likewise, if a drug level is above the therapeutic range and the patient has good seizure control without toxic side effects, the drug dosage does not need to be decreased. Serum drug levels are monitored if seizures continue to occur, if seizure frequency increases, or if drug adherence is questioned. Many of the newer drugs do not require drug-level monitoring because the therapeutic range is very large.

The primary drugs to treat generalized tonic-clonic and focal seizures are phenytoin (Dilantin), carbamazepine (Tegretol), phenobarbital, divalproex, and primidone (Mysoline). The drugs used to treat absence and myoclonic seizures include ethosuximide (Zarontin), divalproex, and clonazepam (Klonopin).

TABLE 59-9 DRUG THERAPY

Seizure Disorders and Epilepsy

Generalized Tonic-Clonic and Focal Seizures
- carbamazepine (Tegretol)
- divalproex (Depakote)
- ezogabine (Potiga)
- felbamate (Felbatol)
- gabapentin (Neurontin)
- lacosamide (Vimpat)
- lamotrigine (Lamictal)
- levetiracetam (Keppra)
- oxcarbazepine (Trileptal)
- perampanel (Fycompa)
- phenobarbital (Luminal)
- phenytoin (Dilantin)
- pregabalin (Lyrica)
- primidone (Mysoline)
- tiagabine (Gabitril)
- topiramate (Topamax)
- valproic acid (Depakene)
- vigabatrin (Sabril)
- zonisamide (Zonegran)

Absence and Myoclonic Seizures
- clonazepam (Klonopin)
- divalproex (Depakote)
- ethosuximide (Zarontin)
- zonisamide (Zonegran)

DRUG ALERT: Carbamazepine (Tegretol)
- Do not take with grapefruit juice.
- Instruct patient to report visual abnormalities.
- Abrupt withdrawal after long-term use may precipitate seizures.

Other antiseizure drugs include gabapentin, topiramate, lamotrigine (Lamictal), tiagabine (Gabitril), levetiracetam (Keppra), and zonisamide (Zonegran). Some of these drugs are broad spectrum and appear to be effective for multiple seizure types. Pregabalin (Lyrica) is used as an "add-on" for control of focal seizures that are not successfully managed with a single medication.

Treatment of status epilepticus requires initiation of a rapid-acting IV antiseizure drug. The drugs most commonly used are lorazepam (Ativan) and diazepam (Valium). Because these are short-acting drugs, their administration is followed with long-acting drugs such as phenytoin or phenobarbital.

Because many of the antiseizure drugs (e.g., phenytoin, phenobarbital, ethosuximide, lamotrigine, topiramate) have a long half-life, they can be given in once- or twice-daily doses. This increases the patient's adherence to the drug regimen by simplifying it and avoiding the need to take the drug at work or school.

DRUG ALERT: Antiseizure Drugs
- Abrupt withdrawal after long-term use may precipitate seizures.
- If weaning is to occur, the patient must be seizure free for a prolonged period (e.g., 2 to 5 yr) and have a normal neurologic examination and EEG.

Side effects of antiseizure drugs involve the CNS and include diplopia, drowsiness, ataxia, and mental slowness. Neurologic assessment for dose-related toxicity involves testing the eyes for nystagmus, hand and gait coordination, cognitive functioning, and general alertness.

As a nurse, you need to be knowledgeable about these side effects so that patients can be informed and institute proper treatment. A common side effect of phenytoin is gingival hyperplasia (excessive growth of gingival tissue) and hirsutism, especially in young adults. Good dental hygiene, including regular tooth brushing and flossing, can limit gingival hyperplasia. If gingival hyperplasia is extensive, the hyperplastic tissue may have to be surgically removed (gingivectomy), and phenytoin replaced with another antiseizure drug.

Medication nonadherence can be a problem in persons with a seizure disorder. Take measures to increase patient adherence to the prescribed drug regimens. If made aware of the issue, health care providers can work with the patient to find an acceptable drug regimen. For example, using pregabalin in some cases as an adjunct medication will allow a decreased dose of the primary antiseizure drug, thus decreasing undesirable side effects.

GERONTOLOGIC CONSIDERATIONS

DRUG THERAPY FOR SEIZURE DISORDERS

The incidence of new-onset seizure disorders is high among older adults. Closely consider the relationship between the action of antiseizure drugs and the normal changes that occur with aging. For example, phenytoin is widely used to treat seizure disorders. However, because the liver metabolizes phenytoin, its use can be a problem for older patients with compromised liver function. Age-related changes in liver enzymes decrease the liver's ability to metabolize drugs. Phenobarbital, carbamazepine, and primidone have potential effects on cognitive function, so their use may be less desirable for the older adult. Carbamazepine, phenytoin, and phenobarbital have many significant drug interactions.[12]

Several of the newer antiseizure medications offer greater treatment benefit to older adults. Compared with older drugs, gabapentin, lamotrigine, oxcarbazepine, and levetiracetam may be safer, have fewer effects on cognitive function, and have fewer interactions with other drugs.[12]

TABLE 59-10 SURGERY FOR SEIZURE DISORDERS

Type of Seizure	Surgical Procedure
Complex focal seizure of temporal lobe origin	Resectioning of epileptogenic tissue
Focal seizures of frontal lobe origin	Resectioning of epileptogenic tissue (if in resectable area)
Generalized seizures (Lennox-Gastaut syndrome or drop attacks)	Sectioning of corpus callosum
Intractable unilateral multifocal epilepsy associated with infantile hemiplegia	Hemispherectomy or callosotomy

Surgical Therapy. A significant number of patients whose epilepsy is not controlled with drug therapy are candidates for surgical intervention to remove the epileptic focus or prevent spread of epileptic activity in the brain (Table 59-10). The most common surgical intervention is an anterior temporal lobe resection. Approximately 70% of patients are essentially seizure free after this procedure.[8]

The benefits of surgery include cessation or reduction in frequency of the seizures. However, not all types of epilepsy benefit from surgery. An extensive preoperative evaluation is important, including continuous EEG monitoring and other specific tests to ensure precise localization of the focal point. Surgical candidates must meet three requirements: (1) a confirmed diagnosis of epilepsy, (2) an adequate trial with drug therapy without satisfactory results, and (3) a defined electroclinical syndrome (type of seizure disorder).

Other Therapies. Vagal nerve stimulation is used as an adjunct to medications when surgery is not feasible. The exact mechanism of action is unknown, but it is thought to interrupt the synchronization of epileptic brain wave activity and stop excessive discharge of neurons. A surgically implanted electrode in the neck is programmed to deliver the electrical impulse to the vagus nerve. The patient can activate it with a magnet when he or she senses a seizure is imminent. Vagal nerve stimulation can cause adverse effects such as coughing, hoarseness, dyspnea, and tingling in the neck. Battery replacement is required via surgery about every 5 years.

The ketogenic diet is a special high-fat, low-carbohydrate diet that has been used to control seizures in some people with epilepsy. When a person is on this diet, ketones are produced and pass into the brain and replace glucose as an energy source. The diet may be effective for some patients with drug-resistant epilepsy, but the long-term effects of the diet are not clear. Patients on this diet who use anticoagulants need close monitoring for bleeding.[13]

Biofeedback to control seizures is aimed at teaching the patient to maintain a certain brain wave frequency that is refractory to seizure activity. Further trials are needed to assess the effectiveness of biofeedback for seizure control.

NURSING MANAGEMENT SEIZURE DISORDERS AND EPILEPSY

NURSING ASSESSMENT

Subjective and objective data to obtain from a patient with a seizure disorder are presented in Table 59-11. Obtain data related to a specific seizure episode from a witness.

NURSING DIAGNOSES

Nursing diagnoses for the patient with seizure disorders and epilepsy may include, but are not limited to, the following:

- Ineffective breathing pattern *related to* neuromuscular impairment
- Ineffective self-health management *related to* drug therapy and lifestyle adjustments
- Risk for injury *related to* loss of consciousness during seizure activity and postictal physical weakness

Additional information on nursing diagnoses for the patient with a seizure disorder is presented in eNursing Care Plan 59-2 (available on the website for this chapter).

PLANNING

The overall goals are that the patient with seizures will (1) be free from injury during a seizure, (2) have optimal mental and physical functioning while taking antiseizure drugs, and (3) have satisfactory psychosocial functioning.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Some cases of seizure disorders can be prevented by promoting general safety measures, such as wearing helmets in situations involving risk of head injury. Improved perinatal, labor, and delivery care have reduced fetal trauma and hypoxia and thereby have reduced brain damage leading to seizure disorders.

The patient with a seizure disorder should practice good general health habits (e.g., maintaining a proper diet, getting adequate rest, exercising). Help the patient identify events or situations that precipitate the seizures and provide suggestions for avoiding them or handling them better. Teach the patient to avoid excessive alcohol intake, fatigue, and loss of sleep. Help the patient handle stress constructively.

ACUTE INTERVENTION. Nursing care for a hospitalized patient with a seizure disorder or a patient who has had seizures from metabolic factors involves several responsibilities, including observation and treatment of the seizure, education, and psychosocial intervention.

When a seizure occurs, carefully observe and record details of the event because the diagnosis and subsequent treatment often rest solely on the seizure description. Note all aspects of the seizure. What events preceded the seizure? When did the seizure occur? How long did each phase (aural [if any], ictal, postictal) last? What occurred during each phase?

Both subjective data (usually the only type of data in the aural phase) and objective data are important. Note the exact onset of the seizure (which body part was affected first and how); the course and nature of the seizure activity (loss of consciousness, tongue biting, automatisms, stiffening, jerking, total lack of muscle tone); the body parts involved and their sequence of involvement; and autonomic signs, such as dilated pupils, excessive salivation, altered breathing, cyanosis, flushing, diaphoresis, or incontinence. Assessment of the postictal period should include a detailed description of the level of conscious-

TABLE 59-11 NURSING ASSESSMENT

Seizure Disorders and Epilepsy

Subjective Data

Important Health Information

Past health history: Previous seizures, birth defects or injuries, anoxic episodes; CNS trauma, tumors, or infections; stroke; metabolic disorders, alcoholism; exposure to metals and carbon monoxide; hepatic or renal failure; fever; pregnancy, systemic lupus erythematosus

Medications: Adherence to antiseizure medication regimen; barbiturate or alcohol withdrawal; use and overdose of cocaine, amphetamines, lidocaine, theophylline, penicillin, lithium, phenothiazines, tricyclic antidepressants, benzodiazepines

Functional Health Patterns

Health perception–health management: Positive family history

Cognitive-perceptual: Headaches, aura, mood or behavioral changes before seizure; mentation changes; abdominal pain, muscle pain (postictal)

Self-perception–self-concept: Anxiety, depression; loss of self-esteem, social isolation

Sexuality-reproductive: Decreased sexual drive, erectile dysfunction; increased sexual drive (postictal)

Objective Data

General

Precipitating factors, including severe metabolic acidosis or alkalosis, hyperkalemia, hypoglycemia, dehydration, or water intoxication

Integumentary

Bitten tongue, soft tissue damage, cyanosis, diaphoresis (postictal)

Respiratory

Abnormal respiratory rate, rhythm, or depth; apnea (ictal); absent or abnormal breath sounds, possible airway occlusion

Cardiovascular

Hypertension, tachycardia or bradycardia (ictal)

Gastrointestinal

Bowel incontinence; excessive salivation

Urinary

Incontinence

Neurologic

Generalized

Tonic-clonic: Loss of consciousness, muscle tightening, then jerking; dilated pupils; hyperventilation, then apnea; postictal somnolence

Absence: Altered consciousness (5–30 sec), minor facial motor activity

Focal

Simple: Aura; consciousness; focal sensory, motor, cognitive, or emotional phenomena (focal motor); unilateral "marching" motor seizure (jacksonian)

Complex: Altered consciousness with inappropriate behaviors, automatisms, amnesia of event

Musculoskeletal

Weakness, paralysis, ataxia (postictal)

Possible Diagnostic Findings

Positive toxicology screen or alcohol level; altered serum electrolytes, acidosis or alkalosis, very low blood glucose level, ↑ blood urea nitrogen or serum creatinine, abnormal liver function tests, ammonia; abnormal CT scan or MRI of head, abnormal findings from lumbar puncture; abnormal discharges on EEG

DELEGATION DECISIONS

Caring for the Patient With a Seizure Disorder

Since any nursing staff member may be present when a patient experiences a seizure, all staff members are responsible for maintaining patient safety.

Role of Registered Nurse (RN)

- Teach patient about factors that increase risk for seizures, such as alcohol use, fatigue, inadequate sleep, and stress.
- Teach patient about prescribed antiseizure medications, including drug regimen, side effects, and required monitoring of drug levels.
- Assess and document details of seizure events, including events preceding the seizure; length of each phase of the seizure; course and nature of the seizure activity; and the level of consciousness, vital signs, and activity during the postictal period.
- Assess airway patency and position patient to maintain airway after any seizures.
- Administer IV antiseizure medications to the patient experiencing status epilepticus.
- Make appropriate referrals to the Epilepsy Foundation and community agencies to assist patient with financial problems, work training, employment, and living arrangements.
- Teach family members and caregivers about management of seizures and status epilepticus.
- In the ambulatory and home care setting, evaluate patient self-management of medications and lifestyle.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- Administer oral antiseizure medications as scheduled.
- In the ambulatory and home setting, monitor patient adherence with medications and lifestyle changes and report problems to the RN.

Role of Unlicensed Assistive Personnel (UAP)

- Place suction equipment, Ambu bag, and O_2 at the patient bedside.
- Remove potentially harmful objects from the bedside and pad side rails.
- Immediately report any seizure activity to the RN.
- Observe and report events of the seizure to the RN.
- Obtain vital signs during the postictal period.
- Provide oropharyngeal suctioning after a seizure (after being trained and evaluated in this procedure).

ness, vital signs, pupil size and position of the eyes, memory loss, muscle soreness, speech disorders (aphasia, dysarthria), weakness or paralysis, sleep period, and the duration of each sign or symptom.

SAFETY ALERT

During a seizure, you should do the following:

- Maintain a patent airway for the patient.
- Protect the patient's head, turn the patient to the side, loosen constrictive clothing, ease patient to the floor (if seated).
- Do not restrain the patient.
- Do not place any objects in the patient's mouth.

After the seizure the patient may require repositioning to open and maintain the airway, suctioning, and oxygen. A seizure can be frightening for the patient and for others who witnessed it. Assess the level of their understanding and provide information about how and why the event occurred. This is an excellent opportunity for you to dispel many common misconceptions about seizures.

AMBULATORY AND HOME CARE. Prevention of recurring seizures is the major goal in the treatment of epilepsy. For treatment to be effective, drugs must be taken regularly and continuously, often for a lifetime. Ensure that the patient knows this, the specifics of the drug regimen, and what to do if a dose is missed. Usually the dose is made up if the omission is remembered within 24 hours. Caution the patient not to adjust drug dosages without professional guidance because this can increase seizure frequency and even cause status epilepticus. Encourage the patient to report any medication side effects and to keep regular appointments with the health care provider.

TABLE 59-12 PATIENT & CAREGIVER TEACHING GUIDE

Seizure Disorders and Epilepsy

Include the following information in the teaching plan for the patient with a seizure disorder.

1. Take drugs as prescribed. Report any and all side effects of drugs to the health care provider. When necessary, blood is drawn to ensure that therapeutic levels are maintained.
2. Use nondrug techniques, such as relaxation therapy and biofeedback training, to potentially reduce the number of seizures.
3. Be aware of availability of resources in the community.
4. Wear a medical alert bracelet or necklace, and carry an identification card.
5. Avoid excessive alcohol intake, fatigue, and loss of sleep.
6. Eat regular meals and snacks in between if feeling shaky, faint, or hungry.

Caregivers should receive the following information.

1. For first aid treatment of tonic-clonic seizure, it is not necessary to call an ambulance or send the patient to the hospital after a single seizure unless the seizure is prolonged, another seizure immediately follows, or extensive injury has occurred.
2. During an acute seizure, it is important to protect the patient from injury. This may involve supporting and protecting the head, turning the patient to the side, loosening constrictive clothing, and easing the patient to the floor, if seated.

You have an important role in teaching the patient and caregiver. Review the guidelines for teaching shown in Table 59-12. Teach the caregiver, family members, and significant others the emergency management of tonic-clonic seizures (see Table 59-8). Remind them that it is not necessary to call an ambulance or send a person to the hospital after a single seizure unless the seizure is prolonged, another seizure immediately follows, or extensive injury has occurred.

Patients with a seizure disorder may experience concerns or fears related to recurrent seizures, incontinence, or loss of self-control. Support the patient through teaching and by helping him or her use effective coping mechanisms.

Perhaps the greatest challenge for a patient with a seizure disorder is adjusting to the personal and societal limitations imposed by the illness. Discrimination in employment is the most serious problem facing the person with a seizure disorder. For issues relating to job discrimination, refer patients to the state department of vocational rehabilitation or the U.S. Equal Employment Opportunity Commission (EEOC).

Assist the patient who has a specific problem in finding appropriate resources. If you believe that associating with others who have a seizure disorder would be beneficial, refer the patient to the local chapter of the Epilepsy Foundation (EF), a volunteer agency that offers a variety of services to patients with epilepsy. Refer the patient who is an eligible veteran to a Department of Veterans Affairs medical center that provides comprehensive care. If intensive psychologic counseling is needed, refer the patient to a community mental health center.

Social workers and welfare agencies can help with financial problems and living arrangements. State agencies specializing

in vocational rehabilitation services can provide vocational assessment, counseling, funding for training, and assistance with job placement for patients whose seizures are not well controlled. They can also offer financial assistance for transportation and medical costs related to vocational rehabilitation or job maintenance.

Driving laws for patients who have had a seizure vary from state to state. For example, some states require a 3-month seizure-free period before issuing or reissuing a driver's license, whereas others require up to 1 year. The EF provides current information on driving laws for each state.

Inform the patient that medical alert bracelets, necklaces, and identification cards are available through the EF, local pharmacies, or companies specializing in identification devices (e.g., Medic Alert). However, the use of these medical identification tags is optional. Some patients have found them beneficial, but others prefer not to be identified as having a seizure disorder.

Encourage the patient to learn more about epilepsy through self-education materials. The EF provides several information pamphlets and may facilitate support groups. Many agencies that offer services to epileptic patients, as well as local chapters of EF, have these available as teaching aids.

EVALUATION

Expected outcomes are that the patient with seizures will

- Experience breathing pattern adequate to meet oxygen needs
- Experience no seizure-related injury
- Express acceptance of seizure disorder by admitting presence of epilepsy and maintaining adherent behavior

Additional expected outcomes are presented in eNursing Care Plan 59-2 available on the website.

RESTLESS LEGS SYNDROME

Etiology and Pathophysiology

Restless legs syndrome (RLS), also called Willis-Ekbom disease, is a relatively common condition characterized by unpleasant sensory (paresthesias) and motor abnormalities of one or both legs. Prevalence rates vary from 5% to 15%. However, the numbers may be higher because the condition is underdiagnosed. RLS is more common in older adults. It is also more common in women than men, and women may have an earlier age of onset.[14]

There are two distinct types of RLS: primary (idiopathic) and secondary. The majority of cases are primary, and many patients with this type of RLS report a positive family history. Secondary RLS can occur with metabolic abnormalities associated with iron deficiency, renal failure, hypertension, diabetes mellitus, or rheumatoid arthritis. Conditions such as anemia, pregnancy, and certain medications can cause or worsen symptoms.

Although the exact pathophysiology of primary RLS is unknown, it is believed that RLS is related to a dysfunction in the brain's basal ganglia circuits that use the neurotransmitter dopamine, which controls movements. In RLS this dysfunction causes the urge to move the legs. Abnormal iron metabolism or brain iron deficiencies may result in abnormalities of the dopamine system, thus leading to RLS.[15]

Clinical Manifestations

The severity of RLS sensory symptoms ranges from infrequent minor discomfort (paresthesias, including numbness, tingling, and "pins and needles" sensation) to severe pain. Sensory symptoms often appear first. Patients describe annoying and uncomfortable (but usually not painful) sensations in the legs. Some describe the sensations like bugs creeping or crawling on the legs. The leg pain is localized within the calf muscles. Patients can also experience pain in the upper extremities and the trunk. The discomfort occurs when the patient is sedentary and is most common in the evening or at night.

The pain at night can disrupt sleep. Physical activity, such as walking, stretching, rocking, or kicking, often relieves the pain. In the most severe cases, patients sleep only a few hours at night, resulting in daytime fatigue and disruption of the daily routine. The motor abnormalities associated with RLS consist of voluntary restlessness and stereotyped, periodic, involuntary movements. The involuntary movements usually occur during sleep. Fatigue further aggravates symptoms. Over time, RLS advances to more frequent and severe episodes.

Diagnostic Studies

RLS is a clinical diagnosis, based in large part on the patient's history or the report of the bed partner related to nighttime activities. The diagnosis of RLS is based on four specific criteria: (1) desire to move the extremities, often associated with paresthesias; (2) motor restlessness; (3) worsening of symptoms at rest with at least temporary relief from activity; and (4) worsening of symptoms in the evening or night.[15]

The patient may undergo polysomnography studies during sleep to distinguish RLS from other clinical conditions that can disturb sleep (e.g., sleep apnea). However, periodic leg movements in sleep are a common feature in RLS patients. Blood tests, such as a complete blood count, serum ferritin levels, and renal function tests (e.g., serum creatinine), may help exclude secondary causes of RLS. A patient's history of diabetes mellitus and its management may provide information to determine whether paresthesias are caused by peripheral neuropathy related to diabetes or RLS.

NURSING AND COLLABORATIVE MANAGEMENT RESTLESS LEGS SYNDROME

The goal of collaborative management is to reduce patient discomfort and distress and to improve sleep quality. When RLS is secondary to renal failure or iron deficiency, treatment of these conditions will decrease symptoms. Nondrug approaches to RLS management include establishing regular sleep habits; exercising; avoiding activities that cause symptoms; and eliminating aggravating factors such as alcohol, caffeine, and certain drugs (neuroleptics, lithium, antihistamines, antidepressants).

If nondrug measures fail to provide symptom relief, drug therapy is an option. No single medication effectively manages RLS for all patients. The main drugs used in RLS include dopamine precursors (e.g., carbidopa/levodopa [Sinemet]) and dopamine agonists (e.g., ropinirole [Requip], pramipexole [Mirapex]) to increase the amount of dopamine in the brain. The antiseizure drug gabapentin enacarbil (Horizant) is used to decrease the sensory sensations. If the patient has iron deficiency or low serum ferritin levels, iron supplementation is considered.

Other drugs may relieve some symptoms of RLS. These include opioids and benzodiazepines. Low doses of opioids (e.g., oxycodone) are usually reserved for patients with severe symptoms who fail to respond to other drug therapies. The

main side effect of opioids is constipation, so the patient may need to take a stool softener or laxative. Clonidine (Catapres) and propranolol (Inderal) are also effective in some patients.

DEGENERATIVE NEUROLOGIC DISORDERS

Degenerative nerve diseases lead to nerve damage that worsens as the disease progresses. These diseases affect many activities, including balance, movement, speech, and respiratory and heart function. There are more than 200 degenerative neurologic disorders. These include the disorders discussed in the remainder of this chapter, as well as disorders such as cerebellar degeneration, Friedreich's ataxia, Creutzfeldt-Jakob disease, and neurofibromatosis. Some have no known cause. However, many of these diseases have a genetic basis. Most degenerative nerve diseases have no cure. Treatment aims to reduce symptoms and help the patient maintain an optimal level of function.

Patients with these diseases have similar concerns and problems. They must deal with not only their disease, but also the impact that the disease has on their quality of life. Many patients have concerns regarding safety, mobility, self-care, and coping. The patient and family often require psychosocial support, especially as the disease progresses and the patient's disability gets worse.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a chronic, progressive, degenerative disorder of the CNS characterized by disseminated demyelination of nerve fibers of the brain and spinal cord. The onset of MS is usually between 20 and 50 years of age, although it can occur in young teens and much older adults. Women are affected two to three times more often than men.

MS is five times more prevalent in temperate climates (between 45 and 65 degrees of latitude), such as those found in the northern United States, Canada, and Europe, as compared with tropical regions. Migration from one geographic area to another may alter a person's risk of developing MS. Immigrants and their descendants tend to take on the risk level (either higher or lower) of the area to which they move. However, the change in risk may not appear immediately. For example, African Americans (in the United States) have a prevalence rate that is 40% that of European Americans, whereas Africans (in Africa) are thought to have a prevalence rate that is approximately 1% that of European Americans. The variations in incidence of MS suggest that geography, ethnicity, and other factors interact in a complex way to cause MS.[16]

Etiology and Pathophysiology

The cause of MS is unknown, although research suggests that it is unlikely MS is related to a single cause. Researchers believe the disease develops in a genetically susceptible person as a result of environmental exposure, like an infection. Multiple genes are believed to be involved in the inherited susceptibility to MS, and first-, second-, and third-degree relatives of patients with MS are at an increased risk.[16]

Possible precipitating factors include infection, smoking, physical injury, emotional stress, excessive fatigue, pregnancy, and a poor state of health. The role of precipitating factors such as exposure to pathogenic agents is controversial. It is possible that their association with MS is random and that there is no cause-and-effect relationship.

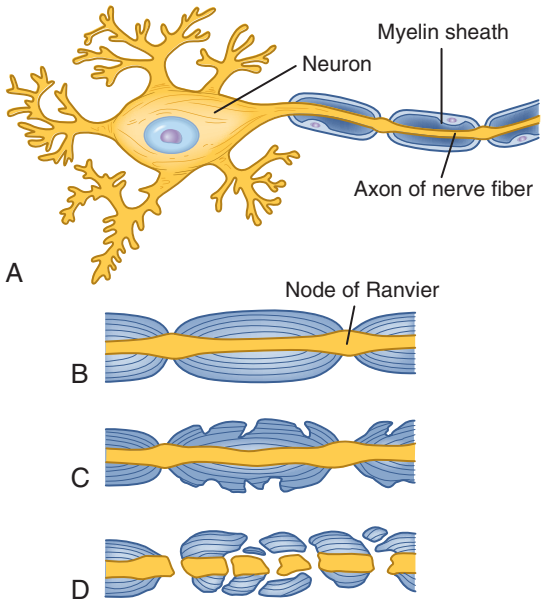

FIG. 59-3 Pathogenesis of multiple sclerosis. **A,** Normal nerve cell with myelin sheath. **B,** Normal axon. **C,** Myelin breakdown. **D,** Myelin totally disrupted; axon not functioning.

Three pathologic processes characterize MS: chronic inflammation, demyelination, and gliosis (scarring) in the CNS. The primary neuropathologic condition is an autoimmune process orchestrated by activated T cells (lymphocytes). An environmental factor or virus in genetically susceptible individuals may initially trigger this process. The activated T cells in the systemic circulation migrate to the CNS, disrupting the blood-brain barrier. This is likely the initial event in the development of MS. Subsequent antigen-antibody reaction within the CNS activates the inflammatory response and leads to the demyelination of axons.

Initially, attacks on the myelin sheaths of the neurons in the brain and spinal cord result in damage to the myelin sheath (Fig. 59-3, *A* to *C*). However, the nerve fiber is not affected. Transmission of nerve impulses still occurs, though transmission is slowed. The patient may complain of a noticeable impairment of function (e.g., weakness). However, the myelin can regenerate, and when it does, symptoms disappear. At that point, the patient experiences a remission.

As ongoing inflammation occurs, the nearby oligodendrocytes are affected, and the myelin loses the ability to regenerate. Eventually damage occurs to the underlying axon. Nerve impulse transmission is disrupted, resulting in the permanent loss of nerve function (Fig. 59-3, *D*). As inflammation subsides, glial scar tissue replaces the damaged tissue, leading to the formation of hard, sclerotic plaques (Fig. 59-4). These plaques are found throughout the white matter of the CNS.

Clinical Manifestations

The onset of MS is often insidious and gradual, with vague symptoms occurring intermittently over months or years that often dissuade the patient from seeking medical attention. Thus the disease may not be diagnosed until long after the onset of the first symptom. The disease is characterized by chronic, progressive deterioration in some patients, and remissions and exacerbations in others. With repeated exacerbations, the overall trend is progressive deterioration in neurologic function.

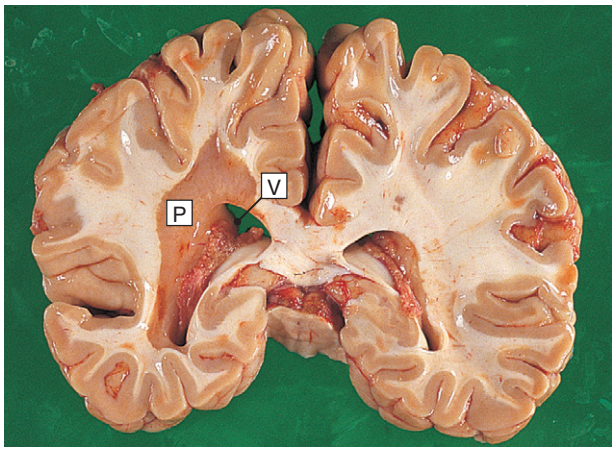

FIG. 59-4 Chronic multiple sclerosis. Demyelination plaque *(P)* at gray-white junction and adjacent partially remyelinated shadow plaque *(V)*.

TABLE 59-13 PATTERNS OF MULTIPLE SCLEROSIS

Category	Characteristics
Relapsing-remitting	• Clearly defined relapses with full recovery or sequelae and residual deficit on recovery. • Approximately 85% of people are initially diagnosed with this type of multiple sclerosis (MS).
Primary-progressive	• Slowly worsening neurologic function from the beginning with no distinct relapses or remissions. • About 10% of people are diagnosed with this type of MS.
Secondary-progressive	• A relapsing-remitting initial course, followed by progression with or without occasional relapses, minor remissions, and plateaus. • New treatments may slow progression. • About 50% of people with relapsing-remitting MS develop this type within 10 yr.
Progressive-relapsing	• Progressive disease from onset, with clear acute relapses, with or without full recovery. Periods between relapses are characterized by continuing progression. • Only 5% of people experience this type of MS.

Since the disease process has a spotty distribution in the CNS, the clinical manifestations vary with each patient according to the areas of the CNS involved. Some patients have severe, long-lasting symptoms early in the course of the disease. Others may experience only occasional and mild symptoms for several years after onset. A classification scheme, with four primary patterns of MS, has been developed based on the clinical course[16,17] (Table 59-13).

Common manifestations of MS include motor, sensory, cerebellar, and emotional problems. Motor symptoms include weakness or paralysis of the limbs, the trunk, or the head; diplopia; scanning speech; and spasticity of the muscles that are chronically affected. Patients with MS experience a variety of sensory abnormalities, including numbness and tingling and other paresthesias, patchy blindness *(scotomas),* blurred vision, vertigo, tinnitus, decreased hearing, and chronic neuropathic pain. Radicular (nerve root) pains may be present, particularly in the low thoracic and abdominal regions. *Lhermitte's sign* is a transient sensory symptom described as an electric shock radiating down the spine or into the limbs with flexion of the neck. Cerebellar signs include nystagmus, ataxia, dysarthria, and dysphagia. Many patients have severe fatigue, sometimes with significant disability. The fatigue is aggravated by heat, humidity, deconditioning, and medication side effects.[16]

Bowel and bladder function can be affected if the sclerotic plaque is located in areas of the CNS that control elimination. Problems with defecation usually involve constipation rather than fecal incontinence. Urinary problems are variable. A common problem in MS patients is a *spastic* (uninhibited) bladder. As a result, the bladder has a small capacity for urine, and its contractions are unchecked. This is accompanied by urinary urgency and frequency and results in dribbling or incontinence.

A *flaccid* (hypotonic) bladder indicates a lesion in the reflex arc controlling bladder function. A flaccid bladder has a large capacity for urine because there is no sensation or desire to void, no pressure, and no pain. Generally, the patient has urinary retention, but urgency and frequency may also occur with this type of lesion. Another urinary problem is a combination of the previous two. Urinary problems cannot be adequately diagnosed and treated without urodynamic studies.

Sexual dysfunction occurs in many persons with MS. Physiologic erectile dysfunction may result from spinal cord involvement in men. Women may experience decreased libido, difficulty with orgasmic response, painful intercourse, and decreased vaginal lubrication. Diminished sensation can prevent a normal sexual response in both sexes. The emotional effects of chronic illness and the loss of self-esteem also contribute to loss of sexual response.

Some women with MS who become pregnant experience remission or an improvement in their symptoms during the gestation period. The hormonal changes associated with pregnancy appear to affect the immune system. However, during the postpartum period, women are at greater risk for exacerbation of the disease.

About half of people with MS experience some problems with cognitive function. For most, the problems are difficulties with short-term memory, attention, information processing, planning, visual perception, and word finding. General intellect remains unchanged and intact, including long-term memory, conversational skills, and reading comprehension. In only about 5% to 10% of MS patients, the cognitive changes are so severe that they significantly impair the person's ability to carry out activities of daily living. Most of the time, cognitive difficulties occur later in the course of the disease. However, they can occur much earlier in the disease process, and occasionally they are present at the onset of MS.

Persons with MS may also experience emotional changes such as anger, depression, or euphoria. Physical and emotional trauma, fatigue, and infection may aggravate or trigger signs and symptoms.

The average life expectancy after the onset of symptoms is more than 25 years. Death usually occurs due to infectious complications (e.g., pneumonia) of immobility or because of an unrelated disease.

Diagnostic Studies

Because there is no definitive diagnostic test for MS, factors considered are the history, clinical manifestations, and results of certain diagnostic tests (Table 59-14). An MRI of the brain and spinal cord may show plaques, inflammation, atrophy, and tissue breakdown and destruction. Cerebrospinal fluid (CSF) analysis may show an increase in immunoglobulin G and the

presence of oligoclonal banding.[17] Evoked potential responses are often delayed in persons with MS because of decreased nerve conduction from the eye and the ear to the brain.

To be diagnosed with MS, the patient must have (1) evidence of at least two inflammatory demyelinating lesions in at least two different locations within the CNS, (2) damage or an attack occurring at different times (usually 1 month or more apart), and (3) all other possible diagnoses ruled out.

Collaborative Care

Drug Therapy. Because currently there is no cure for MS, collaborative care is aimed at treating the disease process and providing symptomatic relief (see Table 59-14). Since no two cases of MS are alike, therapy is tailored specifically to the disease pattern and manifestations that the patient is experiencing (Table 59-15).

The initial treatment of MS is the use of immunomodulator drugs to modify the disease progression and prevent relapses. These drugs include interferon β-1b (Betaseron) and glatiramer acetate (Copaxone), which are given subcutaneously every other day, and interferon β-1a (Avonex), which is given intramuscularly (IM). Another formulation of interferon β-1a is Rebif, which is administered subcutaneously three times weekly.

DRUG ALERT: β-Interferon (Avonex, Betaseron, Rebif)
- Rotate injection sites with each dose.
- Assess for depression, suicidal ideation.
- Wear sunscreen and protective clothing while exposed to sun.
- Know that flu-like symptoms are common after initiation of therapy.

Fingolimod (Gilenya) reduces MS disease activity by preventing lymphocytes from reaching the CNS and causing damage. Teriflunomide (Aubagio) is an immunomodulatory agent with antiinflammatory properties. The exact mechanism of action is unknown but may involve a reduction in the number of activated lymphocytes in the CNS. Teriflunomide is specifically indicated for treatment of relapsing forms of MS.

For more active and aggressive forms of MS, IV natalizumab (Tysabri) and mitoxantrone (Novantrone) may be used. Natalizumab, a monoclonal antibody, is given monthly when patients have had an inadequate response to other drugs. Natalizumab increases the risk of progressive multifocal leukoencephalopathy, a potentially fatal viral infection of the brain. Mitoxantrone, an antineoplastic medication, has serious effects, including cardiotoxicity, leukemia, and infertility.[17]

TABLE 59-15 DRUG THERAPY

Multiple Sclerosis

Drug	Patient Teaching
Disease-Modifying Drugs	
Immunomodulators	
β-Interferon (Betaseron, Extavia, Avonex, Rebif) glatiramer acetate (Copaxone) teriflunomide (Aubagio)	• Perform self-injection techniques. • Report side effects. • Treat flu-like symptoms with an NSAID or acetaminophen. • Because it may cause serious liver disease, monitor liver tests. • Avoid pregnancy.
Immunosuppressant	
mitoxantrone (Novantrone) dimethyl fumarate (Tecfidera)	• Report side effects. • Avoid pregnancy. • Avoid contact with large crowds and people who have an infection.
Sphingosine 1-Phosphate Receptor Modulator	
fingolimod (Gilenya)	• Report side effects. • Monitor blood pressure regularly. • Avoid pregnancy.
Monoclonal Antibody	
natalizumab (Tysabri)	• Report side effects. • Avoid pregnancy.
Drugs for Managing Exacerbations	
Corticosteroids	
ACTH prednisone methylprednisolone	• Restrict salt intake. • Do not abruptly stop therapy. • Know drug interactions.
Drugs for Symptom Management	
Cholinergics	
bethanechol (Urecholine) neostigmine (Prostigmin)	• Consult with health care provider before using other drugs, including over-the-counter drugs.
Anticholinergics	
propantheline (Pro-Banthine) oxybutynin (Ditropan)	• Consult health care provider before using other drugs, especially sleeping aids, antihistamines (possibly leading to potentiated effect).
Muscle Relaxants	
diazepam (Valium) baclofen (Lioresal) dantrolene (Dantrium) tizanidine (Zanaflex)	• Avoid driving and similar activities because of sedative effects. • Do not abruptly stop therapy. • Avoid use with tranquilizers and alcohol.
Nerve Conduction Enhancer	
dalfampridine (Ampyra)	• Be aware that it may cause seizures, especially at higher doses. • Take the tablet whole. Do not take more than 2 in 24 hr.

ACTH, Adrenocorticotropic hormone.

Dimethyl fumarate (Tecfidera) provides a new approach to treating MS by activating the Nrf2 pathway. This pathway provides a way for cells in the body to defend themselves against the inflammation and oxidative stress caused by MS. Dimethyl fumarate is used to treat relapsing-remitting MS.

Corticosteroids (e.g., methylprednisolone, prednisone) are most helpful to treat acute exacerbations of MS. They work by reducing edema and acute inflammation at the site of demyelin-

FIG. 59-5 Water therapy provides exercise and recreation for the patient with a chronic neurologic disease. (Photos.com/AbleStock.com/Thinkstock.)

ation. However, these drugs do not affect the ultimate outcome or the degree of residual neurologic impairment from the exacerbation.

Many other drugs are used to treat the various symptoms of MS, which may include fatigue, spasticity, tremor, vertigo or dizziness, depression, pain, bowel problems, bladder problems, sexual dysfunction, and cognitive changes. For example, muscle relaxants are used for spasticity. Amantadine (Symmetrel) and CNS stimulants (pemoline [Cylert], methylphenidate [Ritalin], and modafinil [Provigil]) are used to treat fatigue. Anticholinergics are used to treat bladder symptoms. Tricyclic antidepressants and antiseizure drugs are used for chronic pain syndromes. Dalfampridine (Ampyra) is used to improve walking speed in MS patients. It is a selective potassium channel blocker and improves nerve conduction in damaged nerve segments. It should not be used in patients with a history of seizure disorders or in those with moderate to severe kidney disease.

Other Therapies. Spasticity is primarily treated with muscle relaxants. However, surgery (e.g., neurectomy, rhizotomy, cordotomy), dorsal-column electrical stimulation, or intrathecal baclofen (Lioresal) delivered by pump may be required. Tremors that become unmanageable with drugs are sometimes treated by thalamotomy or deep brain stimulation.

Neurologic dysfunction sometimes improves with physical and speech therapies. Exercise improves the daily functioning for patients with MS not experiencing an exacerbation. Exercise decreases spasticity, increases coordination, and retrains unaffected muscles to substitute for impaired ones. An especially beneficial type of physical therapy is water exercise (Fig. 59-5). Water gives buoyancy to the body and allows the patient to perform activities that would normally be impossible because the patient has more control over the body.

NURSING MANAGEMENT MULTIPLE SCLEROSIS

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a patient with MS are presented in Table 59-16.

TABLE 59-16 NURSING ASSESSMENT

Multiple Sclerosis

Subjective Data

Important Health Information

Past health history: Recent or past viral infections or vaccinations, other recent infections, residence in cold or temperate climates, recent physical or emotional stress, pregnancy, exposure to extremes of heat and cold

Medications: Adherence to regimen of corticosteroids, immunomodulators, immunosuppressants, cholinergics, anticholinergics, antispasmodics

Functional Health Patterns

Health perception–health management: Positive family history; malaise

Nutritional-metabolic: Weight loss; difficulty in chewing, dysphagia

Elimination: Urinary frequency, urgency, dribbling or incontinence, retention; constipation

Activity-exercise: Generalized muscle weakness, muscle fatigue; tingling and numbness, ataxia (clumsiness)

Cognitive-perceptual: Eye, back, leg, joint pain; painful muscle spasms; vertigo; blurred or lost vision; diplopia; tinnitus

Sexuality-reproductive: Impotence, decreased libido

Coping–stress tolerance: Anger, depression, euphoria, social isolation

Objective Data

General

Apathy, inattentiveness

Integumentary

Pressure ulcers

Neurologic

Scanning speech, nystagmus, ataxia, tremor, spasticity, hyperreflexia, decreased hearing

Musculoskeletal

Muscle weakness, paresis, paralysis, spasms, foot dragging, dysarthria

Possible Diagnostic Findings

↓ T suppressor cells, demyelinating lesions on MRI or MRS scans, ↑ IgG or oligoclonal banding in cerebrospinal fluid, delayed evoked potential responses

IgG, Immunoglobulin G; *MRS,* magnetic resonance spectroscopy.

NURSING DIAGNOSES

Nursing diagnoses for the patient with MS may include, but are not limited to, the following:

- Impaired physical mobility *related to* muscle weakness or paralysis and muscle spasticity
- Impaired urinary elimination *related to* sensorimotor deficits
- Ineffective self-health management *related to* knowledge deficit regarding management of MS

Additional information on nursing diagnoses for the patient with MS is presented in the eNursing Care Plan 59-3 (available on the website for this chapter).

PLANNING

The overall goals are that the patient with MS will (1) maximize neuromuscular function, (2) maintain independence in activities of daily living for as long as possible, (3) manage disabling fatigue, (4) optimize psychosocial well-being, (5) adjust to the illness, and (6) reduce factors that precipitate exacerbations.

INFORMATICS IN PRACTICE

Phone Applications in Multiple Sclerosis

- Patients with multiple sclerosis (MS), especially those who are newly diagnosed, might feel overwhelmed at the thought of living with a chronic disease and managing multiple medications.
- Smart phone applications can improve the lives of MS patients by helping them manage their health care.
- Applications are available that send medication reminders by text message or e-mail, track injection site rotation, and e-mail medication reports to the health care provider. Patients can keep track of their medication inventory and be reminded to order refills.

NURSING IMPLEMENTATION

The patient with MS should be aware of triggers that may cause exacerbations or worsening of the disease. Exacerbations of MS are triggered by infection (especially upper respiratory and urinary tract infections), trauma, immunization, childbirth, stress, and change in climate. Each person responds differently to these triggers. Assist the patient in identifying particular triggers and develop ways to avoid them or minimize their effects.

During the diagnostic phase the patient needs reassurance that, even though there is a tentative diagnosis of MS, certain diagnostic studies must be done to rule out other neurologic disorders. Assist the patient in dealing with the anxiety caused by a diagnosis of a disabling illness. The patient with recently diagnosed MS may need assistance with the grieving process.

During an acute exacerbation, the patient may be immobile and confined to bed. The focus of nursing interventions at this phase is to prevent major complications of immobility, such as respiratory and urinary tract infections and pressure ulcers.

Focus patient teaching on building general resistance to illness, including avoiding fatigue, extremes of heat and cold, and exposure to infection. Encourage vigorous and early treatment of infection when it does occur. Teach the patient to achieve a good balance of exercise and rest; minimize caffeine intake; and eat nutritious, well-balanced meals. A diet high in roughage may help relieve the problem of constipation. Patients should know their treatment regimens, drug side effects, how to watch for and manage side effects, and drug interactions with over-the-counter medications. The patient should consult a health care provider before taking nonprescription drugs.

Bladder control is a major problem for many patients with MS. Although anticholinergics may be beneficial for some patients to decrease spasticity, you may need to teach others self-catheterization (discussed in Chapter 46 on pp. 1092-1094). Bowel problems, particularly constipation, frequently occur in patients with MS. Increasing the dietary fiber intake may help some patients achieve regularity in bowel habits.

The patient with MS and the caregiver need to make many emotional adjustments because of the unpredictability of the disease, the need to change lifestyles, and the challenge of avoiding or decreasing precipitating factors. The National Multiple Sclerosis Society and its local chapters can offer a variety of services to meet the needs of patients with MS.

EVALUATION

The expected outcomes are that the patient with MS will

- Maintain or improve muscle strength and mobility
- Use assistive devices appropriately for ambulation and mobility
- Maintain urinary continence
- Make decisions about health and lifestyle modifications necessary for management of MS

Additional information on expected outcomes for the patient with MS are presented in eNursing Care Plan 59-3 (available on the website for this chapter).

PARKINSON'S DISEASE

Parkinson's disease (PD) is a chronic, progressive neurodegenerative disorder characterized by slowness in the initiation and execution of movement *(bradykinesia),* increased muscle tone *(rigidity),* tremor at rest, and gait disturbance. It is the most common form of *parkinsonism* (a syndrome characterized by similar symptoms).

The prevalence of PD is about 160 per 100,000. The diagnosis of PD increases with age, with the condition affecting about 2% of people over 60 years old. However, as many as 15% of those diagnosed with PD are less than 50 years old. PD is more common in men by a ratio of 3:2.[18]

Etiology and Pathophysiology

Although the exact cause of PD is unknown, a complex interplay of environmental and genetic factors is involved. Between 10% and 15% of PD patients have a family history of the disease, indicating a strong genetic basis. In other persons, exposure to toxins or certain viruses may trigger PD.[18]

There are many forms of parkinsonism other than PD. Parkinsonism-like symptoms have occurred after intoxication with a variety of chemicals, including carbon monoxide and manganese (among copper miners) and the product of meperidine analog synthesis, MPTP. Drug-induced parkinsonism can follow therapy with metoclopramide (Reglan), reserpine (Serpasil), methyldopa (Aldomet), lithium, haloperidol (Haldol), and chlorpromazine (Thorazine). Parkinsonism can also be seen after the use of illicit drugs, including amphetamine and methamphetamine. Other causes of parkinsonism include hydrocephalus, MS, encephalitis, infections, stroke, tumor, Huntington's disease, and trauma.[19]

Many changes found in the brains of people with PD may play a role in development of the disease, including a lack of dopamine (DA). The pathologic process of PD involves degeneration of the DA-producing neurons in the substantia nigra of the midbrain (Figs. 59-6 to 59-8), which in turn disrupts the normal balance between DA and acetylcholine (ACh) in the basal ganglia. DA is a neurotransmitter essential for normal functioning of the extrapyramidal motor system, including control of posture, support, and voluntary motion. Manifestations of PD do not occur until 80% of neurons in the substantia nigra are lost.

Lewy bodies, unusual clumps of protein, are found in the brains of patients with PD. It is not known what causes these bodies to form, but their presence indicates abnormal functioning of the brain. Lewy body dementia is discussed in Chapter 60.

Genetic Link

Approximately 20% of PD patients have a family history of PD. Many autosomal dominant and recessive genes have been linked to familial PD. The most common genetic contributor to PD is the *LRRK2* gene. Mutations in this gene also appear to have a role in sporadic, or noninherited, cases of PD. *LRRK2*

and mutations in another gene, α-synuclein *(SNCA),* have manifestations similar to those of the common, age-related PD. Other genes involved in familial PD are parkin *(PARK2), DJ-1,* and *PINK1.* Mutations in these genes are often associated with a younger age of onset and have additional manifestations than those typically seen with age-related PD. *PINK1* mutations are related to a rare, early-onset form of PD.[18,20,21]

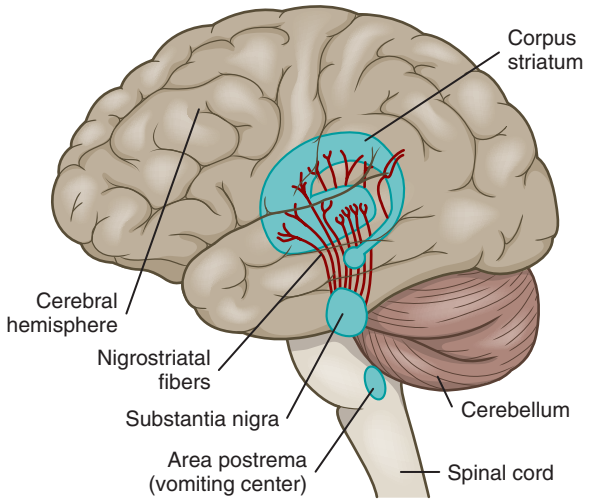

FIG. 59-6 Nigrostriatal disorders produce parkinsonism. Left-sided view of the human brain showing the substantia nigra and the corpus striatum *(shaded area)* lying deep within the cerebral hemisphere. Nerve fibers extend upward from the substantia nigra, divide into many branches, and carry dopamine to all regions of the corpus striatum.

Clinical Manifestations

The onset of PD is gradual and insidious, with an ongoing progression. It may involve only one side of the body initially. The classic manifestations of PD are a triad of tremor, rigidity, and bradykinesia. In the beginning stages, only a mild tremor, a slight limp, or a decreased arm swing may be evident. Later in the disease the patient may have a shuffling, propulsive gait with arms flexed and loss of postural reflexes. Some patients have a slight change in speech patterns. None of these manifestations alone is sufficient evidence for a diagnosis of the disease.

Tremor. *Tremor,* often the first sign, may be minimal initially, so the patient is the only one who notices it. This tremor can affect handwriting, causing it to trail off, particularly toward the ends of words. Parkinsonian tremor is more prominent at

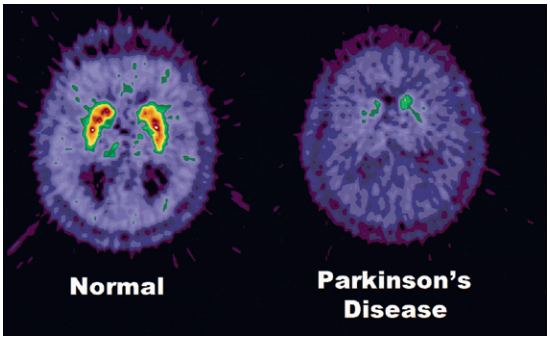

FIG. 59-8 In Parkinson's disease, positron emission tomography (PET) scan showing reduced fluorodopa uptake in the basal ganglia *(right)* compared with a normal control *(left).*

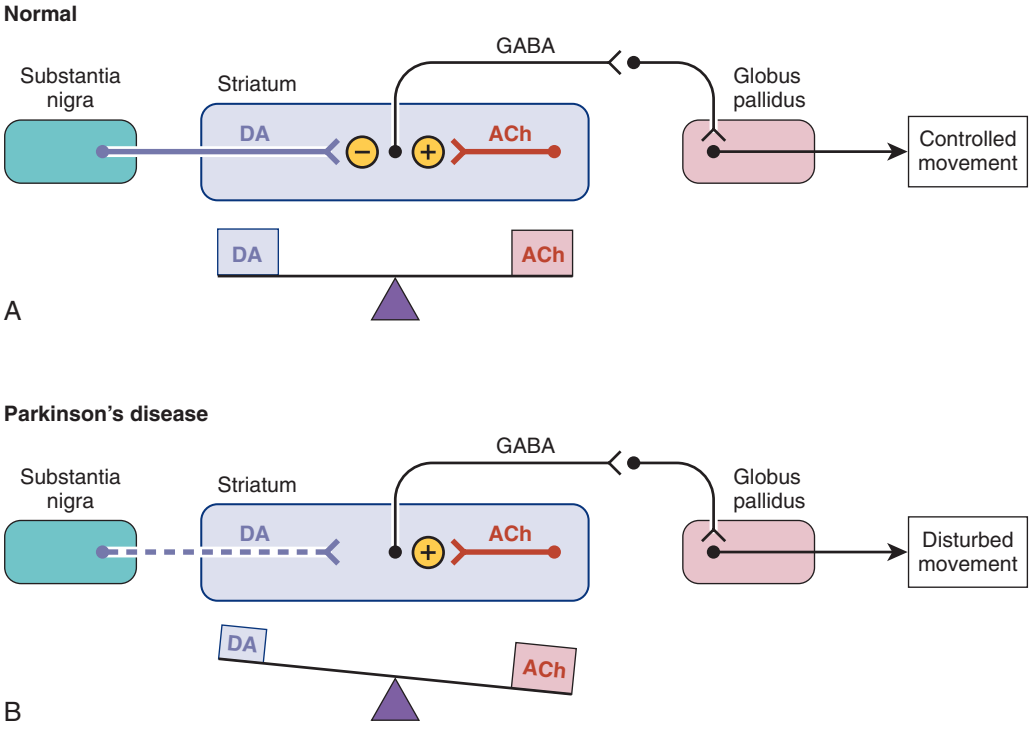

FIG. 59-7 In Parkinson's disease there is a deficit in dopamine. These deficits create an imbalance between dopamine and the excitatory neurotransmitter acetylcholine. **A,** In a healthy person, dopamine *(DA)* released from neurons originating in the substantia nigra inhibits the firing of neurons in the striatum that release γ-aminobutyric acid *(GABA).* Conversely, neurons located within the striatum, which release acetylcholine *(ACh),* excite the GABAergic neurons. Under normal conditions, the inhibitory actions of DA are balanced by the excitatory actions of ACh, and controlled movement results. **B,** In Parkinson's disease, the neurons in the substantia nigra that supply DA to the striatum degenerate. When there is a deficit of DA, the excitatory effects of ACh go unopposed, resulting in disturbed movements (tremor, rigidity).

rest and is aggravated by emotional stress or increased concentration. The hand tremor is described as "pill rolling" because the thumb and forefinger appear to move in a rotary fashion as if rolling a pill, coin, or other small object. Tremor can also involve the diaphragm, tongue, lips, and jaw but rarely causes shaking of the head.

Unfortunately, in many people a benign essential tremor is mistakenly diagnosed as PD. Essential tremor occurs during voluntary movement, has a more rapid frequency than parkinsonian tremor, and is often familial.

Rigidity. *Rigidity,* the second sign of the triad, is the increased resistance to passive motion when the limbs are moved through their range of motion. Parkinsonian rigidity is typified by cogwheel rigidity, or a jerky quality, as if there were intermittent catches in the movement of a cogwheel, when the joint is moved passively. Sustained muscle contraction causes the rigidity and consequently elicits complaints of muscle soreness; feeling tired and achy; or pain in the head, the upper body, the spine, or the legs. Another consequence of rigidity is slowness of movement because it inhibits the alternating of contraction and relaxation in opposing muscle groups (e.g., biceps and triceps).

Bradykinesia. *Bradykinesia* is particularly evident in the loss of automatic movements, which is secondary to the physical and chemical alteration of the basal ganglia and related structures in the extrapyramidal portion of the CNS. In the unaffected patient, automatic movements are involuntary and occur subconsciously. They include blinking of the eyelids, swinging of the arms while walking, swallowing of saliva, self-expression with facial and hand movements, and minor movement of postural adjustment.

The patient with PD does not execute these movements and lacks spontaneous activity. This accounts for the stooped posture, masked face (deadpan expression), drooling of saliva, and shuffling gait *(festination)* that are characteristic of a person with this disease. The posture is that of a slowed "old man" image, with the head and trunk bent forward and the legs constantly flexed (Fig. 59-9).

Postural instability is common. Patients may complain of being unable to stop themselves from going forward (propulsion) or backward (retropulsion). Assessment of postural instability includes the "pull test," in which the examiner stands behind the patient and gives a tug backward on the shoulder, causing the patient to lose his or her balance and fall backward.

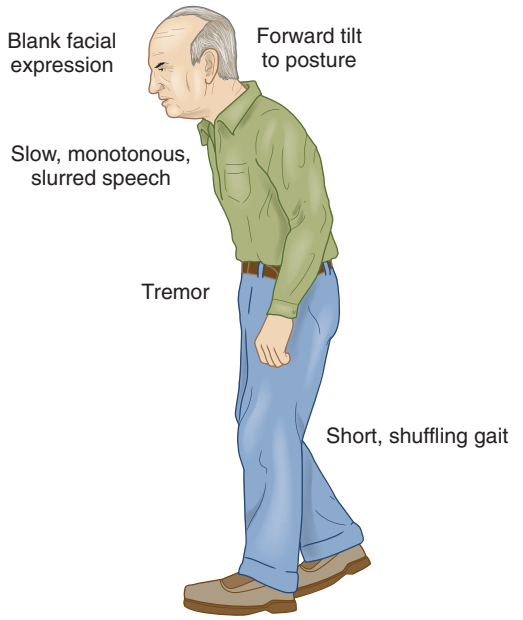

FIG. 59-9 Characteristic appearance of a patient with Parkinson's disease.

In addition to the motor signs of PD, many nonmotor symptoms are common. They include depression, anxiety, apathy, fatigue, pain, constipation, impotence, and short-term memory impairment. Sleep problems are common in patients with PD and include difficulty staying asleep at night, restless sleep, nightmares, and drowsiness or sudden sleep onset during the day.[18]

Complications

As the disease progresses, complications increase. These include motor symptoms (e.g., dyskinesias [spontaneous, involuntary movements], weakness, *akinesia* [total immobility]), neurologic problems (e.g., dementia), and neuropsychiatric problems (e.g., depression, hallucinations, psychosis). As PD progresses, it often results in a severe dementia, which is associated with an increase in mortality.

As swallowing becomes more difficult (dysphagia), malnutrition or aspiration may result. General debilitation may lead to pneumonia, urinary tract infections, and skin breakdown. Orthostatic hypotension may occur in some patients and, along with loss of postural reflexes, may result in falls or other injury.[22]

Diagnostic Studies

Because there is no specific diagnostic test for PD, the diagnosis is based on the history and the clinical features. A firm diagnosis can be made only when at least two of the three signs of the classic triad are present: tremor, rigidity, and bradykinesia. The ultimate confirmation of PD is a positive response to antiparkinsonian drugs. Research is ongoing regarding the role of genetic testing and MRI in diagnosing patients with PD.[23]

Collaborative Care

Because PD has no cure, collaborative care focuses on relieving the symptoms (Table 59-17).

Drug Therapy. Drug therapy for PD is aimed at correcting the imbalance of neurotransmitters within the CNS. Antiparkinsonian drugs either enhance the release or the supply of DA (dopaminergic) or antagonize or block the effects of the overactive cholinergic neurons in the striatum (anticholinergic) (see Fig. 59-7). Levodopa with carbidopa (Sinemet) is often the first drug used. Levodopa is a chemical precursor of DA and can

TABLE 59-17 COLLABORATIVE CARE

Parkinson's Disease

Diagnostic
- History and physical examination
- Tremor, rigidity, and bradykinesia
- Positive response to antiparkinsonian drugs
- MRI
- Rule out side effects of phenothiazines, reserpine, benzodiazepines, haloperidol

Collaborative Therapy
- Antiparkinsonian drugs (see Table 59-18)
- Deep brain stimulation
- Ablation surgery

cross the blood-brain barrier. It is converted to DA in the basal ganglia. Sinemet is the preferred drug because it also contains carbidopa, an agent that inhibits the enzyme dopa-decarboxylase in the peripheral tissues. Dopa-decarboxylase breaks down levodopa before it reaches the brain. The net result of the combination of levodopa and carbidopa is that more levodopa reaches the brain, and therefore less drug is needed. Levodopa has many side effects and drug interactions. Prolonged use can often result in dyskinesias and "off/on" periods when the medication will unpredictably start or stop working.

DRUG ALERT: Carbidopa/Levodopa (Sinemet)

- Monitor for signs of dyskinesia.
- Effects may be delayed for several weeks to months.
- Instruct patient or caregiver to report any uncontrolled movement of face, eyelids, mouth, tongue, arms, hands, or legs; mental changes; palpitations; severe nausea and vomiting; and difficulty urinating.

Many patients are given Sinemet early in the disease course. It is effective for the management of akinetic symptoms. Tremor and rigidity may also respond to this drug.[21] However, some health care providers believe that, after a few years of therapy, the effectiveness of Sinemet wears off. Therefore they prefer to initiate therapy with a DA receptor agonist. These drugs include bromocriptine (Parlodel), pergolide (Permax), ropinirole (Requip), pramipexole (Mirapex), and rotigotine (Neupro). These drugs directly stimulate DA receptors. Sinemet is then added to the drug regimen when more moderate to severe symptoms are present.

DRUG ALERT: Bromocriptine (Parlodel)

- Patient may become dizzy or faint due to orthostatic hypotension, especially after the first dose.
- Notify physician immediately if a severe headache develops that does not let up or continues to get worse.

Selegiline (Eldepryl) and rasagiline (Azilect), monoamine oxidase type B (MAO-B) inhibitors, are sometimes used in combination with Sinemet. By inhibiting MAO-B, the degradative enzyme for DA, these agents increase the levels of DA and prolong the half-life of levodopa. Rasagiline can also be used alone as therapy in early PD.

Entacapone (Comtan) and tolcapone (Tasmar) block the enzyme catechol *O*-methyltransferase (COMT), which breaks down levodopa in the peripheral circulation, thus prolonging the effect of Sinemet. These drugs are used only as adjuncts to levodopa.[18]

Anticholinergic drugs such as trihexyphenidyl (Artane) and benztropine (Cogentin) are also used to manage PD. These drugs decrease the activity of ACh, thus providing balance between cholinergic and dopaminergic actions. Antihistamines (e.g., diphenhydramine [Benadryl]) with anticholinergic properties may be used to manage tremors.

The antiviral agent amantadine is also an effective antiparkinsonian drug. Although its exact mechanism of action is not known, amantadine promotes the effect of DA.[18] Rivastigmine (Exelon) or donepezil (Aricept) is used to treat mild to moderate Parkinson's dementia. Amitriptyline may be used to treat depression.

Table 59-18 summarizes the drugs commonly used in PD. The use of only one drug is preferred because fewer side effects occur and the drug dosage is easier to adjust than when several drugs are used. However, as the disease progresses, combination therapy is often required. Excessive amounts of dopaminergic drugs can lead to *paradoxic intoxication* (aggravation rather than relief of symptoms).

TABLE 59-18 DRUG THERAPY

Parkinson's Disease

Drug	Mechanism of Action
Dopaminergics	
Dopamine Precursors	
levodopa (L-dopa)	Converted to dopamine in basal ganglia
levodopa/carbidopa (Sinemet, Parcopa [orally dissolving tablet])	
Dopamine Receptor Agonists	
bromocriptine (Parlodel)	Stimulate dopamine receptors
pergolide (Permax)	
pramipexole (Mirapex)	
ropinirole (Requip, Requip XL)	
rotigotine (Neupro [skin patch])	
Dopamine Agonists	
amantadine (Symmetrel)	Blocks reuptake of dopamine into presynaptic neurons
apomorphine (Apokyn)	Stimulates postsynaptic dopamine receptors
Anticholinergics	
trihexyphenidyl (Artane)	Block cholinergic receptors, thus helping to balance cholinergic and dopaminergic activity
benztropine (Cogentin)	
biperiden (Akineton)	
Antihistamine	
diphenhydramine (Benadryl)	Has anticholinergic effect
Monoamine Oxidase Inhibitors	
selegiline (Eldepryl, Carbex)	Block breakdown of dopamine
rasagiline (Azilect)	
Catechol *O*-Methyltransferase (COMT) Inhibitors	
entacapone (Comtan)	Block COMT and slow the breakdown of levodopa, thus prolonging the action of levodopa
tolcapone (Tasmar)	

Within 3 to 5 years of standard Parkinson's drug treatments, many patients experience episodes of hypomobility (e.g., inability to rise from chair, to speak, or to walk). The episodes can occur toward the end of a dosing interval with standard medications (so-called end-of-dose wearing off) or at unpredictable times (spontaneous "on/off").

A combination of carbidopa, levodopa, and entacapone (Stalevo) is available for patients with end-of-dose wearing off. Apomorphine (Apokyn) can also be used to treat Parkinson's patients during these episodes of "hypomobility," or "off periods," in which the patient becomes immobile or unable to perform activities of daily living. Apomorphine, which is given by a subcutaneous injection, needs to be taken with an antiemetic drug (e.g., trimethobenzamide [Tigan]) because, when taken alone, it causes severe nausea and vomiting. It must not be taken with the antiemetics in the serotonin (5-HT3) receptor antagonist class (e.g., ondansetron [Zofran]) because the combination of apomorphine and these drugs can lead to very low blood pressure and loss of consciousness.

Surgical Therapy. Surgical procedures are aimed at relieving symptoms of PD and are usually used in patients who are unresponsive to drug therapy or who have developed severe motor complications. Surgical procedures fall into three categories: deep brain stimulation (DBS), ablation (destruction), and transplantation. Today, the most common surgical treatment is

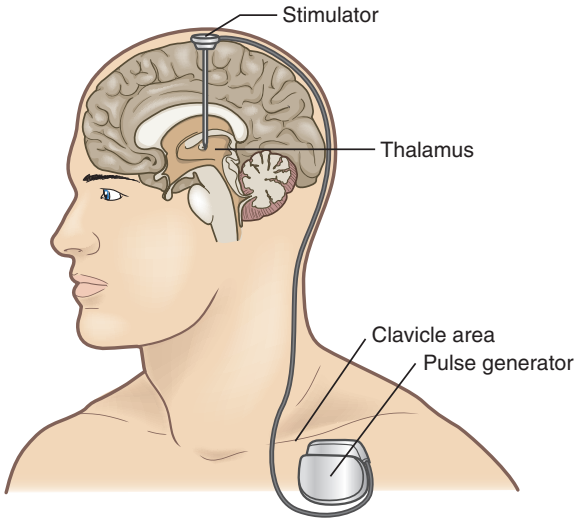

FIG. 59-10 A deep brain stimulator can be used to treat the tremors and uncontrolled movements in Parkinson's disease. Electrodes are surgically placed in the brain and connected to a neurostimulator (pacemaker device) in the chest.

DBS. DBS involves placing an electrode in either the thalamus, globus pallidus, or subthalamic nucleus and connecting it to a generator placed in the upper chest (like a pacemaker) (Fig. 59-10). The device is programmed to deliver a specific current to the targeted brain location. Unlike ablation procedures, DBS can be adjusted to control symptoms better and is reversible (the device can be removed). These ablative and DBS procedures work by reducing the increased neuronal activity produced by DA depletion. DBS has been shown to improve motor function and reduce dyskinesia and medication usage.[18]

Ablation surgery involves stereotactic ablation of areas in the thalamus *(thalamotomy)*, globus pallidus *(pallidotomy)*, and subthalamic nucleus *(subthalamic nucleotomy)*. *Transplantation* of fetal neural tissue into the basal ganglia is designed to provide DA-producing cells in the brains of patients with PD. This form of therapy is still in the experimental stages.

Nutritional Therapy. Diet is of major importance to the patient with PD because malnutrition and constipation can be serious consequences of inadequate nutrition. Patients who have dysphagia and bradykinesia need appetizing foods that are easily chewed and swallowed. The diet should contain adequate roughage and fruit to avoid constipation. Cut food into bite-sized pieces before it is served, and serve it on a warmed plate to preserve its appeal.

Eating six small meals a day may be less exhausting than eating three large meals a day. Plan ample time for eating to avoid frustration. The absorption of levodopa can be impaired by protein ingestion and vitamin B_6. Therefore some patients are advised to limit their protein intake to the evening meal to decrease this problem. They also need to consult with their health care provider regarding the possible supplementation of vitamin B_6 in their multivitamins and fortified cereals.

NURSING MANAGEMENT PARKINSON'S DISEASE

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a patient with PD are presented in Table 59-19.

TABLE 59-19 NURSING ASSESSMENT

Parkinson's Disease

Subjective Data

Important Health Information

Past health history: Central nervous system trauma, cerebrovascular disorders, exposure to metals and carbon monoxide, encephalitis

Medications: Major tranquilizers, especially haloperidol (Haldol), and phenothiazines, reserpine, methyldopa, amphetamines

Functional Health Patterns

Health perception–health management: Fatigue

Nutritional-metabolic: Excessive salivation, dysphagia; weight loss

Elimination: Constipation, incontinence; excessive sweating

Activity-exercise: Difficulty in initiating movements; frequent falls; loss of dexterity; micrographia (handwriting deterioration)

Sleep-rest: Insomnia, nightmares, daytime sleepiness

Cognitive-perceptual: Diffuse pain in head, shoulders, neck, back, legs, and hips; muscle soreness and cramping

Self-perception–self-concept: Depression; mood swings, hallucinations

Objective Data

General

Blank (masked) faces, slow and monotonous speech, infrequent blinking

Integumentary

Seborrhea, dandruff; ankle edema

Cardiovascular

Postural hypotension

Gastrointestinal

Drooling

Neurologic

Tremor at rest, first in hands (pill rolling), later in legs, arms, face, and tongue; aggravation of tremor with anxiety, absence in sleep; poor coordination; subtle dementia, impaired postural reflexes

Musculoskeletal

Cogwheel rigidity, dysarthria, bradykinesia, contractures, stooped posture, shuffling gait

Possible Diagnostic Findings

No specific tests; diagnosis on basis of history and physical findings and ruling out of other diseases

NURSING DIAGNOSES

Nursing diagnoses for the patient with PD may include, but are not limited to, the following:

- Impaired physical mobility *related to* rigidity, bradykinesia, and akinesia
- Imbalanced nutrition: less than body requirements *related to* inability to ingest food
- Impaired swallowing *related to* neuromuscular impairment (e.g., decreased or absent gag reflex)
- Impaired verbal communication *related to* dysarthria, tremor, and bradykinesia

Additional information on nursing diagnoses for the patient with PD is presented in eNursing Care Plan 59-4 (available on the website for this chapter).

PLANNING

The overall goals are that the patient with PD will (1) maximize neurologic function, (2) maintain independence in activities of

daily living for as long as possible, and (3) optimize psychosocial well-being.

NURSING IMPLEMENTATION

Because PD is a chronic degenerative disorder with no acute exacerbations, teaching and nursing care are directed toward maintenance of good health, encouragement of independence, and avoidance of complications such as contractures and falls. Problems secondary to bradykinesia can be alleviated by relatively simple measures.

Promotion of physical exercise and a well-balanced diet are major concerns for nursing care. Exercise can limit the consequences of decreased mobility, such as muscle atrophy, contractures, and constipation. The American Parkinson Disease Association (see Resources at the end of this chapter) publishes a series of booklets and videotapes with helpful exercises that can be used by family members and health care professionals.

A physical therapist may be consulted to design a personal exercise program aimed at strengthening and stretching specific muscles. Overall muscle tone and specific exercises to strengthen the muscles involved with speaking and swallowing should be included. Although exercise will not halt the progress of the disease, it will enhance the patient's functional ability. An occupational therapist can also assist the patient with strategies to increase self-care measures, including eating and dressing.

SAFETY ALERT

- Have patients who are at risk for falling and tend to "freeze" while walking do the following:
  - Consciously think about stepping over imaginary or real lines on the floor.
  - Drop rice kernels and step over them.
  - Rock from side to side.
  - Lift the toes when stepping.
  - Take one step backward and two steps forward.

Work closely with the patient's caregiver and family in exploring creative adaptations that allow maximum independence and self-care. The patient can facilitate getting out of a chair by using an upright chair with arms and placing the back legs of the chair on small (2-in) blocks. Encourage environmental alterations, such as removing rugs and excess furniture to avoid stumbling, using an elevated toilet seat to facilitate getting on and off the toilet, and elevating the legs on an ottoman to decrease dependent ankle edema. Clothing can be simplified by the use of slip-on shoes and Velcro hook-and-loop fasteners or zippers on clothing, instead of buttons and hooks.

Effective management of sleep problems can greatly improve the quality of life for patients with PD. Some PD patients find the use of satin nightwear or satin sheets beneficial. Information on teaching regarding sleep hygiene practices is presented in Chapter 8.

In the early stages of PD, many patients experience depression and anxiety. Patients need to adjust their lifestyle, including work and home responsibilities. As the disease progresses, the impact on the patient's psychologic well-being also increases. Assist the patient by listening, providing teaching, challenging distorted thoughts, and encouraging social interactions. Psychologic therapy and counseling can be helpful.

In the early stage of the disease, the patient has subtle changes in cognitive function, which can progress to dementia. This results in increased caregiver burden and the potential for long-term care placement. Information on care of the patient with dementia is provided in Chapter 60.

Family caregivers (e.g., spouse, children) care for the majority of patients with PD. As the disease progresses, the caregiver burden increases, often while the caregiver's physical and mental health decline. Strategies to reduce caregiver burden are described in Chapter 4. Other interventions for the patient with PD are presented in eNursing Care Plan 59-4 (available on the website for this chapter).

EVALUATION

The expected outcomes are that the patient with PD will

- Perform physical exercise to deter muscle atrophy and joint contractures
- Use assistive devices appropriately for ambulation and mobility
- Maintain nutritional intake adequate for metabolic needs
- Experience safe passage of fluids and/or solids from the mouth to the stomach
- Use methods of communication that meet needs for interaction with others

Additional information on expected outcomes for the patient with PD are presented in eNursing Care Plan 59-4 (available on the website).

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is an autoimmune disease of the neuromuscular junction characterized by the fluctuating weakness of certain skeletal muscle groups. MG occurs in either gender and in persons of any ethnicity. The prevalence rate is 20 per 100,000; currently about 60,000 people have MG in the United States.[24] The peak age at onset in women is during the childbearing years; in men the peak onset of MG is between the ages of 50 and 70 years. However, it does occur in men and women outside of these age ranges.

Etiology and Pathophysiology

MG is caused by an autoimmune process in which antibodies attack acetylcholine (ACh) receptors, resulting in a decreased number of ACh receptor (AChR) sites at the neuromuscular junction. This prevents ACh molecules from attaching and stimulating muscle contraction. Anti-AChR antibodies are detectable in the serum of 90% of patients with generalized MG. In the 10% of patients who lack autoantibodies to AChR, their muscular weakness may be related to autoantibodies to muscle-specific receptor tyrosine kinase, although other autoantibodies may be involved.[25] Thymic tumors are found in about 15% of patients, and abnormal thymus tissue is found in most others.

Clinical Manifestations and Complications

The primary feature of MG is fluctuating weakness of skeletal muscle. The muscles most often involved are those used for moving the eyes and eyelids, chewing, swallowing, speaking, and breathing. These muscles are generally the strongest in the morning and become exhausted with continued activity. A period of rest usually restores strength. Consequently, by the end of the day, muscle weakness is prominent.

In 90% of cases the eyelid muscles or extraocular muscles are involved (Fig. 59-11). Facial mobility and expression can be impaired. The patient may have difficulty chewing and swallowing food. Speech is affected, and the voice often fades after a long conversation. The muscles of the trunk and limbs are less often affected. Of these, the proximal muscles of the neck,

FIG. 59-11 "Peek" sign in myasthenia gravis. During sustained forced eyelid closure he is unable to bury his eyelashes *(left)* and, after 30 sec, he is unable to keep the lids fully closed *(right)*.

shoulder, and hip are more often affected than the distal muscles. No other signs of neural disorder accompany MG. There is no sensory loss, reflexes are normal, and muscle atrophy is rare.

The course of this disease is highly variable. Some patients may have short-term remissions, others may stabilize, and others may have severe, progressive involvement.[24] Exacerbations of MG can be precipitated by emotional stress, pregnancy, menses, another illness, trauma, temperature extremes, and hypokalemia. Ingestion of drugs, including aminoglycoside antibiotics, β-adrenergic blockers, procainamide, quinidine, and phenytoin, can aggravate MG. Psychotropic drugs (e.g., lithium carbonate, phenothiazines, benzodiazepines, tricyclic antidepressants) have also been associated with worsening of myasthenia, as have neuromuscular blocking agents (tubocurarine chloride, pancuronium, succinylcholine [Anectine]).

Myasthenic crisis is an acute exacerbation of muscle weakness triggered by infection, surgery, emotional distress, drug overdose, or inadequate drugs. The major complications of MG result from muscle weakness in areas that affect swallowing and breathing. This results in aspiration, respiratory insufficiency, and respiratory tract infection.

Diagnostic Studies

The diagnosis of MG can be made based on history and physical examination. However, other tests may be used if the diagnosis is still in doubt. EMG may show a decreased response to repeated stimulation of the hand muscles, indicative of muscle fatigue. Single-fiber EMG is sensitive in confirming the diagnosis of MG. Use of drugs may also aid in the diagnosis.

The Tensilon test in a patient with MG reveals improved muscle contractility after IV injection of the anticholinesterase agent edrophonium chloride (Tensilon). (Anticholinesterase blocks the enzyme acetylcholinesterase.) This test also aids in the diagnosis of cholinergic crisis (secondary to overdose of anticholinesterase drug), which occurs when there is too much cholinesterase inhibition. Clinical features include muscle fasciculation, sweating, excessive salivation, and constricted pupils. In this condition, Tensilon does not improve muscle weakness but may actually increase it. Atropine, a cholinergic antagonist, should be readily available to counteract the effects of Tensilon when it is used diagnostically. In patients with a confirmed diagnosis of MG, a chest CT scan may be done to evaluate the thymus.

Collaborative Care

Drug Therapy. Drug therapy for MG includes anticholinesterase drugs, alternate-day corticosteroids, and immunosuppressants (Table 59-20). Anticholinesterase drugs are aimed at enhancing function of the neuromuscular junction. Acetylcholinesterase is the enzyme that breaks down ACh. Thus inhibition of this enzyme by an anticholinesterase inhibitor will prolong the action of ACh and facilitate transmission of impulses at the neuromuscular junction. Pyridostigmine (Mestinon) is the most successful drug of this group in long-term treatment of MG.

Tailoring the dose to avoid a myasthenic or cholinergic crisis often presents a clinical challenge. Corticosteroids (specifically prednisone) are used to suppress the immune response. Drugs such as azathioprine (Imuran), mycophenolate (CellCept), and cyclosporine (Sandimmune) may also be used for immunosuppression.

Many drugs are contraindicated or must be used with caution in patients with MG. Classes of drugs that should be cautiously evaluated before use include anesthetics, antidysrhythmics, antibiotics, quinine, antipsychotics, barbiturates and sedative-hypnotics, cathartics, diuretics, opioids, muscle relaxants, thyroid preparations, and tranquilizers.

Surgical Therapy. Because the presence of the thymus gland in the patient with MG appears to enhance the production of AChR antibodies, removal of the thymus gland results in improvement in a majority of patients. Thymectomy is indicated for almost all patients with thymoma, for patients with generalized MG between the ages of puberty and about 65 years, and for patients with purely ocular MG.

Other Therapies. Plasmapheresis and IV immunoglobulin G can yield a short-term improvement in symptoms and are indicated for patients in myasthenic crisis or in preparation for surgery when corticosteroids must be avoided. Plasmapheresis directly removes circulating AChR antibodies, leading to a decrease in symptoms. (Plasmapheresis is discussed in Chapter 14.) It is not certain how IV immunoglobulin works, but it is probably related to a decrease in antibody production.[24]

TABLE 59-20 COLLABORATIVE CARE

Myasthenia Gravis

Diagnostic	Collaborative Therapy
• History and physical examination • Fatigability with prolonged upward gaze (2-3 min) • Muscle weakness • EMG • Tensilon test • Acetylcholine receptor antibodies • Chest x-ray	• Drugs • Anticholinesterase agents • Corticosteroids • Immunosuppressive agents • Surgery (thymectomy) • Plasmapheresis • IV immunoglobulin G

EMG, Electromyography.

NURSING MANAGEMENT MYASTHENIA GRAVIS

NURSING ASSESSMENT

Assess the severity of MG by asking the patient about fatigability, what body parts are affected, and how severely they are affected. Assess the patient's coping abilities and strategies and understanding of the disorder. Some patients become so fatigued that they are no longer able to work or even walk.

Objective data should include respiratory rate and depth, oxygen saturation, arterial blood gas analyses, pulmonary function tests, and evidence of respiratory distress in patients with acute myasthenic crisis. Assess muscle strength of all face and limb muscles, swallowing, speech (volume and clarity), and cough and gag reflexes.

NURSING DIAGNOSES

Nursing diagnoses for the patient with MG may include, but are not limited to, the following.

- Ineffective airway clearance *related to* intercostal muscle weakness and impaired cough and gag reflex
- Impaired verbal communication *related to* weakness of the larynx, lips, mouth, pharynx, and jaw
- Activity intolerance *related to* muscle weakness and fatigability
- Disturbed body image *related to* inability to maintain usual lifestyle and role responsibilities

PLANNING

The overall goals are that the patient with MG will (1) have a return of normal muscle endurance, (2) manage fatigue, (3) avoid complications, and (4) maintain a quality of life appropriate to the disease course.

NURSING IMPLEMENTATION

The patient with MG who is admitted to the hospital usually has a respiratory tract infection or is in an acute myasthenic crisis. Nursing care is aimed at maintaining adequate ventilation, continuing drug therapy, and watching for side effects of therapy. Be able to distinguish cholinergic from myasthenic crisis (Table 59-21) because the causes and treatment of the two conditions differ greatly.

As with other chronic illnesses, focus care on the neurologic deficits and their impact on daily living. Teach the patient about a balanced diet that can easily be chewed and swallowed. Semisolid foods may be easier to eat than solids or liquids. Scheduling doses of drugs so that peak action is reached at mealtime may make eating less difficult. Arrange diversional activities that require little physical effort and match the patient's interests. Help the patient plan activities of daily living to avoid fatigue. Teaching should focus on the importance of following the medical regimen, complications of the disease, potential adverse reactions to specific drugs, and complications of therapy (crisis conditions) and what to do about them. Explore community resources such as the Myasthenia Gravis Foundation of America and MG support groups.

TABLE 59-21 COMPARISON OF MYASTHENIC AND CHOLINERGIC CRISES

Myasthenic Crisis	Cholinergic Crisis
Causes	
Exacerbation of myasthenia following precipitating factors or failure to take drug as prescribed or drug dose too low	Overdose of anticholinesterase drugs resulting in increased ACh at the receptor sites, remission (spontaneous or after thymectomy)
Differential Diagnosis	
Improved strength after IV administration of anticholinesterase drugs	Weakness within 1 hr after ingestion of anticholinesterase
Increased weakness of skeletal muscles manifesting as ptosis, bulbar signs (e.g., difficulty swallowing, difficulty articulating words), or dyspnea	Increased weakness of skeletal muscles manifesting as ptosis, bulbar signs, dyspnea Effects on smooth muscle include pupillary miosis, salivation, diarrhea, nausea or vomiting, abdominal cramps, increased bronchial secretions, sweating, or lacrimation

ACh, Acetylcholine.

EVALUATION

The expected outcomes are that the patient with MG will

- Maintain optimal muscle function
- Be free from side effects of drugs
- Not experience complications (myasthenic or cholinergic crises) from the disease
- Maintain a quality of life appropriate to the disease course

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS) is a rare progressive neurologic disorder characterized by loss of motor neurons. ALS usually leads to death 2 to 6 years after diagnosis, but a few patients may survive for more than 10 years.[26] This disease became known as Lou Gehrig's disease after the famous baseball player was stricken with it in 1939. The onset is usually between 40 and 70 years of age. ALS is more common in men than women by a ratio of 2:1. Approximately 5000 people in the United States are diagnosed with ALS every year.[26]

For unknown reasons, in ALS motor neurons in the brainstem and the spinal cord gradually degenerate (see eFig. 59-1 available on the website for this chapter). Dead motor neurons cannot produce or transport signals to muscles. Consequently, electrical and chemical messages originating in the brain do not reach the muscles to activate them.

The typical symptoms of ALS are limb weakness, dysarthria, and dysphagia. Muscle wasting and fasciculations result from the denervation of the muscles and lack of stimulation and use. Other symptoms include pain, sleep disorders, spasticity, drooling, emotional lability, depression, constipation, and esophageal reflux.[26] Death usually results from respiratory tract infection secondary to compromised respiratory function.

Unfortunately, there is no cure for ALS. Riluzole (Rilutek) slows the progression of ALS. This drug works to decrease the amount of glutamate (an excitatory neurotransmitter) in the brain.

The illness trajectory for ALS is devastating because the patient remains cognitively intact while wasting away. Guide the patient in the use of moderate-intensity, endurance-type exercises for the trunk and limbs, since this may help reduce ALS spasticity. Nursing interventions include (1) facilitating communication, (2) reducing risk of aspiration, (3) facilitating early identification of respiratory insufficiency, (4) decreasing pain secondary to muscle weakness, (5) decreasing risk of injury related to falls, and (6) providing diversional activities such as reading and companionship,

Support the patient's cognitive and emotional functions. Help the patient and family manage the disease process, including grieving related to the loss of motor function and ultimately death. Discuss with the patient and caregiver issues such as artificial methods of ventilation and advance directives.

GENETICS IN CLINICAL PRACTICE

Huntington's Disease (HD)

Genetic Basis
- Autosomal dominant disorder.
- Caused by mutation in *HTT* gene located on chromosome 4.

Incidence
- 1 in 10,000.
- Higher incidence in people of European ancestry.
- With each pregnancy a heterozygous affected parent has a 5% chance of having a child with HD.

Genetic Testing
- DNA testing is available.
- DNA testing can be done on fetal cells obtained by amniocentesis or chorionic villus sampling.
- Preimplantation genetic diagnosis can be done on embryos before implantation and pregnancy.
- One copy of altered gene is sufficient to cause HD.
- No test is available to predict when symptoms will develop.

Clinical Implications
- HD is a progressive, degenerative brain disorder.
- Onset of disease usually occurs at 30–50 yr of age. No cure is available.
- Drugs are available to control movements and behavioral problems.
- Genetic counseling may be considered if there is a family history of HD.
- Because HD is an autosomal dominant disorder, individuals who are at risk have a strong motivation to seek genetic testing.
- A positive result is not considered a diagnosis, since it may be obtained decades before the symptoms begin.
- A negative test means that the individual does not carry the mutated gene and will not develop HD.

INFORMATICS IN PRACTICE

Social Networking in Huntington's Disease

- Many patients with Huntington's disease experience social isolation and depression.
- Encourage the patient to participate in an online community where people who have Huntington's disease discuss their condition.
- Social contact and a social network with others who have Huntington's disease will help patients deal better with their illness and improve their quality of life.

HUNTINGTON'S DISEASE

Huntington's disease (HD) is a genetically transmitted, autosomal dominant disorder that affects both men and women of all races. The offspring of a person with this disease have a 50% risk of inheriting it (see Genetics in Clinical Practice box above). The onset of HD is usually between 30 and 50 years of age. Often the diagnosis is made after the affected individual has had children. About 15,000 Americans are symptomatic, and 150,000 are at risk for HD.[27]

The diagnostic process begins with a review of the family history and clinical symptoms. Genetic testing confirms the disease in a person with symptoms. People who are asymptomatic but who have a positive family history of HD face the dilemma of whether to be genetically tested. If the test is positive, the person will develop HD, but when and to what extent the disease develops cannot be determined.

Like PD, the pathologic process of HD involves the basal ganglia and the extrapyramidal motor system. However, instead of a deficiency of DA, HD involves a deficiency of the neurotransmitters ACh and γ-aminobutyric acid (GABA). The net effect is an excess of DA, which leads to symptoms that are the opposite of those of parkinsonism.

The clinical manifestations are a movement disorder and cognitive and psychiatric disorders. The movement disorder is characterized by abnormal and excessive involuntary movements *(chorea)*. These are writhing, twisting movements of the face, the limbs, and the body. The movements get worse as the disease progresses. Facial movements involving speech, chewing, and swallowing are affected and may cause aspiration and malnutrition. The gait deteriorates, and ambulation eventually becomes impossible.

Psychiatric symptoms are frequently present in the early stage of the disease, often before the onset of motor symptoms. Depression is common. Other psychiatric symptoms include anxiety, agitation, impulsivity, apathy, social withdrawal, and obsessiveness. Cognitive deterioration is more variable and involves perception, memory, attention, and learning. Eventually all psychomotor processes, including the ability to eat and talk, are impaired.

Death usually occurs 10 to 20 years after the onset of symptoms. The most common cause of death is pneumonia, followed by suicide. Other causes of death include injuries related to a fall and other complications.[27]

Because HD has no cure, collaborative care is palliative. Tetrabenazine (Xenazine) is used to treat the chorea and works to decrease the amount of DA available at synapses in the brain and thus decreases the involuntary movements of chorea.

Other medications used for the movement disorder include neuroleptics such as haloperidol and risperidone (Risperdal), benzodiazepines such as diazepam and clonazepam, and DA-depleting agents such as reserpine and tetrabenazine. Cognitive disorders are treated as needed with nondrug therapies (e.g., counseling, memory books). The psychiatric disorders can be treated with selective serotonin reuptake inhibitors such as sertraline (Zoloft) and paroxetine (Paxil). Antipsychotic medication, such as haloperidol or risperidone, may also be needed.

HD presents a great challenge to health care professionals. The goal of nursing management is to provide the most comfortable environment possible for the patient and caregiver by maintaining physical safety, treating the physical symptoms, and providing emotional and psychologic support.

Because of the choreic movements, caloric requirements are high. Patients may require as many as 4000 to 5000 cal/day to maintain body weight. As the disease progresses, meeting caloric needs becomes a greater challenge when the patient has difficulty swallowing and holding the head still. Depression and mental deterioration can also compromise nutritional intake. Alternative sources of nutrition may be indicated as the disease progresses.

End-of-life issues need to be discussed with the patient and caregiver. These include care in the home or long-term care facility, artificial methods of feeding, advance directives and cardiopulmonary resuscitation (CPR), use of antibiotics to treat infections, and guardianship. These topics should be addressed throughout the course of the disease as the patient and caregiver adapt to increasing disability.

CASE STUDY

Epilepsy With Headache

Purestock/Thinkstock

Patient Profile

J.P. is a 24-yr-old woman who was diagnosed with epilepsy at age 15. At that time, she had a tonic-clonic seizure and was given a prescription for phenytoin (Dilantin). She had a second witnessed seizure 4 mo later, but has since been seizure free. J.P. now has complaints of headaches and says she is afraid that her seizures are going to return. She is single, lives alone, and describes her job as stressful.

Subjective Data

- Describes headache pain on the left side of her forehead as throbbing
- Has vomited with headache
- Describes changes in vision, including flashing lights
- Headache occurs nearly every month on a regular cycle

Objective Data

- Alert and oriented to person
- Neurologic examination negative
- Phenytoin level within normal limits
- EEG normal
- CT of head normal

Discussion Questions

1. What is epilepsy?
2. What is the pathophysiology of epilepsy?
3. What is the significance of the laboratory and diagnostic findings?
4. Is the headache related to seizure activity?
5. ***Priority Decision:*** What is a priority nursing intervention for J.P.?
6. What should be included in the teaching plan for J.P. regarding the course of the disease?
7. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses?
8. ***Evidence-Based Practice:*** Based on current treatment guidelines, what medication may be effective in managing both J.P.'s epilepsy and her migraine headaches?

Evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A 50-year-old man complains of recurring headaches. He describes these as sharp, stabbing, and located around his left eye. He also reports that his left eye seems to swell and get teary when these headaches occur. Based on this history, you suspect that he has
   a. cluster headaches.
   b. tension headaches.
   c. migraine headaches.
   d. medication overuse headaches.
2. A 65-year-old woman was just diagnosed with Parkinson's disease. The priority nursing intervention is
   a. searching the Internet for educational videos.
   b. evaluating the home for environmental safety.
   c. promoting physical exercise and a well-balanced diet.
   d. designing an exercise program to strengthen and stretch specific muscles.
3. The nurse finds that an 87-year-old woman with Alzheimer's disease is continually rubbing, flexing, and kicking out her legs throughout the day. The night shift reports that this same behavior escalates at night, preventing her from obtaining her required sleep. The next step the nurse should take is to
   a. ask the physician for a daytime sedative for the patient.
   b. request soft restraints to prevent her from falling out of her bed.
   c. ask the physician for a nighttime sleep medication for the patient.
   d. assess the patient more closely, suspecting a disorder such as restless legs syndrome.
4. Social effects of a chronic neurologic disease include *(select all that apply)*
   a. divorce.
   b. job loss.
   c. depression.
   d. role changes.
   e. loss of self-esteem.
5. The nurse is reinforcing teaching with a newly diagnosed patient with amyotrophic lateral sclerosis. Which statement would be appropriate to include in the teaching?
   a. "ALS results from an excess chemical in the brain, and the symptoms can be controlled with medication."
   b. "Even though the symptoms you are experiencing are severe, most people recover with treatment."
   c. "You need to consider advance directives now, since you will lose cognitive function as the disease progresses."
   d. "This is a progressing disease that eventually results in permanent paralysis, though you will not lose any cognitive function."

1. a, 2. c, 3. d, 4. a, b, c, d, e, 5. d

LEARNING OUTCOMES

1. Define dementia and describe its impact on society.
2. Compare and contrast different etiologies of dementia.
3. Describe the clinical manifestations, diagnostic studies, and collaborative management of dementia.
4. Describe the clinical manifestations of mild cognitive impairment.
5. Describe the clinical manifestations, diagnostic studies, and collaborative management of Alzheimer's disease.
6. Describe the nursing management of the patient with Alzheimer's disease.
7. Differentiate among other neurodegenerative disorders associated with dementia, including dementia with Lewy bodies, frontotemporal lobar degeneration, Creutzfeldt-Jakob disease, and normal pressure hydrocephalus.
8. Describe the etiology, pathophysiology, clinical manifestations, diagnostic studies, and collaborative management of delirium.

This chapter discusses the cognitive disorders of dementia and delirium, with a focus on the nursing management of patients with Alzheimer's disease. The etiology and pathophysiology of dementia and delirium are differentiated, and the collaborative and nursing management of patients with these cognitive disorders are described.

The three most common cognitive problems in adults are dementia, delirium (acute confusion), and depression (Table 60-1). Although this chapter focuses on dementia and delirium, depression is often associated with these conditions.

DEMENTIA

Dementia is a syndrome characterized by dysfunction or loss of memory, orientation, attention, language, judgment, and reasoning. Personality changes and behavioral problems such as agitation, delusions, and hallucinations may occur. Ultimately these problems result in alterations in the individual's ability to work, fulfill social and family responsibilities, and perform activities of daily living. Dementia is often diagnosed when two or more brain functions, such as memory loss or language skills, are significantly impaired.

Fifteen percent of older Americans have dementia. As the average life span increases, the number of those affected with dementia is growing. There are about 100 causes of dementia, with about 60% to 80% of the patients with dementia having a diagnosis of Alzheimer's disease (AD) (Fig. 60-1). In the United States, about half of all patients in long-term care facilities have AD or a related dementia.[1]

TABLE 60-1 COMPARISON OF DEMENTIA, DELIRIUM, AND DEPRESSION

Feature	Dementia	Delirium	Depression
Onset	Usually insidious.	Rapid, often at night.	Often coincides with life changes. Often abrupt.
Progression	Slow.	Abrupt.	Variable, rapid to slow but may be uneven.
Duration	Years (usually 8-20).	Hours to days to weeks.	Can be several months to years, especially if not treated.
Thinking	Difficulty with abstract thinking, impaired judgment, words difficult to find.	Disorganized, distorted. Slow or accelerated incoherent speech.	Intact but with apathy, fatigue. May be indecisive. Feels sense of hopelessness. May not want to live.
Perception	Misperceptions often present. Delusions and hallucinations.	Distorted. Delusions and hallucinations.	May deny or be unaware of depression. May have feelings of guilt.
Psychomotor behavior	May pace or be hyperactive. As disease progresses, may not be able to perform tasks or movements when asked.	Variable. Can be hyperactive or hypoactive, or mixed.	Often withdrawn and hypoactive.
Sleep-wake cycle	Sleeps during day. Frequent awakenings at night. Fragmented sleep.	Disturbed sleep. Reversed sleep-wake cycle.	Disturbed, often with early morning awakening.

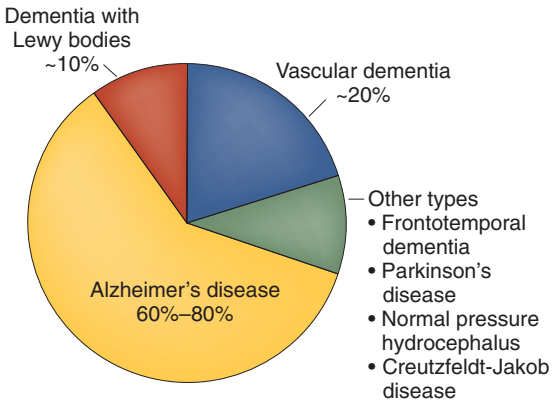

FIG. 60-1 Causes of dementia.

Etiology and Pathophysiology

Dementia is due to both treatable and nontreatable conditions (Table 60-2). The two most common causes of dementia are neurodegenerative conditions (e.g., AD) and vascular disorders. Dementia is sometimes caused by conditions that may initially be reversible (see Table 60-2). However, with prolonged exposure or disease, irreversible changes may occur.

Vascular conditions are the second most common cause of dementia.[1] **Vascular dementia,** also called *multiinfarct dementia,* is loss of cognitive function resulting from ischemic or hemorrhagic brain lesions caused by cardiovascular disease. This type of dementia is the result of decreased blood supply from narrowing and blocking of arteries that supply the brain. Vascular dementia may be caused by a single stroke (infarct) or by multiple strokes.

Risk Factors. The greatest risk factor for dementia is aging, although it is not a normal part of aging. Family history is also an important risk factor, since those with a first-degree relative with dementia are more likely to develop the disease. Those who have more than one first-degree relative with dementia are even at higher risk of developing the disease.[1]

Other risk factors for dementia are diabetes mellitus, obesity, smoking, cardiac dysrhythmias (e.g., atrial fibrillation), hypertension, hypercholesterolemia, and coronary artery disease. Genetic factors (discussed on pp. 1446-1447) also contribute to the risk of dementia.

Diabetes dramatically increases a person's risk of developing AD or other types of dementia. Diabetes can contribute to

TABLE 60-2 CAUSES OF DEMENTIA

Type of Dementia	Cause
Neurodegenerative disorders	• Alzheimer's disease • Dementia with Lewy bodies (DLB) • Frontotemporal lobar degeneration (FTLD) • Down syndrome • Amyotrophic lateral sclerosis (ALS) • Parkinson's disease • Huntington's disease
Vascular diseases	• Vascular (multiinfarct) dementia • Subarachnoid hemorrhage* • Chronic subdural hematoma*
Toxic, metabolic, or nutritional diseases	• Alcoholism • Thiamine (vitamin B_1) deficiency* • Cobalamin (vitamin B_{12}) deficiency* • Folate deficiency* • Hyperthyroidism* • Hypothyroidism*
Immunologic diseases or infections	• Multiple sclerosis • Chronic fatigue syndrome • Infections (e.g., Creutzfeldt-Jakob disease) • Acquired immunodeficiency syndrome (AIDS) • Meningitis* • Encephalitis* • Neurosyphilis* • Systemic lupus erythematosus*
Systemic diseases	• Uremic encephalopathy* • Dialysis dementia* • Hepatic encephalopathy* • Wilson's disease
Trauma	• Head injury*
Tumors	• Brain tumors (primary)* • Metastatic tumors*
Ventricular disorders	• Hydrocephalus*
Drugs†	• Anticholinergics • phenytoin (Dilantin) • Opioids • Hypnotics • Tranquilizers • Antiparkinsonian drugs • Cardiac drugs: digoxin, methyldopa (Aldomet) • Cocaine • Heroin

*Potentially reversible.
†These are examples of drugs that may cause cognitive impairment that is potentially reversible.

dementia in several ways. Insulin resistance, which causes high blood glucose and in some cases leads to type 2 diabetes, may interfere with the body's ability to break down amyloid, a protein that forms brain plaques in AD. High blood glucose also produces oxygen-containing molecules that can damage cells, in a process known as oxidative stress. In addition, high blood glucose along with high cholesterol has a role in atherosclerosis, which contributes to vascular dementia.[2]

Diabetes may contribute to poor memory and diminished mental function in various other ways. The disease causes microangiopathy, which damages small blood vessels throughout the body. Ongoing damage to blood vessels in the brain may be one reason why people with diabetes are at a higher risk of cognitive problems as they grow older. [2]

Head trauma is also a risk factor for dementia. Professional football players and military veterans who had traumatic brain injury or posttraumatic stress disorder have an increased risk for AD and other types of dementia.[3,4]

Clinical Manifestations

Depending on the cause of the dementia, the onset of manifestations may be insidious and gradual or more abrupt. Often dementia associated with neurologic degeneration is gradual and progressive over time. Causes of vascular dementia often result in symptoms that appear suddenly or progress in a stepwise pattern. However, it is difficult to distinguish the etiology of dementia (vascular versus neurodegenerative) based on symptom progression alone. An acute (days to weeks) or subacute (weeks to months) pattern of change may be indicative of an infectious or metabolic cause, including encephalitis, meningitis, hypothyroidism, or drug-related dementia. The manifestations of different types of dementia overlap and can be further complicated by coexisting medical conditions.

Depression is often mistaken for dementia in older adults, and, conversely, dementia for depression. Manifestations of depression (especially in the older adult) include sadness, difficulty thinking and concentrating, fatigue, apathy, feelings of despair, and inactivity. When the depression is severe, poor concentration and attention may result, causing memory and functional impairment. When dementia and depression occur together (as happens in many patients with dementia), the intellectual deterioration can be extreme. Depression, alone or in combination with dementia, is treatable. The challenge is to make an accurate and early assessment and diagnosis (see Table 60-1).

Other clinical manifestations of dementia are discussed in the section on clinical manifestations of AD on pp. 1447-1448.

Diagnostic Studies

The diagnosis of dementia is focused on determining the cause (e.g., reversible versus irreversible factors). An important first step is a thorough medical, neurologic, and psychologic history. A thorough physical examination is performed to rule out other potential medical conditions. Screening for cobalamin (vitamin B_{12}) deficiency and hypothyroidism is often performed. Based on patient history, testing for neurosyphilis (see Chapter 59) may be performed.

Diagnosis of dementia related to vascular causes is based on cognitive loss, vascular brain lesions demonstrated by neuroimaging techniques (computed tomography [CT] or magnetic resonance imaging [MRI]), and the exclusion of other causes of dementia (e.g., AD).

NURSING AND COLLABORATIVE MANAGEMENT DEMENTIA

In many ways, management of the patient with dementia is similar to management of the patient with AD (described later in this chapter). One form of dementia, vascular dementia, can often be prevented. Preventive measures include treatment of risk factors such as hypertension, diabetes, smoking, hypercholesterolemia, and cardiac dysrhythmias. (Stroke is discussed in Chapter 58.) Drugs that are used for patients with AD are also useful in patients with vascular dementia. Drug therapy is discussed on p. 1452 later in this chapter.

ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is a chronic, progressive, degenerative disease of the brain. It is the most common form of dementia, accounting for 60% to 80% of all cases of dementia.[1] AD is named after Alois Alzheimer, a German physician who in 1906 described changes in the brain tissue of a 55-year-old woman who had died of an unusual mental illness.

Approximately 5.2 million Americans suffer from AD. It is estimated that 11% of people age 65 and older, and nearly one third of those over age 85, have AD. Ultimately the disease is fatal, with death typically occurring 4 to 8 years after diagnosis, although some patients live for 20 years. AD is the sixth leading cause of death in the United States.[1] It is the only cause of death among the top 10 in United States that cannot be prevented or cured, or its progression even slowed. The burden of care for the patient with AD on the family, caregivers, and society is staggering. AD has often been referred to as the "long good-bye" or "death in slow motion."

The incidence of AD is slightly higher in African Americans and Hispanic Americans than in whites. AD has been associated with lower socioeconomic status and education level and poor access to health care. Women are more likely than men to develop AD, primarily because they live longer (see the Gender Differences box).

Etiology and Pathophysiology

The exact etiology of AD is unknown, but is likely a combination of genetic and environmental factors. AD is not a normal part of aging, but as with other forms of dementia, age is the most important risk factor for developing AD. Only a small percentage of people younger than 60 years old develop AD. When AD develops in someone younger than 60 years old, it is referred to as *early-onset AD.* AD that becomes evident in individuals more than 60 years old is called *late-onset AD* (see the Genetics in Clinical Practice box).

GENDER DIFFERENCES

Alzheimer's Disease and Dementia

Men	Women
• Men have a higher incidence of vascular dementia than women.	• Nearly two thirds of people with Alzheimer's disease are women. • Women are more likely to develop Alzheimer's disease than men, probably because they live longer. • About twice as many women as men die each year from Alzheimer's disease.

GENETICS IN CLINICAL PRACTICE

Alzheimer's Disease (AD)

Genetic Basis

Early Onset (Familial) (<60 Yr Old at Onset)

- Autosomal dominant disorder.
- Various mutations in the following genes:
  - Amyloid precursor protein *(APP)* gene on chromosome 21
  - Presenilin-1 *(PSEN1)* gene on chromosome 14
  - Presenilin-2 *(PSEN2)* gene on chromosome 1

Late Onset (Sporadic) (>60 Yr Old at Onset)

- Genetically more complex than early-onset form.
- Apolipoprotein E-4 *(ApoE-4)* allele on chromosome 19 increases the likelihood of developing AD.
- Presence of *ApoE-2* allele is associated with a lower risk of AD.

Incidence

Early Onset

- Rare form of AD, accounting for <5% of cases.
- Fifty percent risk of disease for children of affected parents.
- May occur in people as young as 30 yr old.

Late Onset

- *ApoE-4* is present in about 40% of people with late-onset AD. (It is present in 25%–30% of normal population.)
- Many *ApoE-4*-positive people do not develop AD, and many *ApoE-4*-negative people do.

Genetic Testing

Early Onset

- Genetic screening is available for mutations on chromosomes 1, 14, and 21.

Late Onset

- Blood test can identify which *ApoE* allele a person has but cannot predict who will develop disease.*
- *ApoE* testing is mainly used in research to identify people who may have an increased risk of developing AD.

Clinical Implications

- AD is the most common cause of dementia.
- Genetic testing and counseling for family members of patients with early-onset AD may be appropriate.
- If person tests positive for *ApoE-4,* it does not mean that the person will develop AD.

**ApoE* testing is useful for studying AD risk in large groups of people, but not for determining an individual's specific risk.

Individuals with a clear pattern of inheritance within a family have **familial Alzheimer's disease (FAD).** Other cases where no familial connection can be made are termed *sporadic.* FAD is associated with an early onset (before 60 years of age) and a more rapid disease course. In both FAD and sporadic AD, the pathogenesis of AD is similar.

Characteristic findings of AD relate to changes in the brain's structure and function: (1) amyloid plaques, (2) neurofibrillary tangles, (3) loss of connections between neurons, and (4) neuron death. Fig. 60-2 shows the pathologic changes in AD.

As part of aging, people develop some plaques in their brain tissue, but in AD more plaques appear in certain parts of the brain. These plaques consist of clusters of insoluble deposits of a protein called *β-amyloid,* other proteins, remnants of neurons, non-nerve cells such as microglia (cells that surround and digest damaged cells or foreign substances), and other cells such as astrocytes.

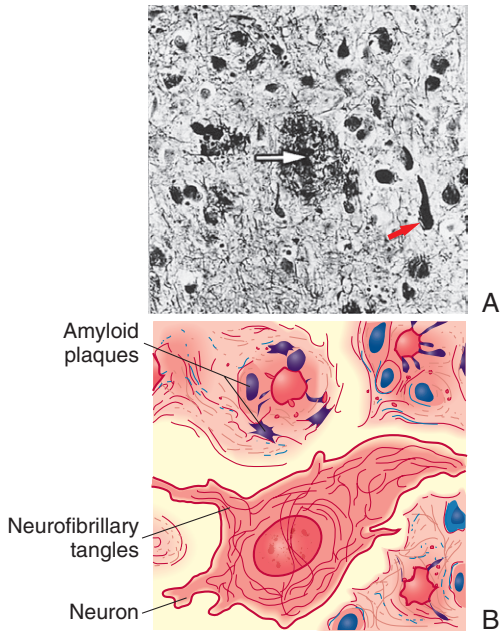

FIG. 60-2 Pathologic changes in Alzheimer's disease **A,** Plaque with central amyloid core *(white arrow)* next to a neurofibrillary tangle *(red arrow)* on the histologic specimen from a brain autopsy. **B,** Schematic representation of amyloid plaque and neurofibrillary tangle.

β-Amyloid is cleaved from amyloid precursor protein (APP), which is associated with the cell membrane (Fig. 60-3). The normal function of APP is unknown. In AD, plaques develop first in areas of the brain used for memory and cognitive function, including the hippocampus (a structure that is important in forming and storing short-term memories). Eventually AD attacks the cerebral cortex, especially the areas responsible for language and reasoning.

Neurofibrillary tangles are abnormal collections of twisted protein threads inside nerve cells. The main component of these structures is a protein called *tau.* Tau proteins in the central nervous system (CNS) are involved in providing support for intracellular structure through their support of microtubules. Tau proteins hold the microtubules together like railroad ties hold railroad tracks together. In AD the tau protein is altered, and as a result, the microtubules twist together in a helical fashion (see Fig. 60-3). This ultimately forms the neurofibrillary tangles found in the neurons of persons with AD.

Plaques and neurofibrillary tangles are not unique to patients with AD or dementia. They are also found in the brains of individuals without evidence of cognitive impairment. However, they are more abundant in the brains of individuals with AD.

The other feature of AD is the loss of connections between neurons and neuron death. These processes result in structural damage. Affected parts of the brain begin to shrink in a process called brain atrophy. By the final stage of AD, brain tissue has shrunk significantly (Fig. 60-4).

Genetic Link

Genetic factors may play a critical role in how the brain processes the β-amyloid protein. Overproduction of β-amyloid appears to be an important risk factor for AD. Abnormally high levels of β-amyloid cause cell damage either directly or by eliciting an inflammatory response and ultimately neuron death. Understanding why neurons produce β-amyloid led

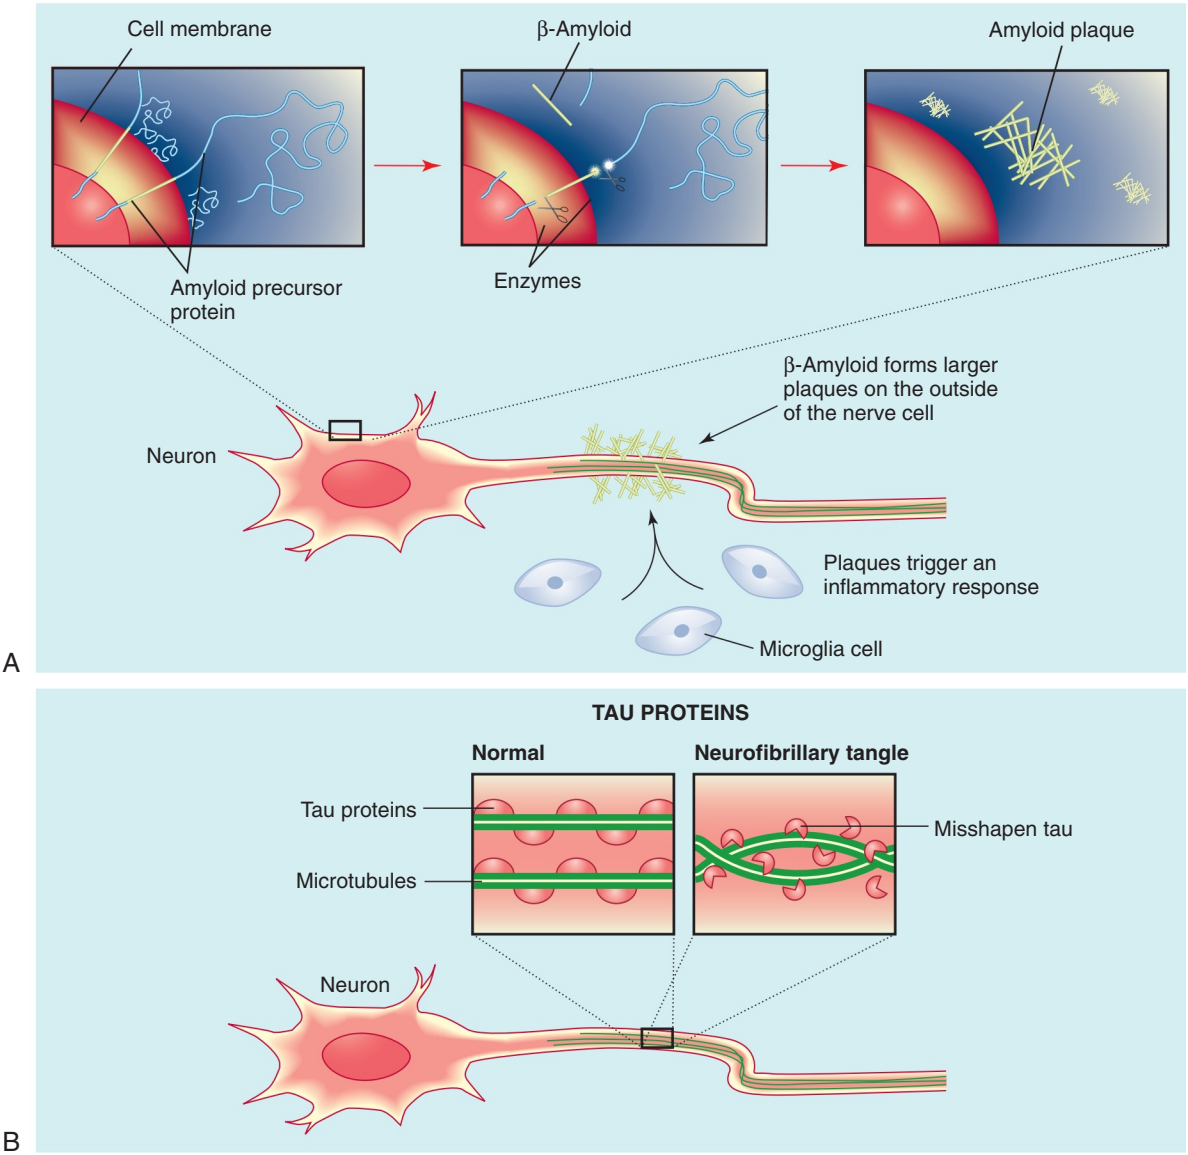

FIG. 60-3 Current etiologic theories for the development of Alzheimer's disease. **A,** Abnormal amounts of β-amyloid are cleaved from the amyloid precursor protein *(APP)* and released into the circulation. The β-amyloid fragments come together in clumps to form plaques that attach to the neuron. Microglia react to the plaque, and an inflammatory response results. **B,** Tau proteins provide structural support for the neuron microtubules. Chemical changes in the neuron produce structural changes in tau proteins. This results in twisting and tangling (neurofibrillary tangles).

researchers to examine the enzymes (and their genes) that are responsible for both the synthesis and processing of APP.

In patients with early-onset AD, three genes have been identified as important in the etiology (see the Genetics in Clinical Practice box on p. 1446). When the *presenilin-1, presenilin-2,* and *APP* genes are mutated, they cause brain cells to overproduce β-amyloid.[5]

The first gene associated with AD was the *epsilon (E)-4* allele of the *apolipoprotein E (ApoE)* gene on chromosome 19. *ApoE* comes in several different alleles or forms, but three alleles occur most commonly. People inherit one allele (i.e., *ApoE-2, ApoE-3, or ApoE-4*) from each parent. *ApoE* contains the instructions to make a protein that helps to carry cholesterol and other types of fat in the bloodstream. *ApoE* may have a role in clearing amyloid plaques. Mutations in this gene result in greater amyloid deposition. The presence of *ApoE-4,* which is a risk-factor gene, increases the risk of a person developing late-onset AD.[5] However, the presence of the gene alone is not adequate to account for AD, since many people with *ApoE-4* do not develop AD.

Environmental Factors. As previously mentioned in the section on risk factors for dementia (pp. 1444-1445), diabetes mellitus, hypertension, current smoking, hypercholesterolemia, obesity, and trauma are associated with an increased risk of dementia, including AD.

Clinical Manifestations

Pathologic changes often precede clinical manifestations of dementia by anywhere from 5 to 20 years.[6] The Alzheimer's Association has developed a list of warning signs that include common manifestations of AD (Table 60-3). The stages of AD can be categorized as mild, moderate, and severe (Table 60-4). The rate of progression from mild to severe is highly variable and ranges from 3 to 20 years.

FIG. 60-4 Effects of Alzheimer's disease on the brain. This figure compares a normal brain *(left)* with a brain that has been affected by Alzheimer's disease *(right)*.

The initial manifestations are usually related to changes in cognitive functioning. Patients may have complaints of memory loss, mild disorientation, or trouble with words and numbers. Often it is a family member, in particular the spouse, who reports the patient's declining memory to the health care provider.

Normal age-related memory decline is characterized by mild changes that do not interfere with activities of daily living (Table 60-5). In AD the memory loss initially relates to recent events, with remote memories still intact. With time and progression of AD, memory loss includes both recent and remote memory and ultimately affects the ability to perform self-care.

As AD progresses, personal hygiene deteriorates, as does the ability to concentrate and maintain attention. Ongoing loss of neurons in AD can cause a person to act in altered or unpredictable ways. Behavioral manifestations of AD (e.g., agitation, aggression) result from changes that take place within the brain. They are neither intentional nor controllable by the individual with the disease. Some patients develop delusions and hallucinations.

With progression of AD, additional cognitive impairments are noted. These include *dysphasia* (difficulty comprehending language and oral communication), *apraxia* (inability to manipulate objects or perform purposeful acts), *visual agnosia* (inability to recognize objects by sight), and *dysgraphia* (difficulty communicating via writing). Eventually long-term memories cannot be recalled, and patients lose the ability to recognize family members and friends. Other problems include aggression and a tendency to wander.

Later in the disease, the ability to communicate and to perform activities of daily living is lost. In the late stages of AD, the patient is unresponsive and incontinent and requires total care.

Retrogenesis. **Retrogenesis** is the process in AD patients in which degenerative changes occur in the reverse order in which they were acquired.[7] This theory compares the developmental stages in children with the deterioration in AD patients. As seen in Table 60-6, a relationship exists between the developmental stage and deterioration of function. For example, it is appropriate for a person with AD in the moderate stage to feel good about putting together puzzles that belong to his 3-year-old grandson. In fact, they may play well together on the same task or project.

TABLE 60-3 PATIENT & CAREGIVER TEACHING GUIDE

Early Warning Signs of Alzheimer's Disease

Include the following information in the teaching plan for the patient with Alzheimer's disease.

1. **Memory loss that affects job skills**
   - Frequent forgetfulness or unexplainable confusion at home or in the workplace may signal that something is wrong.
   - This type of memory loss goes beyond forgetting an assignment, colleague's name, deadline, or phone number.
2. **Difficulty performing familiar tasks**
   - It is normal for most people to become distracted and to forget something (e.g., leave something on the stove too long).
   - People with AD may cook a meal but then forget not only to serve it but also that they made it.
3. **Problems with language**
   - Most people have trouble finding the "right" word from time to time.
   - Persons with AD may forget simple words or substitute inappropriate words, making their speech difficult to understand.
4. **Disorientation to time and place**
   - Most individuals occasionally forget the day of the week or what they need from the store.
   - People with AD can become lost on their own street, not knowing where they are, how they got there, or how to get back home.
5. **Poor or decreased judgment**
   - Many individuals from time to time may choose not to dress appropriately for the weather (e.g., not bringing a coat or sweater on a cold evening).
   - The person with AD may dress inappropriately in more noticeable ways, such as wearing a bathrobe to the store or a sweater on a hot day.
6. **Problems with abstract thinking**
   - For the person with AD, this goes beyond challenges such as balancing a checkbook.
   - The person with AD may have difficulty recognizing numbers or doing even basic calculations.
7. **Misplacing things**
   - For many individuals, temporarily misplacing keys, purses, or wallets is a normal albeit frustrating event.
   - The person with AD may put items in inappropriate places (e.g., eating utensils in clothing drawers) but have no memory of how they got there.
8. **Changes in mood or behavior**
   - Most individuals experience mood changes.
   - The person with AD tends to exhibit more rapid mood swings for no apparent reason.
9. **Changes in personality**
   - As most individuals age, they may demonstrate some change in personality (e.g., become less tolerant).
   - The person with AD can change dramatically, either suddenly or over time. For example, someone who is generally easygoing may become angry, suspicious, or fearful.
10. **Loss of initiative**
    - The person with AD may become and remain uninterested and uninvolved in many or all of his or her usual pursuits.

Adapted from Alzheimer's Association: *Early warning signs,* Chicago, The Association.

Diagnostic Criteria for Alzheimer's Disease

The original 1984 clinical criteria for AD defined it as having a single stage, dementia, and based the diagnosis solely on clinical symptoms. It assumed that people free of dementia symptoms were disease-free. Since then, research has determined that AD may cause changes in the brain many years before symptoms

TABLE 60-4 STAGES OF ALZHEIMER'S DISEASE

Mild	Moderate	Severe
• Forgetfulness beyond what is seen in a normal person • Short-term memory impairment, especially for new learning • Loss of initiative and interests • May forget recent events or the names of people or things • Small personality changes • May no longer be able to solve simple math problems • Slowly loses the ability to plan and organize	• Memory loss and confusion become more obvious • Has more trouble organizing, planning, and following directions • May need help getting dressed • May start having incontinence • Trouble recognizing family members and friends • Agitation, restlessness • May lack judgment and begin to wander, gets lost • May have trouble sleeping • Delusions, hallucinations, paranoia • Behavioral problems	• Severe impairment of all cognitive functions • Little memory, unable to process new information • Unable to perform self-care activities • Often needs help with daily needs • May not be able to talk • Cannot understand words • May have difficulty eating, swallowing • May not be able to walk or sit up without help • Immobility • Incontinence

TABLE 60-5 COMPARISON OF NORMAL FORGETFULNESS AND MEMORY LOSS

Normal Forgetfulness	Memory Loss in Mild Cognitive Impairment	Memory Loss in Alzheimer's Disease
• Sometimes misplaces keys, eyeglasses, or other items	• Frequently misplaces items	• Forgets what an item is used for or puts it in an inappropriate place
• Momentarily forgets an acquaintance's name	• Frequently forgets people's names and is slow to recall them	• May not remember knowing a person
• Occasionally has to search for a word	• Has increasing difficulty finding desired words	• Begins to lose language skills and may withdraw from social interaction
• Occasionally forgets to run an errand	• Begins to forget important events and appointments	• Loses sense of time, does not know what day it is
• May forget an event from the distant past	• May forget recent events or newly learned information	• Has seriously impaired recent memory and difficulty learning and remembering new information
• When driving, may momentarily forget where to turn, but quickly orients self	• Becomes temporarily lost more often, may have trouble understanding and following a map	• Becomes easily disoriented or lost in familiar places, sometimes for hours
• Jokes about memory loss	• Worries about memory loss, family and friends notice lapses	• May have little or no awareness of cognitive problems

Adapted from Rabins P: Memory. In *The Johns Hopkins white papers,* Baltimore, 2007, Johns Hopkins University.

TABLE 60-6 RETROGENESIS IN ALZHEIMER'S DISEASE

Stage	Alzheimer's Disease	Reisberg Stage*	Developmental Age	Diversion/Distraction Activities
Mild	No difficulty at all.	1	Adult	—
	Some memory trouble begins to affect job and home. Forgets familiar names.	2	—	—
	Much difficulty maintaining job performance. Withdrawal from difficult situations.	3	12+ yr	Can function with understanding. Enjoy things they have always enjoyed—watch TV, play and listen to music, play games.
	Can no longer hold a job, plan and prepare meals, handle personal finances, etc. Driving becomes difficult, although can drive to familiar places.	4	8-12 yr	Can still enjoy simple games, watch TV and videos. Enjoys family photos and memories.
Moderate	Can no longer select proper clothing for occasion or season. Needs help to remain safe in home. Forgets to bathe.	5	5-7 yr	Needs age-appropriate toys and games.
	Requires help with dressing.	6a	5 yr	Needs activities appropriate for preschoolers. Enjoys many of the same activities as preschoolers.
	Requires help with bathing.	6b	4 yr	
	Requires help with toileting.	6c	4 yr	
	Urinary incontinence.	6d	3-4 yr	
	Fecal incontinence.	6e	2-3 yr	
Severe	Speech limited to 5-6 intelligent words/day.	7a	15 mo	Enjoys infant toys, mobiles, dangling ribbons.
	Speech limited to one word/day.	7b	1 yr	
	Can no longer walk without assistance.	7c	1 yr	
	Can no longer sit up without assistance.	7d	6-10 mo	
	Can no longer smile.	7e	2-4 mo	
	Can no longer hold up head.	7f	1-3 mo	

*These stages are based on Functional Assessment Staging. Reisberg B: Functional assessment staging (FAST), *Psychopharmacol Bull* 24:653, 1988.

TABLE 60-7 DIAGNOSTIC CRITERIA FOR ALZHEIMER'S DISEASE*

	Stage and Description	Recommendations for Biomarkers
Preclinical Alzheimer's Disease (AD)	• Brain changes, including amyloid buildup and other early neuron changes, may already be in process. • At this point, significant clinical symptoms are not yet evident. • In some people, amyloid buildup can be detected with positron emission tomography (PET) scans and cerebrospinal fluid (CSF) analysis.	• Use of imaging and biomarker tests at this stage are recommended only for research. • Biomarkers are still being developed and standardized and are not used by clinicians in general practice.
Mild Cognitive Impairment (MCI) due to Alzheimer's Disease	• The MCI stage is marked by symptoms of memory problems, enough to be noticed and measured, but not compromising a person's independence. • People with MCI may or may not progress to Alzheimer's dementia.	• Used primarily by researchers. • May be used in specialized clinical settings to supplement standard clinical tests to help determine possible causes of MCI. • May help confirm that the person's impairment is related to AD.
Dementia due to Alzheimer's Disease	• Characterized by memory, thinking, and behavioral symptoms that impair a person's ability to function in daily life. • Dementia marks the terminal stage of AD. • Encompasses all stages presented in Table 60-4.	• May be used in some cases to increase the level of certainty about a diagnosis of AD. • Also may be used to distinguish AD from other dementias.

Source: Jack CR, Albert MS, Knopman DS, et al: Introduction to the recommendations from the National Institute on Aging–Alzheimer's Association workgroups on diagnostic guidelines for Alzheimer's disease, *Alzheimers Dement* 7:257, 2011.
*Note that these are recommended criteria and guidelines. More research is needed, especially biomarker research, before the new criteria and guidelines can be used in clinical settings.

appear and that symptoms do not always directly relate to abnormal changes in the brain caused by AD.

In 2011 updated criteria and guidelines classified AD as a spectrum, where dementia marks the terminal stage of the disease (Table 60-7). The stages in the new classification spectrum are preclinical AD, mild cognitive impairment, and dementia due to AD.[8] The guidelines address the use of imaging and biomarkers (discussed in section on diagnostic studies below) that may help determine whether changes are due to AD.[9]

Preclinical Stage. A long lag exists between pathologic changes in the brain and manifestations of AD. The future goal would be to modify the disease process of AD before it becomes symptomatic. Once plaques and tangles have formed in sufficient quantity, it may be too late to intervene to prevent the disease or its progression. Although currently all attempts at modifying the disease process have failed, research is ongoing. The model for early intervention is seen in other diseases, such as removing polyps to prevent colon cancer, controlling blood glucose in diabetes before the disease progresses to heart and kidney disease, and treating cardiac risk factors before a person has a myocardial infarction.

Mild Cognitive Impairment. Mild cognitive impairment (MCI), the second stage in the AD spectrum, is a state of cognitive function in which individuals have problems with memory, language, or another essential cognitive function that are severe enough to be noticeable to others and show up on tests, but not severe enough to interfere with activities of daily living. Because the problems do not interfere with daily activities, the person does not meet the criteria for being diagnosed with dementia.[10] To the casual observer, an individual with MCI may seem fairly normal. However, the person with MCI is often aware of a significant change in memory, and family members may observe changes in the individual's abilities (see Table 60-5).

Between 10% and 20% of people 65 years old and older have MCI and are at high risk of developing AD. Some individuals with MCI show no progression and do not go on to develop AD, but an estimated 15% of people with MCI eventually do. Although not in clinical use, biomarkers can be a useful tool to predict who will develop dementia.[10]

No drugs have been approved for the treatment of MCI. Research is being conducted to determine whether patients with MCI would benefit from the medications used in AD (e.g., cholinesterase inhibitors). There is little evidence that cholinesterase inhibitors affect progression to dementia or cognitive test scores in people with MCI.[11]

Currently the primary treatment of MCI consists of ongoing monitoring. Recognize the importance of monitoring the patient with MCI for changes in memory and thinking skills that would indicate a worsening of symptoms or a progression to dementia. It is critical that you understand the 10 early warning signs of AD (see Table 60-3).

Diagnostic Studies

No definitive diagnostic test exists for AD. The diagnosis of AD is primarily a diagnosis of exclusion. In patients with cognitive impairment, there is increased emphasis on early and careful evaluation. As indicated earlier in this chapter, many conditions can cause manifestations of dementia, some of which are treatable or reversible (see Table 60-2).

When all other possible conditions that can cause cognitive impairment have been ruled out, a clinical diagnosis of AD can be made. A comprehensive patient evaluation includes a complete health history, physical examination, neurologic and mental status assessments, and laboratory tests (Table 60-8). Brain imaging tests (e.g., CT or MRI) may show brain atrophy in the later stages of the disease, although this finding occurs in other diseases and can also be seen in persons without cognitive impairment. Positron emission tomography (PET) scanning can be used to differentiate AD from other forms of dementia (Fig. 60-5). Neuroimaging techniques allow for detection of changes early in the disease and monitoring of treatment response. A definitive diagnosis of AD usually requires examination of brain tissue at autopsy and findings of neurofibrillary tangles and neuritic plaques.

The new criteria and guidelines identify two biomarker categories: (1) biomarkers showing the level of β-amyloid accumulation in the brain and (2) biomarkers showing that nerve cells in the brain are injured or actually degenerating. Biomarkers include (1) cerebrospinal fluid (CSF) neurochemical markers:

TABLE 60-8 COLLABORATIVE CARE

Alzheimer's Disease

Diagnostic

- History and physical examination, including psychologic evaluation
- Neuropsychologic testing, including Mini-Cog (Table 60-9), Mini-Mental State Examination (eTable 60-1)
- Brain imaging tests: CT, MRI, MRS, PET
- Complete blood count
- Electrocardiogram
- Serum glucose, creatinine, BUN
- Serum levels of vitamins B_1, B_6, B_{12}
- Thyroid function tests
- Liver function tests
- Screening for depression

Collaborative Therapy

- Drug therapy for cognitive problems (see Table 60-10)
- Behavioral modification
- Moderate exercise
- Assistance with functional independence
- Assistance and support for caregiver

MRS, Magnetic resonance spectroscopy; *PET,* positron emission tomography

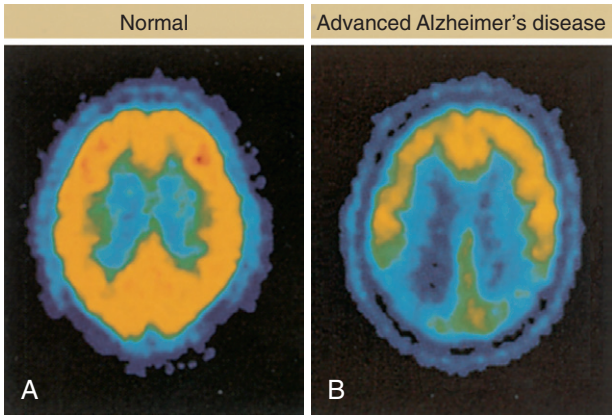

FIG. 60-5 Positron emission tomography (PET) scan can be used to assist in the diagnosis of Alzheimer's disease (AD). Radioactive fluorine is applied to glucose (fluorodeoxyglucose), and the yellow areas indicate metabolically active cells. **A,** A normal brain. **B,** Advanced AD is recognized by hypometabolism in many areas of the brain.

β-amyloid and tau proteins and (2) imaging biomarkers: volumetric MRI and PET. The level of tau in the CSF is an indication of neurodegeneration. (Plasma levels of tau or β-amyloid are not of any value in diagnosing AD.) In AD multiple brain structures atrophy and the volume of the brain correlates with neurodegeneration. PET determines brain metabolism using glucose tracers (see Fig. 60-5). PET can also be used to detect amyloid.

Some imaging biomarkers are used in specialized clinical settings. CSF biomarkers are mainly used for research. Biomarkers may be used in some cases to increase the level of certainty about a diagnosis of Alzheimer's dementia and to distinguish Alzheimer's dementia from other dementias. However, more research is needed with biomarkers before they are used routinely in clinical practice.

Neuropsychologic testing with tools such as the Mini-Cog (Table 60-9) and the Mini-Mental State Examination (see eTable 60-1, available on the website for this chapter) can help document the degree of cognitive impairment. The clock drawing test can be used as part of the Mini-Cog or by itself to assess cognitive function (Fig. 60-6). Neuropsychologic testing is important not only for diagnostic purposes but also to establish a baseline for evaluating changes over time.

TABLE 60-9 THE MINI-COG

Introduction

The Mini-Cog is used as a brief assessment tool for cognitive impairment. It can be quickly administered and can guide the need for further evaluation.

Administration

1. Instruct the patient to listen carefully to and remember three unrelated words and then to repeat the words. *Example:* apple, table, penny. (This initial step is not scored.)
   The same three words may be repeated to the patient up to three tries to register all three words.
2. Instruct the patient to draw the face of a clock, either on a blank sheet of paper or on a sheet with the clock circle already drawn on the page. After the patient puts the numbers on the clock face, ask him or her to draw the hands of the clock to read a specific time (11:10). The test is considered normal if all numbers are present in the correct sequence and position, and the hands readably display the requested time.
3. Ask the patient to repeat the three previously stated words.
   Scoring (out of total of 5 points)
   Give 1 point for each recalled word after the clock drawing test.
   - Patients recalling none of the three words are classified as cognitively impaired (score = 0).
   - Patients recalling all three words are classified as not cognitively impaired (score = 3).
   - Patients with intermediate word recall of one or two words are classified on the clock drawing test:
     The clock drawing test is scored 2 if normal and 0 if abnormal.
     Interpretation of results
     0-2: Positive screen for dementia
     3-5: Negative screen for dementia

Source: Borson S, Scanlan J, Brush M, et al: The Mini-Cog: a cognitive "vital signs" measure for dementia screening in multi-lingual elderly, *Intern J Geriatr Psychiatry* 15(11):1021, 2000.

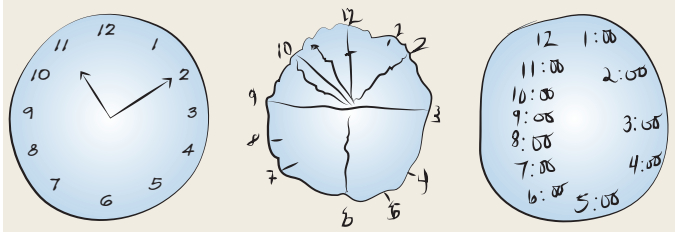

FIG. 60-6 Clock drawing is a simple test that can be used as an assessment technique in dementia. The person undergoing testing is asked to draw a clock, put in all of the numbers, and set the hands at 10 past 11. **A,** Shows a clock drawn by a person with no dementia. **B** and **C** show clocks drawn by people with dementia.

Collaborative Care

At this time there is no cure for AD. No treatment is available to stop the deterioration of brain cells in AD. Nothing stops or really slows the progression of the disease.

The collaborative management of AD is aimed at (1) controlling the undesirable behavioral manifestations that the patient may exhibit and (2) providing support for the family caregiver.

Drug Therapy. Although drug therapy for AD is available (Table 60-10), these drugs do not cure or reverse the progression of the disease. Drugs help many people, but not for very long and not very well. The use of drugs may lead to a modest decrease in the rate of decline of cognitive function. However, the drugs have no effect on overall disease progression.[12,13]

Cholinesterase inhibitors block cholinesterase, the enzyme responsible for the breakdown of acetylcholine in the synaptic cleft (Fig. 60-7). Cholinesterase inhibitors include donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne). Rivastigmine is available as a patch.

Memantine (Namenda) protects the brain's nerve cells against excess amounts of glutamate, which is released in large amounts by cells damaged by AD. The attachment of glutamate to *N*-methyl-D-aspartate (NMDA) receptors permits calcium to flow freely into the cell, which in turn may lead to cell degeneration. Memantine may prevent this destructive sequence by blocking the action of glutamate.

Treating the depression that is often associated with AD may improve cognitive ability. Depression is often treated with selective serotonin reuptake inhibitors, including fluoxetine (Prozac), sertraline (Zoloft), fluvoxamine (Luvox), and citalopram (Celexa). The antidepressant trazodone (Desyrel) may help with problems related to sleep.

Although antipsychotic drugs are approved for treating psychotic conditions (e.g., schizophrenia), they have been used for the management of behavioral problems (e.g., agitation, aggressive behavior) that occur in patients with AD. However, these drugs have been shown to increase the risk of death in older dementia patients.[14] The U.S. Food and Drug Administration (FDA) has warned that antipsychotics are not indicated for the treatment of dementia-related psychosis. However, the warning does not mean that the drugs cannot be used for these patients with dementia.

TABLE 60-10 DRUG THERAPY

Alzheimer's Disease

Problem	Drugs
Decreased memory and cognition	Cholinesterase inhibitors • donepezil (Aricept) • rivastigmine (Exelon) • galantamine (Razadyne) *N*-methyl-D-aspartate (NMDA) receptor antagonist • memantine (Namenda)
Depression	Selective serotonin reuptake inhibitors (SSRIs) • sertraline (Zoloft) • fluvoxamine (Luvox) • citalopram (Celexa) • fluoxetine (Prozac) Atypical antidepressants • mirtazapine (Remeron) • trazodone (Desyrel)
Behavioral problems (e.g., agitation, physical aggression, disinhibition)	Antipsychotics* • haloperidol (Haldol) • risperidone (Risperdal) • olanzapine (Zyprexa) • quetiapine (Seroquel) • aripiprazole (Abilify) Benzodiazepines • lorazepam (Ativan) • clonazepam (Klonopin)
Sleep disturbances	zolpidem (Ambien)

*The use of these drugs in older patients with dementia is associated with an increased risk of death.

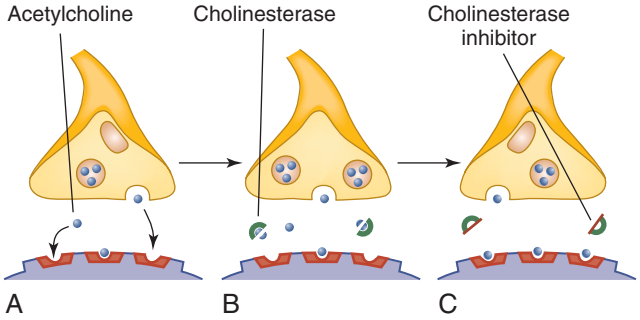

FIG. 60-7 Mechanism of action of cholinesterase inhibitors. **A,** Acetylcholine is released from the nerve synapses and carries a message across the synapse. **B,** Cholinesterase breaks down acetylcholine. **C,** Cholinesterase inhibitors block cholinesterase, thus giving acetylcholine more time to transmit the message.

NURSING MANAGEMENT ALZHEIMER'S DISEASE

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a person with AD are presented in Table 60-11. Useful questions for the patient and caregiver are, "When did you first notice the memory loss?" and "How has the memory loss progressed since then?"

NURSING DIAGNOSES

Nursing diagnoses for AD may include, but are not limited to, the following:

- Impaired memory *related to* the effects of dementia
- Self-neglect *related to* memory deficit, cognitive impairment, and neuromuscular impairment
- Risk for injury *related to* impaired judgment, gait instability, muscle weakness, and sensory/perceptual alteration
- Wandering *related to* cognitive impairment

Additional information on nursing diagnoses for the patient with AD is presented in eNursing Care Plan 60-1 (available on the website for this chapter).

PLANNING

The overall goals are that the patient with AD will (1) maintain functional ability for as long as possible, (2) be maintained in a safe environment with a minimum of injuries, (3) have personal care needs met, and (4) have dignity maintained. The overall goals for the caregiver of a patient with AD are to (1) reduce caregiver stress; (2) maintain personal, emotional, and physical health; and (3) cope with the long-term effects of caregiving.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Can AD be prevented? Although there is no known definitive way to prevent AD, several steps can help keep your brain healthy:

- *Avoid harmful substances.* Excessive drinking and drug abuse can damage brain cells.
- *Challenge yourself.* Read frequently, do crossword puzzles. Keep mentally active. Learn new skills. This strengthens the brain connections and promotes new ones.
- *Exercise regularly.* Even low to moderate level activity such as walking or gardening three to five times per

TABLE 60-11 NURSING ASSESSMENT

Alzheimer's Disease

Subjective Data

Important Health Information

Past health history: Repeated head trauma, stroke, previous CNS infection, family history of dementia

Medications: Use of any drug to decrease symptoms (e.g., tranquilizers, hypnotics, antidepressants, antipsychotics)

Functional Health Patterns

Health perception–health management: Positive family history; emotional lability

Nutritional-metabolic: Anorexia, malnutrition, weight loss

Elimination: Incontinence

Activity-exercise: Poor personal hygiene; gait instability, weakness; inability to perform activities of daily living

Sleep-rest: Frequent nighttime awakening, daytime napping

Cognitive-perceptual: Forgetfulness, inability to cope with complex situations, difficulty with problem solving (early signs); depression, withdrawal, suicidal ideation (early)

Objective Data

General

Disheveled appearance, agitation

Neurologic

Mild: Loss of recent memory; disorientation to date and time; flat affect; lack of spontaneity; impaired abstraction, cognition, and judgment

Moderate: Agitation; impaired ability to recognize close family and friends; loss of remote memory; confusion, apraxia, agnosia, alexia (inability to understand written language); aphasia; inability to do simple tasks

Severe: Inability to do self-care; incontinence; immobility; limb rigidity; flexor posturing

Possible Diagnostic Findings

Diagnosis by exclusion, cerebral cortical atrophy on CT scan, poor scores on mental status tests, hippocampal atrophy on MRI scan, abnormal changes on PET

week can make you feel better. Daily physical activity, even in older adults, can decrease the risk for cognitive decline.[15]

- *Stay socially active.* Family, friends, church, and a sense of community may all contribute to better brain health.
- *Avoid trauma to the brain.* Because traumatic brain injury may be a risk factor for developing AD, promote safety in physical activities and driving.
- *Treat depression.* Recognize and treat depression early. Depression may cause or worsen memory loss and other cognitive impairment.

Early recognition and treatment of AD are important. You have a responsibility to inform patients and their families regarding the early signs of AD (see Table 60-3).

ACUTE INTERVENTION. The diagnosis of AD is traumatic for both the patient and the family. It is not unusual for the patient to respond with depression, denial, anxiety, fear, withdrawal, and feelings of loss. In the early stages of AD, patients are often aware that their memory is faulty and do things to cover up or mask the problem. See the Resources at the end of this chapter for a link to *What Happens Next?,* a booklet specifically for people dealing with the beginning stages of dementia.

You are in an important position to assess for depression. Antidepressant drugs and counseling may be indicated. Family caregivers may also be in denial and may not seek medical attention early in the disease. Along with patient assessment, assess family caregivers and their ability to accept and cope with the diagnosis.

Although no current treatment is available for reversing AD, there is a need for ongoing monitoring of both the patient with AD and the patient's caregiver. An important nursing responsibility is to work collaboratively with the caregiver to manage clinical manifestations effectively as they change over time. You are often responsible for teaching the caregiver to perform the many tasks that are required to manage the patient's care. Consider both the patient with AD and the caregiver as patients with overlapping but unique problems.[16]

Patients with AD may be hospitalized for other health problems. Patients with AD are subject to acute and other chronic illnesses and may require surgical interventions. Their inability to communicate symptoms of health problems places the responsibility for assessment and diagnosis on caregivers and health care professionals. Hospitalization of the patient with AD can be a traumatic event for both the patient and caregiver and can precipitate a worsening of the disease or delirium. Patients with AD in the acute care setting need to be observed more closely because of concerns for safety, frequently oriented to place and time, and given reassurance. Anxiety or disruptive behavior may be reduced through the use of consistent nursing staff.

AMBULATORY AND HOME CARE. Currently, family members and friends care for most individuals with AD in their homes. Others with AD reside in various facilities, including long-term care and assisted living facilities. A facility that is good for one person may not be suitable for another. Also, what is helpful for a person at one point in the disease process may be completely different from what is best when the disease progresses.

Patients with AD move through the stages at variable rates. The nursing care required by the patient with AD changes as the disease progresses, emphasizing the need for regular assessment and support. Regardless of the setting, the severity of the problems and the amount of nursing care required intensify over time. The specific manifestations of the disease depend on the area of the brain involved. Nursing care focuses on decreasing clinical manifestations, preventing harm, and supporting the patient and caregiver throughout the disease process.

In the early stages of AD, memory aids (e.g., calendars) may be beneficial. Patients often develop depression during this phase. Depression may be related to the diagnosis of an incurable disorder and the impact of the disease on activities of daily living (e.g., driving, socializing with friends, participating in hobbies or recreational activities).

After the initial diagnosis, patients need to be aware that the progression of the disease is variable. Effective management of the disease may slow the progress of the disease and decrease the burden on the patient, caregiver, and family. However, decisions related to care should be made with the patient, family members, and health care team early in the disease. You have a role in advising the patient and caregiver to initiate health care decisions, including advance directives, while the patient has the capacity to do so. This can ease the burden for the caregiver as the disease progresses.

Adult day care is one of the options available to the person with AD. Although programs vary in size, structure, physical environment, and staff experience, the common goals of all day care programs are to provide respite for the family and a protec-

tive environment for the patient. During the early and moderate stages of AD, the person can still benefit from stimulating activities that encourage independence and decision making in a protective environment.[17] The patient returns home tired, content, less frustrated, and ready to be with the family. The respite from the demands of care allows the caregiver to be more responsive to the patient's needs.

As the disease progresses, the demands on the caregiver eventually exceed the resources, and the person with AD may need to be placed in a long-term care facility. Special units to care for persons with AD are becoming increasingly common in long-term care settings. The Alzheimer's unit is designed with an emphasis on safety. For example, many facilities have designated areas that allow the patient to walk freely within the unit, while the unit is secured so that the patient cannot wander outside of it.

As the patient with AD progresses to the late stages (severe impairment) of AD, he or she has increased difficulty with the most basic functions, including walking and talking. Total care is required.

Specific problems relate to the care of the patient with AD in all phases of the disease. These problems are described below.

Behavioral Problems. Behavioral problems occur in about 90% of patients with AD. These problems include repetitiveness (asking the same question repeatedly), delusions (false beliefs), hallucinations, agitation, aggression, altered sleeping patterns, wandering, and resisting care. Many times these behaviors are unpredictable and may challenge caregivers. Caregivers need to be aware that these behaviors are not intentional and are often difficult to control. Behavioral symptoms often lead to the placement of patients in institutional care settings.

These behaviors are often the patient's way of responding to a precipitating factor (e.g., pain, frustration, temperature extremes, anxiety). When these behaviors become problematic, you must plan interventions carefully. Initially assess the patient's physical status. Check the patient for changes in vital signs, urinary and bowel patterns, and pain that could account for behavioral problems. Then assess the environment to identify factors that may trigger behavior disruptions. Extremes in temperature or excessive noise may lead to behavior changes. When the patient is agitated by the environment, either move the patient or remove the stimulus.

When a patient resists or pulls tubes or dressings, cover these items with stretch tube gauze or remove them from the visual field. Reassure the patient that you are present to keep him or her safe. Do not ask the confused or agitated patient challenging "why" questions. If the patient cannot verbalize distress, validate his or her mood. Rephrase the patient's statement to validate its meaning. Closely observe the patient's emotional state.

Nursing strategies that address difficult behavior include redirection, distraction, and reassurance. For the patient who is restless or agitated, redirecting involves changing the patient's focus (e.g., having the patient perform activities such as sweeping, raking, or dusting). Ways to distract the agitated patient may include providing snacks, taking a car ride, sitting on a porch swing or rocker, listening to favorite music, watching videotapes, looking at family photographs, or walking. Reassurance involves communicating to the patient that he or she will be protected from danger, harm, or embarrassment. Use of repetitive activities, songs, poems, music, massage, aromas, or a favorite object can be soothing to patients.[18]

When dealing with the difficult patient, do not threaten to restrain the patient or call the physician. A calming family member can be asked to stay with the patient until the patient becomes calmer. Monitor the patient frequently, and document all interventions. As verbal skills decline, you and the caregiver must rely more on the patient's body language to communicate care needs. The use of positive nurse actions can reduce the use of chemical (drug therapy) restraints.

Disruptive behaviors have been treated with antipsychotic drugs (see Table 60-10). However, as discussed on p. 1452, these drugs have adverse side effects. Before these drugs are used, all other measures of treating behavioral issues should be exhausted.

A specific type of agitation, termed **sundowning,** is when the patient becomes more confused and agitated in the late afternoon or evening. Behaviors commonly exhibited include agitation, aggressiveness, wandering, resistance to redirection, and increased verbal activity such as yelling. The cause of sundowning is unclear, but several theories propose that it is due to a disruption of circadian rhythms. Other possible causes include fatigue, unfamiliar environment and noise (especially in an acute care setting), medications, reduced lighting, and sleep fragmentation. When a patient experiences sundowning, remain calm and avoid confrontation. Assess the situation for possible causes of the agitation. Nursing interventions that may be helpful include (1) creating a quiet, calm environment; (2) maximizing exposure to daylight (open blinds and turn on lights during the day); (3) evaluating medications to determine if any could cause sleep disturbance; (4) limiting naps and caffeine; and (5) consulting with the health care provider regarding drug therapy. Management of sundowning can be challenging for you, the patient, and the family.

Safety. The person with AD is at risk for problems related to personal safety. Potential hazards include falling, ingesting dangerous substances, wandering, injuring others and self with sharp objects, being burned, and being unable to respond to crisis situations. These concerns require careful attention to the home environment to minimize risk. Supervision is also required. As the patient's cognitive function declines over time, the patient may have difficulty navigating physical spaces and interpreting environmental cues. Assist the caregiver in assessing the home environment for safety risks.

SAFETY ALERT

Teach the caregiver to take the following steps:

- Have stairwells well lit.
- Handrails should be graspable.
- Tack down carpet edges.
- Remove throw rugs and extension cords.
- Use nonskid mats in tub or shower.
- Install handrails in the bath and by the commode.

Wandering is a major concern for caregivers. Wandering may be related to loss of memory or to side effects of drugs, or it may be an expression of a physical or emotional need, restlessness, curiosity, or stimuli that trigger memories of earlier routines. As with other behaviors, observe for factors or events that may precipitate wandering. For example, the patient may be sensitive to stress and tension in the environment. In such cases, wandering may reflect an attempt to leave.[19]

When someone with AD is discovered missing, every second counts. To assist caregivers with locating them, the Alzheimer's Association and the MedicAlert Foundation have created an alliance called MedicAlert + Alzheimer's Association Safe Return.[20] This program includes identification products (e.g.,

DELEGATION DECISIONS

Caring for the Patient With Alzheimer's Disease

All staff members who care for a patient with Alzheimer's disease (AD) are responsible for ensuring the patient's physiologic and psychosocial safety. The registered nurse (RN) is responsible for ongoing assessments of the patient's level of function and for development of the plan of care. Since most patients with AD are cared for at home or in long-term care settings, many routine nursing activities are delegated to licensed practical/vocational nurses (LPN/LVNs), unlicensed assistive personnel (UAP), or family caregivers.

Role of Registered Nurse (RN)

- Assess patient memory and level of function.
- Teach patient and caregivers memory enhancement aids (e.g., calendars, notes).
- Monitor for physiologic problems associated with AD, such as pain, swallowing difficulties, urinary tract infection, pneumonia, skin breakdown, and constipation.
- Assess patient's nutritional and fluid intake and develop a plan to ensure adequate intake.
- Evaluate patient's safety risk factors.
- Determine possible precipitating factors for behavioral changes and develop strategies to address difficult behavior.
- Assess the family caregiver's stress level and coping strategies.
- Make referrals for community services such as adult day care and respite care.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- Monitor for behavioral changes that may indicate physiologic problems.
- Check patient environment for potential safety hazards.
- Administer enteral feedings to patients who are unable to swallow (if ordered).
- Administer ordered drug therapy.

Role of Unlicensed Assistive Personnel (UAP)

- Assist patient to use the toilet, commode, or bedpan at frequent intervals.
- Provide personal hygiene, skin care, oral care.
- Help patients with eating.
- Assist patients with daily activities.
- Use bed alarms and surveillance to decrease risk for falls.

bracelet, necklace, wallet cards), a national photo and information database, a 24-hour toll-free emergency crisis line, local chapter support, and wandering behavior education and training for caregivers and families.

Pain Management. Because of difficulties with oral and written language, AD patients may have difficulty expressing physical complaints, including pain. You need to rely on other clues such as the patient's behavior. Pain can result in alterations in the patient's behavior, such as increased vocalization, agitation, withdrawal, and changes in function. Pain should be recognized and treated promptly and the patient's response monitored.

Eating and Swallowing Difficulties. Undernutrition is a problem in the moderate and severe stages of AD, with patients in long-term facilities having the highest incidence of undernutrition. Loss of interest in food and decreased ability to self-feed *(feeding apraxia),* as well as co-morbid conditions, can result in significant nutritional deficiencies in the patient with AD. In long-term care facilities, inadequate assistance with feeding may add to the problem.

Use pureed foods, thickened liquids, and nutritional supplements when chewing and swallowing become problematic for the patient. Patients may need reminders to chew their food and to swallow. Patients need a quiet and unhurried environment for eating. Avoid distractions at mealtimes, including the television. Low lighting, music, and simulated nature sounds may improve eating behaviors. Easy-grip eating utensils and finger foods may allow the patient to self-feed. Offer liquids frequently.

When oral feeding is not possible, explore alternative routes. Nasogastric (NG) feeding may be used for short periods. However, for the long term the NG tube is uncomfortable and may add to the patient's agitation. A percutaneous endoscopic gastrostomy (PEG) tube provides another option (see Fig. 40-7). However, PEG tubes can be problematic, since patients with AD are particularly vulnerable to aspiration of feeding formula and tube dislodgment. The potential positive outcomes to be gained from nutritional therapies are considered in light of overall outcome goals and potential adverse effects of the specific therapy. Nutritional support therapies are described in Chapter 40.

Oral Care. In the late stages of AD the patient is unable to perform oral self-care. With decreased tooth brushing and flossing, dental problems are likely to occur. Because of swallowing difficulties, patients may retain food in the mouth, adding to the potential for tooth decay. Dental caries and tooth abscess can add to patient discomfort or pain and subsequently may increase agitation. Inspect the mouth regularly and provide mouth care to those patients unable to do self-care.

Infection Prevention. Urinary tract infection and pneumonia are the most common infections in patients with AD. Such infections are ultimately the cause of death in many patients with AD. Because of feeding and swallowing problems, the patient is at risk for aspiration pneumonia. Immobility can also predispose the patient to pneumonia. Reduced fluid intake, prostate hyperplasia in men, poor hygiene, and urinary drainage devices (e.g., catheters) can predispose patients to bladder infection. Any manifestations of infection, such as a change in behavior, fever, cough (pneumonia), or pain on urination (bladder), need prompt evaluation and treatment.

Skin Care. It is important to monitor the patient's skin over time. Note and treat rashes, areas of redness, and skin breakdown. In the late stages, incontinence along with immobility and undernutrition can place the patient at risk for skin breakdown. Keep the skin dry and clean, and change the patient's position regularly to avoid areas of pressure over bony prominences.

Elimination Problems. During the moderate and severe stages of AD, urinary and fecal incontinence lead to increased need for nursing care. When possible, habit or behavioral retraining of bladder and bowel function (e.g., scheduled toileting) may help decrease episodes of incontinence.

Another common elimination problem is constipation. Causes may relate to immobility, dietary intake (e.g., reduced fiber intake), and decreased fluid intake. Increased dietary fiber, fiber supplements, and stool softeners are the first lines of management. The combination of aging, other health problems, and swallowing difficulties may increase the risk of complications associated with the use of mineral oil, stimulants, osmotic agents, and enemas. Management of constipation is discussed in Chapter 43.

Caregiver Support. An estimated 15 million Americans provide unpaid care for people with AD or other dementia.[1] The majority of these are family members providing care in the home (Fig. 60-8). AD is a disease that disrupts all aspects of personal and family life. Caregivers for persons with AD describe it as very

FIG. 60-8 Caregivers of patients with dementia face an incredible challenge that often causes deterioration in their own physical and emotional health. (iStockphoto/Thinkstock.)

stressful (see Table 4-5). These caregivers also exhibit adverse consequences relating to their own emotional and physical health.

The chronic and often severe stress associated with dementia caregiving increases the risk for the development of dementia in spouse caregivers. One mechanism proposed is that the detrimental effects of the chronic stress of caregiving can affect the hippocampus, a region of the brain responsible for memory.[21]

As the disease progresses, the relationship of the caregiver to the patient changes. Family roles may be altered or reversed (e.g., son caring for father). Decisions must be made, including when to tell the patient about the diagnosis, when to have the patient stop driving or doing activities that might be dangerous, when to ask for assistance, and when to place the patient in adult day care or a long-term care facility. With early-onset AD, the patient is affected during his or her most productive years in terms of career and family. The consequences can be devastating for the patient and the family.[22]

Sexual relations for couples are also seriously affected by AD. As the disease progresses, sexual interest may decline for both the patient and partner. A number of reasons account for this, including fatigue, memory impairment, and episodes of incontinence. The patient may also become sexually driven as the disease progresses and the patient becomes more uninhibited.

Work with the caregiver to assess stressors (see Table 4-4) and to identify coping strategies to reduce the burden of caregiving.[23] For example, ask which behaviors are most disruptive to family life at a given time, while remembering that this is likely to change as the disease progresses. Determining what the caregiver views as most disruptive or distressful can help to establish priorities for care. Risk to the safety of the patient and caregiver is given high priority. It is also important to assess what the caregiver's expectations are regarding the patient's behavior. Are the expectations reasonable given the progression of the disease? A family and caregiver teaching guide based on the disease stages is provided in Table 60-12. Other tips for caregivers are listed in Table 60-13. A nursing care plan for the family caregiver (eNursing Care Plan 60-2) is available on the website for this chapter.

TABLE 60-12 FAMILY & CAREGIVER TEACHING GUIDE

Alzheimer's Disease

Include the following instructions when teaching families and caregivers the management of the patient with Alzheimer's disease.

Mild Stage

- Many treatable (and potentially reversible) conditions can mimic dementia (see Table 60-2). Try to get a definitive diagnosis.
- Get the person to stop driving. Confusion and poor judgment can impair driving skills and potentially put others at risk.
- Encourage activities such as visiting with friends and family, listening to music, participating in hobbies, and exercising.
- Provide cues in the home, establish a routine, and determine a specific location where essential items (e.g., glasses) need to be kept.
- Do not correct misstatements or faulty memory.
- Register with MedicAlert + Alzheimer's Association Safe Return, a program established by the MedicAlert Foundation and the Alzheimer's Association to locate individuals who wander from their homes.
- Make plans for the future in terms of advance directives, care options, financial concerns, and personal preference for care.

Moderate Stage

- Install door locks for patient safety.
- Provide protective wear for urinary and fecal incontinence.
- Ensure that the home has good lighting, install handrails in stairways and bathroom, and remove area rugs.
- Label drawers and faucets (hot and cold) to ensure safety.
- Develop strategies such as distraction and diversion to cope with behavioral problems. Identify and reduce potential triggers (e.g., reduce stress, extremes in temperature) for disruptive behavior.
- Provide memory triggers, such as pictures of family and friends.

Severe Stage

- Provide a regular schedule for toileting to reduce incontinence.
- Provide care to meet needs, including oral care and skin care.
- Monitor diet and fluid intake to ensure their adequacy.
- Continue communication through talking and touching.
- Consider placement in a long-term care facility when providing total care becomes too difficult.

Support groups for caregivers and family members (Fig. 60-9) can provide an atmosphere of understanding and give current information about the disease itself and related topics such as safety, legal, ethical, and financial issues. The needs of family caregivers are discussed in Chapter 4 on pp. 51-52. Strategies related to stress management are discussed in Chapter 7.

The Alzheimer's Association has many educational and support systems available to help family caregivers. The link to a booklet for caregivers, *Caring for a Person With Alzheimer's Disease,* is provided in the Resources section at the end of this chapter.

EVALUATION

Expected outcomes are that the patient with AD will

- Function at the highest level of cognitive ability
- Perform basic personal care activities of daily living, including bathing, dressing, feeding, and toileting by self or with assistance as needed

TABLE 60-13 GUIDELINES FOR DEALING WITH DEMENTIA PATIENTS

Do

- Treat them like adults, with respect and dignity, even when their behavior is childlike.
- Use gentle touch and direct eye contact.
- Remain patient, flexible, calm, and understanding.
- Anticipate challenging behaviors, since the patient's ability to think logically has been affected.
- Give directions using gestures or pictures.
- Simplify tasks. Focus on one thing at a time.
- Avoid questions or topics that require extensive thought, memory, or words.
- Be flexible. If one approach does not work, try another.
- Use distraction, changing the subject, redirecting to another activity.
- Provide reassurance. Praise sincerely for success.

Do Not

- Criticize, correct, or argue.
- Rush or hurry the patient.
- Force participation in activities or events.
- Talk about the patient as if he or she is not there.
- Blame the person with AD. Instead blame the disease.
- Take challenging behaviors personally. These behaviors are due to the patient's disease.
- Use condescending terms, such as "honey" or "sweetie."
- Use threatening gestures.
- Overreact to the person with AD.
- Try to explain "why" or rationalize.

FIG. 60-9 Support groups are an effective way to help caregivers cope. (iStockphoto/Thinkstock.)

- Experience no injury
- Remain in restricted area during ambulation and activity

Additional information on the expected outcomes for the patient with AD is addressed in eNursing Care Plan 60-1 (available on the website for this chapter).

OTHER NEURODEGENERATIVE DISEASES

Parkinson's disease and Huntington's disease are both neurodegenerative diseases (see Chapter 59). Both diseases are chronic, progressive, and incurable. Despite differences in the etiology and pathophysiology of these diseases, both are associated with the development of dementia in the later stages of disease.

Dementia with Lewy bodies (DLB) is a condition characterized by the presence of Lewy bodies (abnormal deposits of the protein α-synuclein) in the brainstem and cortex. Patients typically have symptoms of parkinsonism, hallucinations, short-term memory loss, unpredictable cognitive shifts, and sleep disturbances. A possible diagnosis of DLB is indicated by dementia plus two of the following symptoms: (1) extrapyramidal signs such as bradykinesia, rigidity, and postural instability, but not always a tremor; (2) fluctuating cognitive ability; and (3) hallucinations. This disease has features of both AD and Parkinson's disease, and it is imperative that a correct diagnosis be reached.

Medications for DLB are determined on an individual basis. Medications may include levodopa/carbidopa and acetylcholinesterase inhibitors. Nursing care for these patients relates to

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Does Cognitive Reframing Help Caregivers of Patients With Dementia?

Clinical Question

What are the effects of cognitive reframing interventions (I) on psychologic morbidity and stress (O) in family caregivers (P) of patients with dementia?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Eleven RCTs (n = 1139) on family caregivers of community-dwelling people with dementia.
- Cognitive reframing is changing distressing cognitions and thoughts into ones that support adaptive behavior.
- Interventions focused on (1) family caregivers' beliefs about their own responsibilities and interpretation of problem behaviors of their relatives with dementia and/or (2) beliefs about their own need for support and assistance.
- Outcomes were psychologic morbidity (depression, anxiety); caregiver stress; and caregiver appraisals of burden, coping, and problem behaviors in their relative with dementia.
- Cognitive reframing reduced caregivers' anxiety, depression, and stress but did not affect their appraisals of coping or burden or reactions to their relatives' behaviors.

Conclusion

- Cognitive reframing for family caregivers reduces psychologic morbidity and stress.

Implications for Nursing Practice

- Assess the intensity and complexity of family caregivers' responsibilities and demands.
- Help caregivers access stress management resources (e.g., support groups) in their communities.
- Support and encourage caregivers to identify and implement strategies to reduce their stress, depression, and anxiety.

Reference for Evidence

Vernooij-Dassen M, Draskovic I, McCleery J, et al: Cognitive reframing for carers of people with dementia, *Cochrane Database Syst Rev* 11: CD005318, 2011.

P, Patient population of interest; *I*, intervention or area of interest; *O*, outcomes of interest (see p. 12).

management of the dementia and of problems related to dysphagia and immobility. Swallowing problems can lead to impaired nutrition. These patients are at risk for falls from impaired mobility and balance. Pneumonia is a common complication. The diagnostic criteria for LBD are based on clinical signs and symptoms and confirmed at autopsy by histologic examination of brain tissue.

Frontotemporal lobar degeneration (FTLD) is a clinical syndrome associated with shrinking of the frontal and temporal anterior lobes of the brain. In Pick's disease, one type of FTLD, the brain has abnormal microscopic deposits called Pick bodies (though these are not always present). In FTLD, portions of the frontal and temporal lobes atrophy. FTLD is often misdiagnosed as a psychiatric problem or as AD. However, FTLD tends to occur at a younger age than does AD, typically between ages 40 and 70. The major distinguishing characteristic between these disorders and AD is marked symmetric lobar atrophy of the temporal and/or frontal lobes.

FTLD is characterized by disturbances in behavior, sleep, personality, and eventually memory. The disease progresses relentlessly and may ultimately include language impairment, erratic behavior, and dementia. Because of the strange behavior associated with FTLD, psychiatrists often see these patients first. There is no specific treatment. The diagnosis can be confirmed at autopsy.

Normal pressure hydrocephalus is an uncommon disorder characterized by an obstruction in the flow of CSF, causing a buildup of CSF in the brain. Symptoms of the condition include dementia, urinary incontinence, and difficulty walking. Meningitis, encephalitis, or head injury may cause the condition. If diagnosed early, normal pressure hydrocephalus is treatable by surgery in which a shunt is inserted to divert the fluid away from the brain.

Creutzfeldt-Jakob disease (CJD) is a rare and fatal brain disorder caused by a prion protein. A *prion* is a small infectious pathogen containing protein but lacking nucleic acids. The source of infection of a variant form of CJD (vCJD) is beef obtained from animals contaminated with bovine spongiform encephalopathy, which is also called *mad cow disease.* The risk of contracting vCJD is extremely low.

The earliest symptom of the disease may be memory impairment and behavior changes. The disease progresses rapidly with mental deterioration, involuntary movements (muscle jerks), weakness in the limbs, blindness, and eventually coma. There is no diagnostic test for CJD. Only autopsy and examination of brain tissue can confirm the diagnosis. There is no treatment for CJD.

Mixed dementia occurs when two or more types of dementia are present at the same time. It is characterized by the hallmark abnormalities of Alzheimer's and another type of dementia. Usually the other type of dementia is vascular dementia, but it can be other types, such as DLB.

DELIRIUM

Delirium, a state of temporary but acute mental confusion, is a common, life-threatening, and possibly preventable syndrome. Delirium is the most frequent complication of hospitalization in older patients. In the hospital setting, 15% to 53% of older adults experience delirium postoperatively, and as many as 80% of patients in an intensive care unit (ICU) experience delirium.[24]

TABLE 60-14 FACTORS THAT PRECIPITATE DELIRIUM

Demographic Characteristics
- Age 65 yr or older
- Male gender

Cognitive Status
- Dementia
- Cognitive impairment
- History of delirium
- Depression

Environmental
- Admission to an intensive care unit
- Use of physical restraints
- Pain (especially untreated)
- Emotional stress
- Sleep deprivation

Functional Status
- Functional dependence
- Immobility
- History of falls

Sensory
- Sensory deprivation
- Sensory overload
- Visual or hearing impairment

Decreased Oral Intake
- Dehydration
- Malnutrition

Drugs
- Sedative-hypnotics
- Opioids
- Anticholinergic drugs
- Aminoglycosides
- Treatment with multiple drugs
- Alcohol or drug abuse or withdrawal

Coexisting Medical Conditions
- Severe acute illness
- Electrolyte imbalances
- Chronic renal or hepatic disease
- History of stroke
- Neurologic disease
- Acute infection, sepsis, fever
- Fracture or trauma
- Terminal illness

Surgery
- Orthopedic surgery
- Cardiac surgery
- Prolonged cardiopulmonary bypass
- Noncardiac surgery

Etiology and Pathophysiology

The pathophysiologic mechanism of delirium is poorly understood. The main hypothesis is reversible impairment of cerebral oxidative metabolism and multiple neurotransmitter abnormalities. Cholinergic deficiency, excess release of dopamine, and both increased and decreased serotonergic activity may contribute to delirium. Proinflammatory cytokines, including interleukin-1, interleukin-2, interleukin-6, tumor necrosis factor–α (TNF-α), and interferon, appear to play a role. Stress and sleep deprivation have also been linked to the onset of delirium.[25]

Clinically, delirium is rarely caused by a single factor. It is often the result of the interaction of the patient's underlying condition with a precipitating event. Delirium can occur after a relatively minor insult in a vulnerable patient. For example, a patient with underlying health problems such as heart failure, cancer, cognitive impairment, or sensory limitations may develop delirium in response to a relatively minor change (e.g., use of a sleeping medication). In other nonvulnerable patients, it may take a combination of factors (e.g., anesthesia, major surgery, infection, prolonged sleep deprivation) to precipitate delirium. Delirium can also be a symptom of a serious medical illness such as bacterial meningitis.

Understanding factors that can lead to delirium can help in determining effective interventions. Several factors that can precipitate or cause delirium are listed in Tables 60-14 and 60-15. Many of these factors are more common in older patients.[26] In addition, older patients have limited compensatory mechanisms to deal with physiologic insults such as hypoxia, hypoglycemia, and dehydration. Older adults are more susceptible to drug-induced delirium, in part because of their

TABLE 60-15 MNEMONIC FOR CAUSES OF DELIRIUM

Dementia, dehydration
Electrolyte imbalances, emotional stress
Lung, liver, heart, kidney, brain
Infection, intensive care unit
Rx Drugs
Injury, immobility
Untreated pain, unfamiliar environment
Metabolic disorders

increased use of multiple drugs. Many medications, including sedative-hypnotics, opioids (especially meperidine [Demerol]), benzodiazepines, and drugs with anticholinergic properties, can cause or contribute to delirium, especially in older or vulnerable patients. An important risk factor for delirium is preexisting dementia.[27]

Clinical Manifestations

Patients with delirium can have a variety of manifestations ranging from hypoactivity and lethargy to hyperactivity, agitation, and hallucinations. Patients can also have mixed delirium, manifesting both hypoactive and hyperactive symptoms. Delirium can develop over the course of hours to days. In most patients, delirium usually develops over a 2- to 3-day period. The early manifestations often include inability to concentrate, irritability, insomnia, loss of appetite, restlessness, and confusion. Later manifestations may include agitation, misperception, misinterpretation, and hallucinations.

Acute delirium occurs frequently in hospitalized older adults. This transient condition is characterized by disorganized thinking, difficulty concentrating, and sensory misperceptions that last from 1 to 7 days. However, some delirium manifestations may persist up to and after discharge. Delirium is one of the most frequent consequences of unscheduled surgery on the older adult, especially when the patient has not been stabilized physically or prepared emotionally. Often this patient experiences a decline in ability to perform activities of daily living and an increased risk for falls.

Manifestations of delirium are sometimes confused with those of dementia. A key distinction between delirium and dementia is that the person who exhibits sudden cognitive impairment, disorientation, or clouded sensorium is more likely to have delirium rather than dementia. (A comparison of delirium and dementia is presented in Table 60-1.)

Diagnostic Studies

Diagnosing delirium is complicated because many critically ill patients cannot communicate their needs. A careful medical and psychologic history and physical examination are the first steps in diagnosing delirium. This includes careful attention to medications, both prescription and over-the-counter drugs. The Confusion Assessment Method (CAM) has been extensively studied and is a reliable tool for assessing delirium (Table 60-16). It is important to distinguish whether the delirium is part of an underlying problem of dementia.

Once delirium has been diagnosed, explore potential causes. Carefully review the patient's health history and medication record. Laboratory tests include complete blood count, serum electrolytes, blood urea nitrogen, and creatinine levels; electrocardiogram; urinalysis; liver and thyroid function tests; and oxygen saturation level. Drug and alcohol levels may be obtained. If unexplained fever or nuchal rigidity is present and meningitis or encephalitis is suspected, a lumbar puncture may be performed. CSF is examined for glucose, protein, and bacteria. If the patient's history includes head injury, appropriate x-rays or scans may be ordered. In general, brain imaging studies such as CT and MRI are used only in situations in which head injury is known or suspected.

TABLE 60-16 CONFUSION ASSESSMENT METHOD (CAM)

Delirium is diagnosed with the presence of features 1 and 2, and either 3 or 4.

Feature 1 ***Acute Onset and Fluctuating Course***	Data usually obtained from a family member or nurse. Shown by positive responses to following questions: • Is there evidence of an acute change in mental status from the patient's baseline? • Did the (abnormal) behavior fluctuate during the day (i.e., tend to come and go, or increase and decrease in severity)?
Feature 2 ***Inattention***	Shown by positive response to following question: • Did the patient have difficulty focusing attention (e.g., being easily distractible, or having difficulty keeping track of what was being said)?
Feature 3 ***Disorganized Thinking***	Shown by a positive response to following question: • Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?
Feature 4 ***Altered Level of Consciousness***	Shown by any answer other than "alert" to the following question: • Overall, how would you rate this patient's level of consciousness (alert [normal], vigilant [hyperalert], lethargic [drowsy, easily aroused], stupor [difficult to arouse], or coma [unarousable])?

Adapted from Inouye S, van Dyck C, Alessi C, et al: Clarifying confusion: the Confusion Assessment Method, *Ann Intern Med* 113(12):941, 1990.

NURSING AND COLLABORATIVE MANAGEMENT DELIRIUM

In caring for the patient with delirium, your roles include prevention, early recognition, and treatment. Prevention of delirium involves recognition of high-risk patients.[28] Patient groups at risk include those with neurologic disorders (e.g., stroke, dementia, CNS infection, Parkinson's disease), sensory impairment, and advanced age. Other risk factors, including hospitalization in an ICU and untreated pain, are listed in Table 60-14.

Care of the patient with delirium focuses on eliminating precipitating factors.[29] If it is drug induced, medications are discontinued. Keep in mind that delirium can also accompany drug and alcohol withdrawal. Depending on patient history, drug screening may be performed. Fluid and electrolyte imbalances and nutritional deficiencies (e.g., thiamine) are corrected

ETHICAL/LEGAL DILEMMAS

Board of Nursing Disciplinary Action

Situation

The State Board of Nursing has received multiple complaints about J.R., a registered nurse (RN) who works in a long-term care facility. J.R. has signed off on three controlled substances count sheets that have been determined to be inaccurate. During an investigation it was discovered that several members of the nursing staff knew about J.R.'s reported behavior, but they did not report their observations to the unit administrator. After the investigation, the board of nursing subpoenas J.R. to a meeting to discuss charges in preparation for a disciplinary hearing.

Ethical/Legal Points for Consideration

- Regulation of professional nursing practice is the right of each of the 50 states, most of which have separate regulatory agencies charged with writing regulations and rules to implement the State Nurse Practice Act. The regulations approved by these agencies carry the weight of law. Failure to behave accordingly places a nurse at risk for disciplinary action.
- The RN who is charged with unprofessional behavior has been charged with an offense and is entitled to the same legal rights as any other individual, including a fair and timely hearing, opportunity to confront the accusers, right to be represented by an attorney, and right to prepare a defense.
- Possible disciplinary actions include temporary suspension of the nursing license, revocation of the nursing license, mandatory rehabilitation for substance abuse, and mandated supervision and evaluation of practice. Sometimes the disciplinary action includes fines and requires re-education. In addition, the State Board of Nursing may report the action to the state attorney general if evidence suggests that a crime has been committed. The RN who has been found guilty of unprofessional practice must report this action on all future applications for nursing positions.
- All RNs should be familiar with their state's nurse practice act and regulations, as well as the composition and actions of the State Board of Nursing. Nurses should pay particular attention to the regulation that lists examples of actionable behavior and disciplinary actions sanctioned by the state.
- RNs have a legal and ethical obligation to report suspected illegal behavior to their administrators and to continue reporting until the situation is resolved. By failing to report, the RN may be charged as an accessory to the act or aiding and abetting the behavior. This RN may be charged with unprofessional behavior and risks losing his or her nursing license. Shifting the obligation to someone else to report or failure to continue reporting each incident does not satisfy this duty.

Discussion Questions

1. How would you handle a situation where retaliation for reporting unprofessional behavior is likely?
2. What would you do if the nurse suspected of illegal behavior is related to someone in the administrative hierarchy?

if appropriate. If the problem is related to environmental conditions (e.g., an overstimulating or understimulating environment), changes should be made. If delirium is secondary to infection, appropriate antibiotic therapy is started. Similarly, if delirium is secondary to chronic illness such as chronic kidney disease or heart failure, treatment focuses on these conditions.[30]

Care of the patient experiencing delirium includes protecting the patient from harm. Give priority to creating a calm and safe environment. This may include encouraging family members to stay at the bedside, providing familiar objects, transferring the patient to a private room or one closer to the nurses' station, and planning for consistent nursing staff if possible. Use reorientation and behavioral interventions in patients with delirium. Provide the patient with reassurance and reorienting information as to place, time, and procedures. Clocks, calendars, and lists of the patient's scheduled activities are also useful in reducing confusion. Reduce environmental stimuli, including noise and light levels.

Personal contact through touch and verbal communication can be an important reorienting strategy. If the patient uses eyeglasses or a hearing aid, they should be readily available because sensory deprivation can precipitate delirium. Avoid the use of restraints. Other interventions, including relaxation techniques, music therapy, and massage, may also be appropriate for some patients with delirium.

Comprehensive, multicomponent interventions to prevent delirium are the most effective and should be implemented through institution-based programs that are interdisciplinary. These interdisciplinary teams may also address issues related to polypharmacy, pain, nutritional status, and potential for incontinence. The patient experiencing delirium is also at risk for the adverse consequences of immobility, including skin breakdown. Give attention to increasing physical activity or providing range-of-motion exercises, when appropriate, and maintaining skin integrity.

Also focus on supporting the family and caregivers during episodes of delirium. Family members need to understand factors that may have precipitated the delirium, as well as the potential outcomes. *Delirium in the ICU: A Guide for Patients and Families* is available in eTable 66-1 (available on the website for Chapter 66).

DRUG THERAPY

Drug therapy is reserved for patients with severe agitation, especially when it interferes with needed medical therapy (e.g., fluid replacement, intubation, dialysis). Agitation can put the patient at risk for falls and injury. Drug therapy is used cautiously because many of the drugs used to manage agitation have psychoactive properties. Drugs should be used only when nonpharmacologic interventions have failed.

Dexmedetomidine (Precedex), an α-adrenergic receptor agonist, has been used in ICU settings for sedation. In addition, low-dose antipsychotics (neuroleptics) may be used such as haloperidol (Haldol), risperidone (Risperdal), olanzapine (Zyprexa), and quetiapine (Seroquel). Haloperidol can be administered IV, intramuscularly, or orally and will produce sedation. In addition to sedation, other side effects of antipsychotics include hypotension; extrapyramidal side effects, including *tardive dyskinesia* (involuntary muscle movements of face, trunk, and arms) and *athetosis* (involuntary writhing movements of the limbs); muscle tone changes; and anticholinergic effects. Carefully monitor older patients receiving antipsychotic agents.

Short-acting benzodiazepines (e.g., lorazepam [Ativan]) can be used to treat delirium associated with sedative and alcohol withdrawal or in conjunction with antipsychotics to reduce extrapyramidal side effects. However, these drugs may worsen delirium caused by other factors and must be used cautiously.

CASE STUDY

Alzheimer's Disease

iStockphoto/Thinkstock

Patient Profile

M.Y., an 80-yr-old Asian American man, was diagnosed with Alzheimer's disease (AD) 3 yr ago. Today his 78-yr-old wife brings him to the emergency department because he wandered from his home, fell, and injured his left hip.

Subjective Data

- Can state his name
- Confused as to place and time
- Denies memory of wandering or falling
- Agitated, trying to get up
- Denies pain

Objective Data

Physical Examination

- Left leg shorter than right leg
- Tense and anxious

Diagnostic Studies

- X-ray of left hip indicates a fracture
- Mini-Cog testing indicates cognitive impairment

Discussion Questions

1. What is the pathogenesis of AD?
2. What precipitating factors may have resulted in M.Y.'s fall?
3. What precautions need to be taken regarding the inpatient care of M.Y.?
4. ***Priority Decision:*** What is the priority nursing intervention for M.Y.?
5. What teaching plan should you develop for M.Y. and his wife?
6. Surgery is planned to repair his fractured hip. Why is he at risk for delirium?
7. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Delegation Decision:*** What nursing activities can the RN delegate to unlicensed assistive personnel (UAP)?
9. ***Evidence-Based Practice:*** M.Y.'s wife asks you if she should give her husband ginkgo to help his memory. How would you respond?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Dementia is defined as a
   - a. syndrome that results only in memory loss.
   - b. disease associated with abrupt changes in behavior.
   - c. disease that is always due to reduced blood flow to the brain.
   - d. syndrome characterized by cognitive dysfunction and loss of memory.
2. Vascular dementia is associated with
   - a. transient ischemic attacks.
   - b. bacterial or viral infection of neuronal tissue.
   - c. cognitive changes secondary to cerebral ischemia.
   - d. abrupt changes in cognitive function that are irreversible.
3. The clinical diagnosis of dementia is based on
   - a. CT or MRS.
   - b. brain biopsy.
   - c. electroencephalogram.
   - d. patient history and cognitive assessment.
4. Which statement(s) accurately describe(s) mild cognitive impairment *(select all that apply)?*
   - a. Always progresses to AD
   - b. Caused by variety of factors and may progress to AD
   - c. Should be aggressively treated with acetylcholinesterase drugs
   - d. Caused by vascular infarcts that, if treated, will delay progression to AD
   - e. Patient is usually not aware that there is a problem with his or her memory
5. The early stage of AD is characterized by
   - a. no noticeable change in behavior.
   - b. memory problems and mild confusion.
   - c. increased time spent sleeping or in bed.
   - d. incontinence, agitation, and wandering behavior.
6. A major goal of treatment for the patient with AD is to
   - a. maintain patient safety.
   - b. maintain or increase body weight.
   - c. return to a higher level of self-care.
   - d. enhance functional ability over time.
7. Creutzfeldt-Jakob disease is characterized by
   - a. remissions and exacerbations over many years.
   - b. memory impairment, muscle jerks, and blindness.
   - c. parkinsonian symptoms, including muscle rigidity and tremors at rest.
   - d. increased intracranial pressure secondary to decreased CSF drainage.
8. Which patient is most at risk for developing delirium?
   - a. A 50-year-old woman with cholecystitis
   - b. A 19-year-old man with a fractured femur
   - c. A 42-year-old woman having an elective hysterectomy
   - d. A 78-year-old man admitted to the medical unit with complications related to heart failure

1. d, 2. c, 3. d, 4. b, 5. b, 6. a, 7. b, 8. d

LEARNING OUTCOMES

1. Explain the etiology, clinical manifestations, collaborative care, and nursing management of trigeminal neuralgia and Bell's palsy.
2. Explain the etiology, clinical manifestations, collaborative care, and nursing management of Guillain-Barré syndrome, botulism, tetanus, and neurosyphilis.
3. Describe the classification of spinal cord injuries and associated clinical manifestations.
4. Describe the clinical manifestations, collaborative care, and nursing management of neurogenic and spinal shock.
5. Relate the clinical manifestations of spinal cord injury to the level of disruption and rehabilitation potential.
6. Describe the nursing management of the major physical and psychologic problems of the patient with a spinal cord injury.
7. Describe the effects of spinal cord injury on the older adult.
8. Explain the types, clinical manifestations, collaborative care, and nursing management of spinal cord tumors.

This chapter discusses peripheral nerve and spinal cord problems, including cranial nerve disorders, polyneuropathies, spinal cord injuries, and spinal cord tumors. A focus of this chapter is the nursing management of the many problems encountered by the patient with a spinal cord injury.

CRANIAL NERVE DISORDERS

Cranial nerve disorders are commonly classified as peripheral neuropathies. The 12 pairs of cranial nerves are considered the peripheral nerves of the brain. The disorders usually involve the motor or sensory (or both) branches of a single nerve *(mononeuropathies)*. Causes of cranial nerve problems include tumors, trauma, infections, inflammatory processes, and idiopathic (unknown) causes. Two cranial nerve disorders discussed in this chapter are trigeminal neuralgia and Bell's palsy.

TRIGEMINAL NEURALGIA

Trigeminal neuralgia *(tic douloureux)* is sudden, usually unilateral, severe, brief, stabbing, recurrent episodes of pain in the distribution of the trigeminal nerve. It is diagnosed in approximately 150,000 Americans each year and is the most commonly diagnosed neuralgic condition. It is seen approximately twice as often in women as in men. The majority of cases (more than 90%) are diagnosed in individuals over age 40.[1]

Etiology and Pathophysiology

The trigeminal nerve is the fifth cranial nerve (CN V) and has both motor and sensory branches. In trigeminal neuralgia the sensory or afferent branches, primarily the maxillary and mandibular branches, are involved (Fig. 61-1).

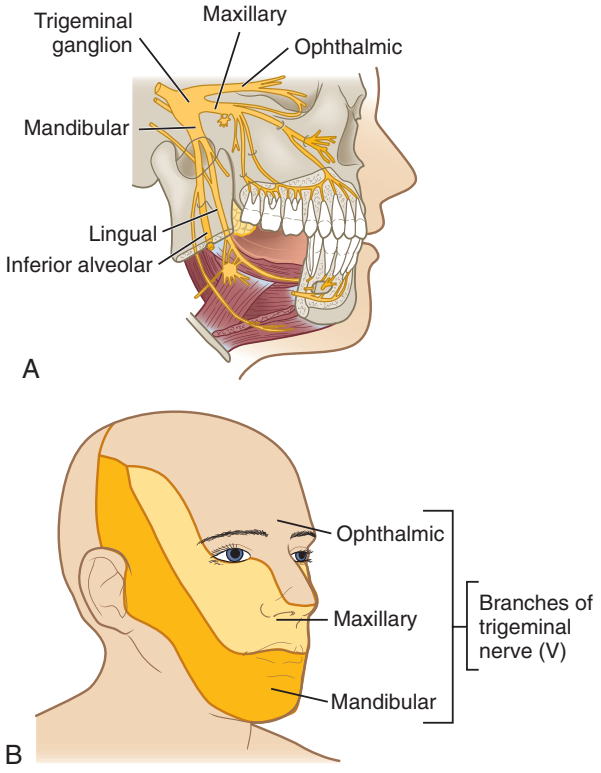

FIG. 61-1 **A,** Trigeminal (fifth cranial) nerve and its three main divisions: ophthalmic, maxillary, and mandibular nerves. **B,** Cutaneous innervation of the head.

The etiology and pathophysiology of trigeminal neuralgia is not fully understood.[2] One theory is that blood vessels, especially the superior cerebellar artery, become compressed, resulting in chronic irritation of the trigeminal nerve at the root entry zone. This irritation leads to increased firing of the afferent or sensory fibers. Risk factors are multiple sclerosis and hypertension. Other factors that may cause neuralgia include herpesvirus infection, infection of the teeth and jaw, and a brainstem infarct.

Clinical Manifestations

The classic feature of trigeminal neuralgia is an abrupt onset of paroxysms of excruciating pain described as a burning, knife-like, or lightning-like shock in the lips, upper or lower gums, cheek, forehead, or side of the nose. Intense pain, twitching, grimacing, and frequent blinking and tearing of the eye occur during the acute attack (giving rise to the term *tic*). Some patients may also experience facial sensory loss. The attacks are usually brief, lasting only seconds to 2 or 3 minutes, and are generally unilateral.

Recurrences, which are unpredictable, may occur several times a day, or weeks or months apart. After the refractory (pain-free) period, a phenomenon known as clustering can occur. *Clustering* is characterized by a cycle of pain and refractoriness that continues for hours.

The painful episodes are usually initiated by a triggering mechanism of light touch at a specific point *(trigger zone)* along the distribution of the nerve branches. Precipitating stimuli include chewing, tooth brushing, feeling a hot or cold blast of air on the face, washing the face, yawning, or even talking. As a result, the patient may eat improperly, neglect hygienic practices, wear a cloth over the face, and withdraw from interaction with other individuals. The patient may sleep excessively as a means of coping with the pain.

Although this condition is considered benign, the severity of the pain and the disruption of lifestyle can result in almost total physical and psychologic dysfunction or even suicide.

Diagnostic Studies

A computed tomography (CT) scan or magnetic resonance imaging (MRI) of the brain is performed to rule out any lesions (including multiple sclerosis), tumors, or vascular abnormalities. A complete neurologic assessment is done, including audiologic evaluation. The results are usually normal.

Collaborative Care

Once the diagnosis is made, the goal of treatment is relief of pain either medically or surgically (Tables 61-1 and 61-2).

Drug Therapy. Antiseizure drug therapy may reduce pain by stabilizing the neuronal membrane and blocking nerve

TABLE 61-1 COLLABORATIVE CARE

Trigeminal Neuralgia

Diagnostic	Collaborative Therapy
• History and physical examination (including neurologic examination) • CT scan • MRI	• Drug therapy • Antiseizure drugs (e.g., carbamazepine [Tegretol], oxcarbazepine [Trileptal]) • gabapentin (Neurontin) • Tricyclic antidepressants (e.g., amitriptyline [Elavil]) • Local nerve block • Surgical therapy (see Table 61-2)

TABLE 61-2 SURGICAL THERAPY FOR TRIGEMINAL NEURALGIA

Procedure	Description	Effect
Peripheral		
Glycerol rhizotomy (injection into one or more branches of the trigeminal nerve)	Chemical ablation	Total pain relief with sparing of touch and corneal reflex.
Intracranial		
Percutaneous radiofrequency rhizotomy	Destruction of sensory fibers by low-voltage current	Total pain relief, sparing of touch and corneal reflex (increased risk for sensory changes).
Microvascular decompression	Lifting of artery pressing on nerve root in posterior fossa with wedge of sponge, leading to removal of pressure at nerve-root entry zone, or removing the involved vessel	Pain relief without loss of sensation.
Gamma knife radiosurgery	Technique that uses high doses of radiation focused on the trigeminal nerve root using stereotactic localization	Pain relief 1 day–4 mo posttreatment. Noninvasive with no loss of sensation.

FIG. 61-2 A, Patient with trigeminal neuralgia having needle placed. **B,** Physician injecting glycerol.

firing.[2] These first-line drugs include carbamazepine (Tegretol), oxcarbazepine (Trileptal), topiramate (Topamax), clonazepam (Klonopin), phenytoin (Dilantin), lamotrigine (Lamictal), and divalproex (Depakote). Gabapentin (Neurontin) or baclofen (Lioresal) can be used in combination with any of the antiseizure drugs if a single agent is not effective. Tricyclic antidepressants such as amitriptyline (Elavil) or nortriptyline (Pamelor, Aventyl) can be used to treat constant burning, or aching pain.[2] Analgesics or opioids are usually not effective in controlling pain.

Conservative Therapy. Nerve blocking with local anesthetics is another treatment option. Relief of pain is temporary, lasting from 6 to 18 months. This treatment is usually tolerated well by older adults.

Some patients use complementary and alternative therapies, usually in combination with drug treatment. These techniques include acupuncture, biofeedback, vitamin therapy, nutritional therapy, and electrical stimulation of the nerves.

Surgical Therapy. If a conservative approach including drug therapy is not effective, surgical therapy is available (see Table 61-2). *Glycerol rhizotomy* is a percutaneous procedure that consists of an injection of glycerol through the foramen ovale into the trigeminal cistern (Fig. 61-2).

Percutaneous radiofrequency rhizotomy is an outpatient procedure consisting of placing a needle into the trigeminal rootlets that are adjacent to the pons and destroying the area by means of a radiofrequency current. This can result in facial numbness (although some degree of sensation may be retained), corneal anesthesia, and trigeminal motor weakness.[3]

Microvascular decompression of the trigeminal nerve is another commonly used procedure for neuralgia. It is done by first performing a small craniotomy behind the ear (suboccipital craniotomy). The next step involves displacing and repositioning the blood vessels that appear to be compressing the nerve at the root entry zone where it exits the pons. This procedure relieves pain without residual sensory loss, but it is potentially dangerous.[3]

Gamma knife radiosurgery is another surgical treatment that is used to treat trigeminal neuralgia. Radiosurgery (see Chapter 57) using a gamma knife provides precise radiation of the proximal trigeminal nerve identified on high-resolution imaging.

NURSING MANAGEMENT TRIGEMINAL NEURALGIA

Patients with trigeminal neuralgia are primarily treated on an outpatient basis. Assessment of the attacks, including the triggering factors, characteristics, frequency, and pain management techniques, helps you plan for patient care. The nursing assessment should include the patient's nutritional status, hygiene (especially oral), and behavior (including withdrawal). Evaluate the degree of pain and its effects on the patient's lifestyle, drug use, emotional state, and suicidal tendencies.

Monitor the patient's response to drug therapy and note any side effects. Alternative pain relief measures, such as acupuncture and biofeedback, should be explored for the patient who is not a surgical candidate and whose pain is not controlled by other measures. Environmental management is essential during an acute period to decrease triggering stimuli. The room should be kept at an even, moderate temperature and free of drafts. Many patients prefer to carry out their own care, fearing that someone else will inadvertently injure them.

Teach the patient about the importance of nutrition, hygiene, and oral care and convey understanding if previous oral neglect is apparent. A small, soft-bristled toothbrush or a warm mouthwash assists in promoting oral care. Hygiene activities are best carried out when analgesia is at its peak.

Food should be high in protein and calories and easy to chew. It should be served lukewarm and offered frequently. When oral intake is sharply reduced and the patient's nutritional status is compromised, a nasogastric tube can be inserted on the unaffected side for enteral feedings.

Appropriate teaching related to surgical procedures depends on the type of procedure planned (e.g., percutaneous). Patients need to know that they will be awake during local procedures so that they can cooperate when corneal and ciliary reflexes and facial sensations are checked. After the procedure the patient's pain is compared with the preoperative level. The corneal reflex, extraocular muscles, hearing, sensation, and facial nerve function are evaluated frequently (see Chapter 56). If the corneal reflex is impaired, take special care to protect the eyes. This includes the use of artificial tears or eye shields.

If intracranial surgery is performed, general postoperative nursing care after a craniotomy is appropriate. (Nursing care related to craniotomy is discussed in Chapter 57 on p. 1379.)

After a percutaneous radiofrequency procedure, apply an ice pack to the jaw on the operative side for 3 to 5 hours. To avoid injuring the mouth, the patient should not chew on the operative side until sensation has returned.

Plan for regular follow-up care, and instruct the patient on the dosage and side effects of medications. Although relief of pain may be complete, encourage the patient to keep environmental stimuli to a moderate level and to use stress management techniques. Long-term management after surgical intervention depends on the residual effects of the procedure. If anesthesia is present or the corneal reflex is altered, teach the patient to (1) chew on the unaffected side; (2) avoid hot foods or beverages, which can burn the mucous membranes; (3) check the oral cavity after meals to remove food particles; (4) practice meticulous oral hygiene and continue with semiannual dental visits; (5) protect the face against extremes of temperature; (6) use an electric razor; (7) wear a protective eye shield or avoid rubbing eyes; and (8) examine eye regularly for symptoms of infection or irritation.

BELL'S PALSY

Bell's palsy (peripheral facial paralysis, acute benign cranial polyneuritis) is a disorder characterized by inflammation of the facial nerve (CN VII) on one side of the face in the absence of any other disease such as a stroke. Bell's palsy is an acute, peripheral facial paresis of unknown cause. Each year approximately 40,000 Americans are diagnosed with Bell's palsy. It can affect any age-group. Despite its good prognosis, Bell's palsy leaves more than 8000 people a year in the United States with permanent, potentially disfiguring facial weakness.[4]

Etiology and Pathophysiology

Although the exact etiology is not known, it is believed that a viral infection such as viral meningitis or activation of herpes simplex virus 1 (HSV1) may trigger Bell's palsy. The viral infection causes inflammation, edema, ischemia, and eventual demyelination of the nerve, creating pain and alterations in motor and sensory function. Bell's palsy has also been associated with influenza or a flu-like illness, headaches, chronic middle ear infection, hypertension, diabetes, sarcoidosis, tumors, Lyme disease, and trauma such as skull fracture or facial injury.[4]

Bell's palsy is considered benign, with full recovery in 3 to 6 months, especially if treatment is begun immediately. A small group of patients have long-term facial paralysis.[4]

FIG. 61-3 Facial characteristics of Bell's palsy. **A,** At rest the face may look almost normal, but the patient is not able to wrinkle her forehead on the affected side and the right corner of the mouth droops. **B,** When she is asked to close her eyes and show her teeth, the differences between the affected and unaffected sides become more obvious.

Clinical Manifestations and Diagnostic Studies

The onset of Bell's palsy is often accompanied by an outbreak of herpes vesicles in or around the ear. Patients may complain of pain around and behind the ear. Additional manifestations may include fever, tinnitus, and hearing deficit. Paralysis of the motor branches of the facial nerve typically results in flaccidity of the affected side of the face, with drooping of the mouth accompanied by drooling (Fig. 61-3).

An inability to close the eyelid, with an upward movement of the eyeball when closure is attempted, is also evident. Other manifestations include a widened *palpebral fissure* (the opening between the eyelids); flattening of the nasolabial fold; and inability to smile, frown, or whistle. Unilateral loss of taste is common. Decreased muscle movement may alter chewing ability. Although some patients experience a loss of tearing, many patients complain of excessive tearing. The muscle weakness causes the lower lid to turn out, allowing overflow of normal tear production. Pain may be present behind the ear on the affected side, especially before the onset of paralysis.

Complications include psychologic withdrawal because of changes in appearance, malnutrition, dehydration, mucous membrane trauma, corneal abrasions, muscle stretching, and facial spasms and contractures.

The diagnosis of Bell's palsy is one of exclusion. There is no definitive test. The diagnosis and prognosis are indicated by observing the typical pattern of onset and signs and testing percutaneous nerve excitability by electromyography (EMG).

Collaborative Care

Methods of treatment for Bell's palsy include moist heat, gentle massage, and electrical stimulation of the nerve and prescribed exercises. Stimulation may maintain muscle tone and prevent atrophy. Care is primarily focused on relief of symptoms, prevention of complications, and protection of the eye on the affected side.

Corticosteroids (prednisone) are started immediately, with best results if corticosteroids are initiated before paralysis is complete. When the patient improves to the point that the corticosteroids are no longer necessary, the drug should be tapered over a 2-week period. Because HSV is implicated in approximately 70% of cases of Bell's palsy, treatment with acyclovir (Zovirax), alone or in conjunction with prednisone, may be used. Additional antiviral agents, including valacyclovir

(Valtrex) and famciclovir (Famvir), have also been used in the management of Bell's palsy.

NURSING MANAGEMENT BELL'S PALSY

The patient with Bell's palsy is treated on an outpatient basis. Mild analgesics can relieve pain. Hot wet packs can reduce the discomfort of herpetic lesions, aid circulation, and relieve pain. Tell the patient to protect the face from cold and drafts because trigeminal *hyperesthesia* (extreme sensitivity to pain or touch) may occur. Maintenance of good nutrition is important. Teach the patient to chew on the unaffected side of the mouth to avoid trapping food and to enjoy the taste of food. Thorough oral hygiene must be carried out after each meal to prevent parotitis, caries, and periodontal disease from accumulated residual food.

The patient may wear dark glasses for protective and cosmetic reasons. Artificial tears (methylcellulose) should be instilled frequently during the day to prevent drying of the cornea. Ointment and an impermeable eye shield can be used at night to retain moisture. In some patients, taping the lids closed at night may be necessary to provide protection. Instruct the patient to report ocular pain, drainage, or discharge.

A facial sling may be helpful to support affected muscles, improve lip alignment, and facilitate eating. The facial sling is usually made and fitted by a physical or occupational therapist. When function begins to return, active facial muscle exercises are performed several times a day.

The change in physical appearance as a result of Bell's palsy can be devastating. Reassure the patient that a stroke did not occur and that chances for a full recovery are good. Enlisting support from family and friends is important. Tell the patient that most patients recover within about 6 weeks of the onset of symptoms.

POLYNEUROPATHIES

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (Landry-Guillain-Barré-Strohl syndrome, postinfectious polyneuropathy, ascending polyneuropathic paralysis) is an acute, rapidly progressing, and potentially fatal form of polyneuritis. It is characterized by ascending, symmetric paralysis that usually affects cranial nerves and the peripheral nervous system. The syndrome is rare, affecting an estimated 3000 to 6000 Americans each year. It affects males and females equally.[5,6]

Etiology and Pathophysiology

The etiology of this disorder is unknown. Both cellular and humoral immune mechanisms play a role in the immune reaction directed at the nerves. The result is a loss of myelin (a segmental demyelination) and edema and inflammation of the affected nerves. As demyelination occurs, the transmission of nerve impulses is stopped or slowed down. The muscles innervated by the damaged peripheral nerves undergo denervation and atrophy. In the recovery phase, remyelination occurs slowly, and neurologic function returns in a proximal-to-distal pattern.[6] Guillain-Barré syndrome is similar in presentation to multiple sclerosis (MS), and therefore a full diagnostic workup should be performed to rule out MS (see Chapter 59).

The syndrome is often preceded by immune system stimulation from a viral infection, trauma, surgery, or viral immunizations. *Campylobacter jejuni* gastroenteritis is thought to precede Guillain-Barré syndrome in approximately 30% of cases.[5-7]

Clinical Manifestations and Complications

Guillain-Barré syndrome is a heterogeneous condition with manifestations ranging from mild to severe. Weakness of the lower extremities (evolving more or less symmetrically) occurs over hours to days to weeks, usually peaking about the fourteenth day. *Paresthesia* (numbness and tingling) is common, with paralysis usually following in the extremities. *Hypotonia* (reduced muscle tone) and *areflexia* (lack of reflexes) are common manifestations.[5-7]

In Guillain-Barré syndrome, autonomic nervous system dysfunction results, with manifestations of orthostatic hypotension, hypertension, and abnormal vagal responses (bradycardia, heart block, asystole). Other autonomic dysfunctions include bowel and bladder dysfunction, facial flushing, and diaphoresis. Patients may also have syndrome of inappropriate antidiuretic hormone (SIADH) secretion.[8] (SIADH is discussed in Chapter 50.) Cranial nerve involvement is manifested as facial weakness, extraocular eye movement difficulties, dysphagia, and paresthesia of the face.

Pain is a common symptom in the patient with Guillain-Barré syndrome. The pain can be paresthesias, muscular aches and cramps, and hyperesthesias. Pain appears to be worse at night. Opioids may be indicated for those experiencing severe pain. Pain may lead to a decrease in appetite and may interfere with sleep.

The most serious complication is respiratory failure, which occurs as the paralysis progresses to the nerves that innervate the thoracic area. Constant monitoring of the respiratory system by checking respiratory rate and depth provides information about the need for immediate intervention, including intubation and mechanical ventilation. Respiratory or urinary tract infections (UTIs) may occur. Immobility from the paralysis can cause problems such as paralytic ileus, muscle atrophy, deep vein thrombosis, pulmonary emboli, skin breakdown, orthostatic hypotension, and nutritional deficiencies.

Diagnostic Studies

Diagnosis is based primarily on the patient's history and clinical signs. Cerebrospinal fluid (CSF) is normal or has a low protein content initially, but after 7 to 10 days it shows an elevated protein level (normal protein is 15 to 45 mg/dL [0.15 to 0.45 g/L]) with a normal cell count. Results of EMG and nerve conduction studies are markedly abnormal (reduced nerve conduction velocity) in the affected extremities. A brain MRI can be done to rule out MS.

NURSING AND COLLABORATIVE MANAGEMENT GUILLAIN-BARRÉ SYNDROME

Management of Guillain-Barré syndrome is aimed at supportive care, particularly ventilatory support, during the acute phase. Plasmapheresis is used in the first 2 weeks. (Plasmapheresis is discussed in Chapter 14.) IV administration of high-dose immunoglobulin (Sandoglobulin) has been as effective as plasma exchange and is more readily available.

Beyond 3 weeks after disease onset, plasmapheresis and immunoglobulin therapies have little value. Corticosteroids appear to have little effect on the prognosis or duration of the disease.

Assessment of the patient is the most important aspect of nursing care during the acute phase. During the routine

assessment, monitor the ascending paralysis; assess respiratory function; monitor arterial blood gases (ABGs); and assess the gag, corneal, and swallowing reflexes. Reflexes are usually decreased or absent.

Monitor blood pressure (BP) and cardiac rate and rhythm during the acute phase because dysrhythmias may occur. Autonomic dysfunction is common and usually takes the form of bradycardia and dysrhythmias. Orthostatic hypotension secondary to muscle atony may occur in severe cases. Vasopressor agents and volume expanders may be needed to treat the low BP. However, the presence of SIADH may require fluid restriction.

The objective of therapy is to support body systems until the patient recovers. Respiratory failure and infection are serious threats. Monitoring the vital capacity and ABGs is essential. If the vital capacity drops to less than 800 mL or the ABGs deteriorate, endotracheal intubation or tracheostomy may be done so that the patient can be mechanically ventilated (see Chapter 68). If fever develops, obtain sputum cultures to identify the pathogen. Appropriate antibiotic therapy is then initiated.

Nutritional needs must be met in spite of possible problems associated with delayed gastric emptying, paralytic ileus, and potential for aspiration if the gag reflex is lost. In addition to testing for the gag reflex, note drooling and other difficulties with secretions that may indicate an inadequate gag reflex. Initially, enteral or parenteral nutrition may be used to ensure adequate caloric intake. Because of delayed gastric emptying, assess residual volumes of the feedings at regular intervals or before feedings (see Chapter 40).

Throughout the course of the illness, provide support and encouragement to the patient, caregiver, and family. Although 85% to 95% of patients almost completely recover, it is generally a slow process that takes months or years. About 30% of those with Guillain-Barré have some residual weakness.[5-7]

BOTULISM

Botulism is rare but the most serious type of food poisoning. It is caused by gastrointestinal (GI) absorption of the neurotoxin produced by *Clostridium botulinum.* This organism is found in the soil, and the spores are difficult to destroy. It can grow in any food contaminated with the spores. Improper home canning of foods is often the cause.[9] It is thought that the neurotoxin destroys or inhibits the neurotransmission of acetylcholine at the myoneural junction, resulting in disturbed muscle innervation.

Neurologic manifestations can develop rapidly or evolve over several days. They include a descending paralysis with muscle incoordination and weakness, difficulty swallowing, seizures, and respiratory muscle weakness that can rapidly deteriorate to respiratory and/or cardiac arrest.

The clinical manifestations, prevention, and treatment are presented in Table 42-24. Patient and caregiving teaching related to food poisoning are presented in Table 42-25. Nursing care during the acute illness is similar to that for Guillain-Barré syndrome. Supportive nursing interventions include rest, activities to maintain respiratory function, adequate nutrition, and prevention of loss of muscle mass.

TETANUS

Tetanus (lockjaw) is a severe infection of the nervous system affecting spinal and cranial nerves. It results from the effects of a potent neurotoxin released by the anaerobic bacillus *Clostridium tetani.* The spores of the bacillus are present in soil, garden mold, and manure. *C. tetani* enters the body through a wound that provides an appropriate low-oxygen environment for the organisms to mature and produce toxin. Examples of possible wounds include IV drug use injection sites, human and animal bites, burns, frostbite, open fractures, and gunshot wounds.[10,11]

Initial manifestations of tetanus include stiffness in the jaw *(trismus)* and neck and signs of infection (e.g., fever). As the disease progresses, the neck muscles, back, abdomen, and extremities become progressively rigid. In severe forms, continuous tonic seizures may occur with *opisthotonos* (extreme arching of the back and retraction of the head). Laryngeal and respiratory spasms cause apnea and anoxia. The slightest noise, jarring motion, or bright light can set off a seizure. These seizures are agonizingly painful. Mortality rate is almost 100% in the severe form.[11]

Tetanus prevention and immunizations, which are the most important factors influencing the incidence of this disease, are summarized in Table 69-6. Adults should receive a tetanus and diphtheria toxoid booster every 10 years. Teach the patient that immediate, thorough cleansing of all wounds with soap and water is important to prevent tetanus. If an open wound occurs and the patient has not been immunized within 5 years, the health care provider should be contacted so that a tetanus booster can be given.

The management of tetanus includes administration of a tetanus toxoid, diphtheria toxoid, and pertussis (Tdap) booster and tetanus immune globulin (TIG) in different sites before the onset of symptoms to neutralize circulating toxins (see Table 69-6). A much larger dose of TIG is administered to patients with clinical manifestations of tetanus.[10-12]

Control of spasms is essential and is managed by sedation and skeletal muscle relaxation, usually with diazepam (Valium), barbiturates, and, in severe cases, neuromuscular blocking agents such as vecuronium (Norcuron) that act to paralyze skeletal muscles. Opioid analgesics such as morphine or fentanyl are also indicated for pain management. A 10- to 14-day course of penicillin, metronidazole, tetracycline, or doxycycline is recommended to inhibit further growth of *C. tetani.*[11]

Because of laryngospasm and the potential need for neuromuscular blocking drugs, a tracheostomy is usually performed early and the patient is maintained on mechanical ventilation. Sedative agents and opioid analgesics are given concomitantly to all patients who are pharmacologically paralyzed. Any recognized wound should be debrided or an abscess drained. Antibiotics may be given to prevent secondary infections.

NEUROSYPHILIS

Neurosyphilis is caused by *Treponema pallidum,* the bacteria that cause syphilis. It usually occurs about 10 to 20 years after a person is first infected with syphilis. Not everyone who has syphilis will develop this complication. It is the result of untreated or inadequately treated syphilis (see Chapter 53). The organism can invade the central nervous system within a few months of the original infection. Untreated neurosyphilis, although not contagious, can be fatal.

Late neurosyphilis results from degenerative changes in the spinal cord (tabes dorsalis) and brainstem (general paresis). *Tabes dorsalis* (progressive locomotor ataxia) is characterized by

vague, sharp pains in the legs; ataxia; "slapping" gait; loss of proprioception and deep tendon reflexes; and zones of hyperesthesia. *Charcot's joints,* which are characterized by enlargement, bone destruction, and hypermobility, also occur as a result of joint effusion and edema. Other manifestations of neurosyphilis include seizures, vision and hearing problems, and cognitive impairment.[13]

Management includes treatment with penicillin, symptomatic care, and protection from physical injury.[13] The prognosis after treatment depends on how severe the neurosyphilis is before treatment. The neurologic deficits may remain or progress after treatment.

SPINAL CORD PROBLEMS

SPINAL CORD INJURY

Spinal cord injury (SCI) is caused by trauma or damage to the spinal cord. It can result in either a temporary or permanent alteration in the function of the spinal cord. About 12,000 Americans suffer SCIs each year. About 260,000 persons in the United States are living with SCI.[14,15] With improved treatment strategies, even the very young patient with an SCI can anticipate a long life. The potential for disruption of individual growth and development, altered family dynamics, economic loss in terms of employment, and the high cost of rehabilitation and long-term health care make SCI a major problem.

Young adult men between ages 16 and 30 years have the greatest risk for SCI. Eighty-one percent of people with SCI are male. There has also been an increase in the number of older adults with SCIs. This trend toward older age at time of injury is reflected in the overall increase in mean age of people with SCI from 28 years in the 1970s to 40 years at this time.[15]

Although many people with SCIs can care for themselves independently, those with the highest level of injury may require round-the-clock care at home or in a long-term care facility. Almost 90% of patients with SCI are discharged from the hospital to home or another noninstitutional residence. The remaining 10% are discharged to nursing homes, chronic care facilities, or group homes.

Etiology and Pathophysiology

SCIs are usually a result of trauma. The most common causes are motor vehicle collisions (42%), falls (27%), violence (15%), sports injuries (7%), and other miscellaneous causes (8%).[15]

Types of Injury. The extent of the neurologic damage caused by an SCI results from *primary injury* (actual physical disruption of axons) and *secondary injury* (ischemia, hypoxia, hemorrhage, and edema).

Primary Injury. The spinal cord is wrapped in tough layers of dura and is rarely torn or transected by direct trauma. SCI can be due to cord compression by bone displacement, interruption of blood supply to the cord, or traction resulting from pulling on the cord. Penetrating trauma, such as gunshot and stab wounds, can result in tearing and transection. The initial mechanical disruption of axons as a result of stretch or laceration is referred to as the *primary injury.*

Secondary Injury. *Secondary injury* refers to the ongoing, progressive damage that occurs after the primary injury.[16] Several theories exist on what causes this ongoing damage, including free radical formation, uncontrolled calcium influx, ischemia, and lipid peroxidation. *Apoptosis* (cell death) occurs and sometimes may continue for weeks or months after the initial injury. Thus the complete cord damage (previously thought to be transection) in severe trauma is related to autodestruction of the cord. Hemorrhagic areas in the center of the spinal cord appear within 1 hour, and by 4 hours there may be infarction in the gray matter.[16] This ongoing destructive process makes it critical that the initial care and management of the patient with an SCI be initiated as soon as possible to limit further destruction of the spinal cord.

Fig. 61-4 illustrates the cascade of events causing secondary injury after traumatic SCI. The resulting hypoxia reduces the oxygen levels below the metabolic needs of the spinal cord. Lactate metabolites and an increase in vasoactive substances, including norepinephrine, serotonin, and dopamine, are noted. At high levels, these vasoactive substances cause vasospasms and hypoxia, leading to subsequent necrosis. Unfortunately, the spinal cord has minimal ability to adapt to vasospasm.

By 24 hours or less, permanent damage may occur because of the development of edema. The edema secondary to the inflammatory response is particularly harmful because of lack

ETHICAL/LEGAL DILEMMAS

Right to Refuse Treatment

Situation

R.D., a 25-yr-old man, suffered a spinal cord injury (SCI) to C7-8 following a motorcycle accident. He was diagnosed with anterior cord syndrome and has motor paralysis, which may prevent him from riding motorcycles again. He has become extremely depressed and no longer wishes to live. Because of his emotional state, R.D. is now refusing to eat. Can he be forced to receive enteral nutrition (tube feeding)?

Ethical/Legal Points for Consideration

- Withholding treatment in a newly injured but otherwise healthy young adult may present an ethical dilemma for some nurses. They may consider it assisted suicide and believe that it violates an ethical principle.
- A competent adult has the right to consent to or refuse medical treatment under the right to privacy, the Fourteenth Amendment of the Constitution, and case law.*
- Case law has also supported the concept that forced treatment constitutes battery (unlawful use of force on somebody). Furthermore, a mentally competent, physically incapacitated adult can refuse feeding by nasogastric tube and compel the health facility to follow the patient's wishes.†
- To be competent to participate in informed consent or refusal, an adult must be able to understand the information provided about the procedure or treatment, consider choices between alternatives available, and make a choice based on his values and preferences. Depression may not be a determinant in competency to make informed treatment choices.
- If, after adequate treatment for pain, depression, or other medical conditions, the patient persists in his refusal, his wishes must be respected.
- Refusal to eat or drink has never been upheld as illegal, and the alternative—forced eating and drinking—is clearly a violation of patient rights and the criminal act of battery.

Discussion Questions

1. What are your feelings about requests to withhold treatment in a young person with a newly acquired disability?
2. What resources are available to help R.D., his family, and the staff work through this emotionally charged and ethically complex situation?

of space for tissue expansion. Therefore compression of the spinal cord occurs. Edema extends above and below the injury, thus increasing the ischemic damage. Because secondary injury progresses over time, the extent of the injury and prognosis for recovery are most accurately determined at least 72 hours or more after injury.

Spinal and Neurogenic Shock. About 50% of people with acute SCI experience a temporary neurologic syndrome known as **spinal shock.** This type of shock is characterized by decreased reflexes, loss of sensation, and flaccid paralysis below the level of injury.[16] This syndrome lasts days to months and may mask postinjury neurologic function.

Neurogenic shock, in contrast to spinal shock, is due to the loss of vasomotor tone caused by injury and is characterized by hypotension and bradycardia. Loss of sympathetic nervous system innervation causes peripheral vasodilation, venous pooling, and a decreased cardiac output. These effects are generally associated with a cervical or high thoracic injury (T6 or higher).

Classification of Spinal Cord Injury. SCIs are classified by the (1) mechanism of injury, (2) level of injury, and (3) degree of injury.

Mechanisms of Injury. The major mechanisms of injury are flexion, hyperextension, flexion-rotation, extension-rotation, and compression[17] (Fig. 61-5). The flexion-rotation injury is the most unstable of all because the ligamentous structures that stabilize the spine are torn. This injury is most often implicated in severe neurologic deficits.

Level of Injury. *Skeletal level* of injury is the vertebral level where there is the most damage to vertebral bones and ligaments. *Neurologic level* is the lowest segment of the spinal cord with normal sensory and motor function on both sides of the body. The level of injury may be cervical, thoracic, lumbar, or sacral. Cervical and lumbar injuries are most common because these levels are associated with the greatest flexibility and movement. If the cervical cord is involved, paralysis of all four extremities occurs, resulting in **tetraplegia** (formerly termed *quadriplegia*). However, when the damage is low in the cervical cord, the arms are rarely completely paralyzed.

If the thoracic, lumbar, or sacral spinal cord is damaged, the result is **paraplegia** (paralysis and loss of sensation in the legs). Fig. 61-6 shows affected structures and functions at different levels of cord injury.

Degree of Injury. The degree of spinal cord involvement may be either complete or incomplete (partial). *Complete cord involvement* results in total loss of sensory and motor function below the level of injury. *Incomplete cord involvement* results in a mixed loss of voluntary motor activity and sensation and leaves some tracts intact. The degree of sensory and motor loss varies depending on the level of injury and reflects the specific nerve tracts damaged.[16]

Six syndromes are associated with incomplete injuries: central cord syndrome, anterior cord syndrome, Brown-Séquard syndrome, posterior cord syndrome, cauda equina syndrome, and conus medullaris syndrome[16] (Table 61-3).

Clinical Manifestations

The manifestations of SCI are generally the direct result of trauma that causes cord compression, ischemia, edema, and possible cord transection. Manifestations of SCI are related to the level and degree of injury. The patient with an incomplete injury may demonstrate a mixture of manifestations. The higher the injury, the more serious the sequelae because of the proximity of the cervical cord to the medulla and brainstem.[16,17]

American Spinal Injury Association (ASIA) Impairment Scale. The American Spinal Injury Association (ASIA) Impairment Scale is commonly used for classifying the severity of impairment resulting from SCI. It combines assessments of motor and sensory function to determine neurologic level and completeness of injury (Fig. 61-7, and eFig. 61-2, available on the website for this chapter).

The sensory regions are called *dermatomes,* with each segment of the spinal cord innervating a particular area of skin. Each dermatome has a specific point recommended for testing, as shown in eFig. 61-2. A dermatome map is also shown in Fig. 56-6.

The ASIA Impairment Scale is useful for recording changes in neurologic status and identifying appropriate goals for rehabilitation. Movement and rehabilitation potential related to specific locations of the SCI are described in Table 61-4. In general, sensory function closely parallels motor function at all levels.

Respiratory System. Respiratory complications closely correspond to the level of injury. Cervical injuries above the level of C4 present special problems because of the total loss of respiratory muscle function. Mechanical ventilation is required to keep the patient alive. At one time the majority of these patients died at the scene of the injury, but with improved emergency medical services, more of these patients are surviving the initial events of their SCI.

Injury or fracture below the level of C4 results in diaphragmatic breathing if the phrenic nerve is functioning. Even if the injury is below C4, spinal cord edema and hemorrhage can affect the function of the phrenic nerve and cause respiratory insufficiency. Hypoventilation almost always occurs with dia-

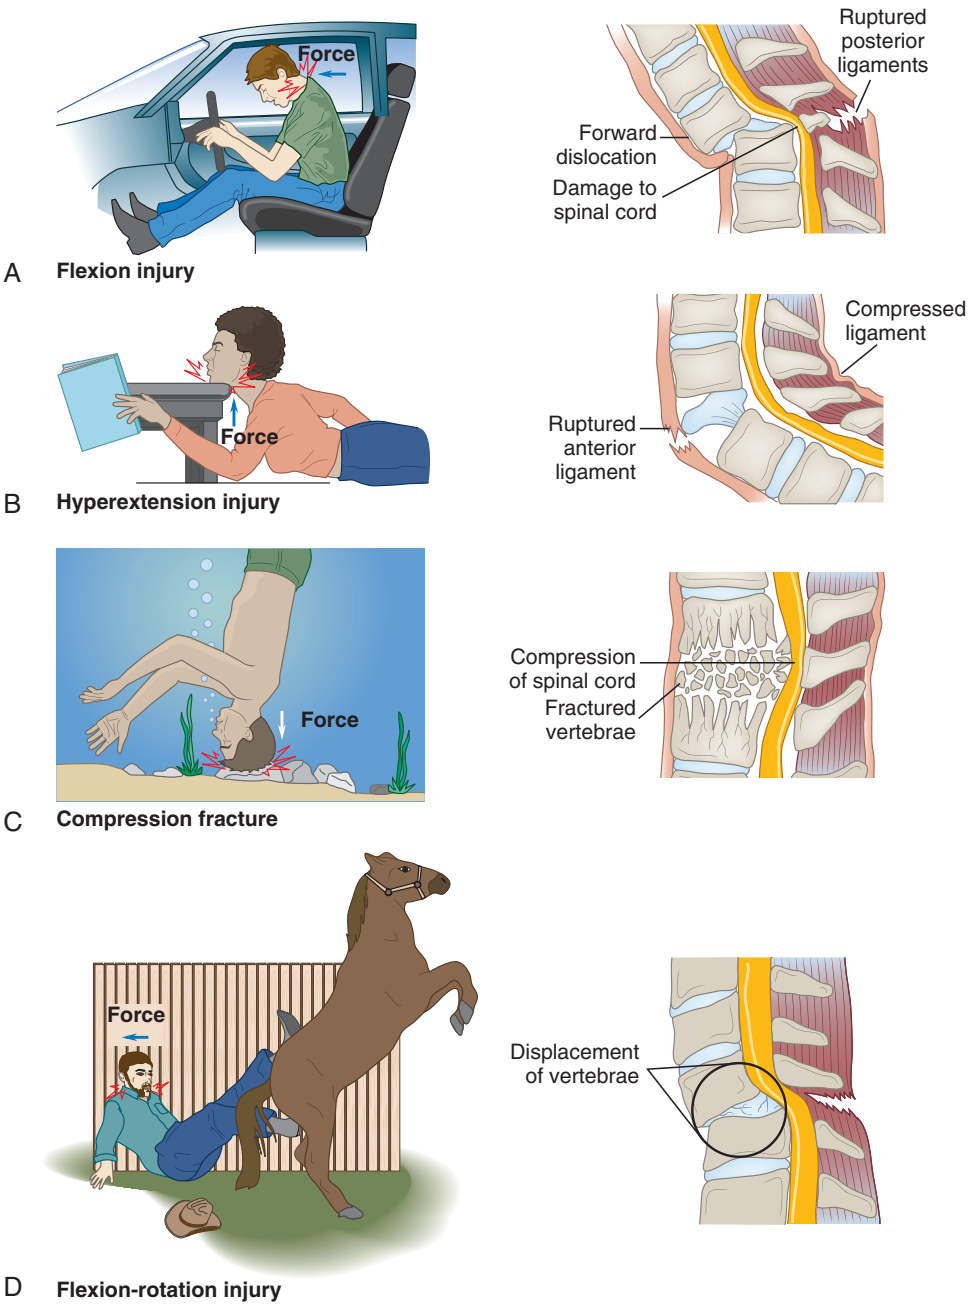

FIG. 61-5 Mechanisms of spinal cord injury. Many situations may produce these injuries. This only shows some examples. **A,** Flexion injury of the cervical spine ruptures the posterior ligaments. **B,** Hyperextension injury of the cervical spine ruptures the anterior ligaments. **C,** Compression fractures crush the vertebrae and force bony fragments into the spinal canal. **D,** Flexion-rotation injury of the cervical spine often results in tearing of ligamentous structures that normally stabilize the spine.

phragmatic respirations because of the decrease in vital capacity and tidal volume, a result of impairment of the intercostal muscles.

Cervical and thoracic injuries cause paralysis of abdominal muscles and often the intercostal muscles. Therefore the patient cannot cough effectively enough to remove secretions, leading to atelectasis and pneumonia. An artificial airway provides direct access for pathogens, making bronchial hygiene and chest physiotherapy extremely important measures to reduce infection. Neurogenic pulmonary edema may occur secondary to a dramatic increase in sympathetic nervous system activity at the time of injury, which shunts blood to the lungs. In addition, pulmonary edema may occur in response to fluid overload.

Cardiovascular System. Any cord injury above the level of T6 greatly decreases the affect of the sympathetic nervous system. Bradycardia occurs. Peripheral vasodilation results in hypotension. A relative hypovolemia exists because of the increase in the capacity of the dilated veins. Cardiac monitoring is necessary. In marked bradycardia (heart rate less than 40 beats/minute), appropriate drugs (e.g., atropine) to increase the heart rate and prevent hypoxemia are necessary. The peripheral vasodilation reduces the venous return of blood to the

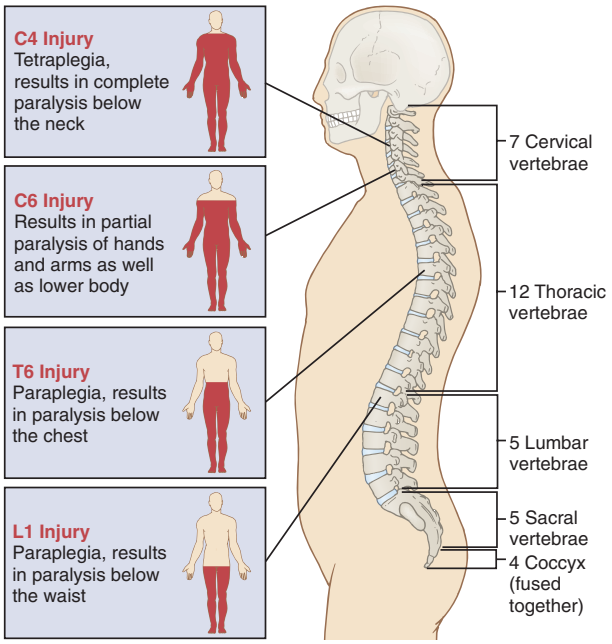

FIG. 61-6 Symptoms, degree of paralysis, and potential for rehabilitation depend on the level of the injury.

American Spinal Injury Association (ASIA) Impairment Scale

- ☐ **A = Complete:** No motor or sensory function is preserved in the sacral segments S4-5.
- ☐ **B = Incomplete:** Sensory but not motor function is preserved below the neurologic level and includes the sacral segments S4-5.
- ☐ **C = Incomplete:** Motor function is preserved below the neurologic level, and more than half of key muscles below the neurologic level have a muscle grade less than 3.
- ☐ **D = Incomplete:** Motor function is preserved below the neurologic level, and at least half of key muscles below the neurologic level have a muscle grade of 3 or more.
- ☐ **E = Normal:** Motor and sensory function are normal.

FIG. 61-7 The American Spinal Injury Association Impairment Scale. See eFig. 61-2 on the website for this chapter for standard neurologic classification of spinal cord injury.

TABLE 61-3 INCOMPLETE SPINAL CORD INJURY SYNDROMES

Description	Manifestations
Central Cord Syndrome	
• Caused by damage to the central spinal cord (see eFig. 61-1). • Occurs most commonly in the cervical cord region. • More common in older adults.	• Motor weakness and sensory loss are present in both upper and lower extremities. • Upper extremities are affected more than the lower ones.
Anterior Cord Syndrome	
• Caused by damage to the anterior spinal artery. • Results in compromised blood flow to the anterior spinal cord. • Typically results from injury causing acute compression of anterior portion of the spinal cord, often a flexion injury (see eFig. 61-1).	• Motor paralysis and loss of pain and temperature sensation below the level of injury. • Because posterior cord tracts are not injured, sensations of touch, position, vibration, and motion remain intact.
Brown-Séquard Syndrome	
• Results from damage to one half of the spinal cord (see eFig. 61-1). • Typically results from penetrating injury to spinal cord.	• *Ipsilateral* (same side as injury): Loss of motor function and position and vibratory sense, vasomotor paralysis. • *Contralateral* (opposite side of injury): Loss of pain and temperature sensation below the level of injury.
Posterior Cord Syndrome	
• Results from compression or damage to the posterior spinal artery. • Very rare condition.	• Generally the dorsal columns are damaged, resulting in loss of proprioception. • Pain, temperature sensation, and motor function below the level of injury remain intact.
Conus Medullaris Syndrome and Cauda Equina Syndrome	
• Result from damage to conus (lowest portion of the spinal cord) and cauda equina (lumbar and sacral nerve roots).	• Flaccid paralysis of the lower limbs and areflexic (flaccid) bladder and bowel.

heart and subsequently decreases cardiac output, resulting in hypotension. IV fluids or vasopressor drugs may be required to support the BP.

Urinary System. Urinary retention is a common development in acute SCI and spinal shock. While the patient is in spinal shock, the bladder is atonic and becomes overdistended. An indwelling catheter is inserted to drain the bladder. In the postacute phase the bladder may become hyperirritable, with a loss of inhibition from the brain resulting in reflex emptying. Chronic indwelling catheterization increases the risk of infection.

Gastrointestinal System. If the SCI has occurred above the level of T5, the primary GI problems are related to hypomotility. Decreased GI motor activity contributes to the development of paralytic ileus and gastric distention. A nasogastric tube for intermittent suctioning may relieve the gastric distention. Metoclopramide (Reglan) may be used to treat delayed gastric emptying. The development of stress ulcers is common because of excessive release of hydrochloric (HCl) acid in the stomach.

Intraabdominal bleeding may occur and is difficult to diagnose because the person with an SCI may experience no pain or tenderness. Continued hypotension in spite of vigorous treatment and decreased hemoglobin and hematocrit may be indications of bleeding. Expanding girth of the abdomen may also be noted.

Loss of voluntary neurologic control over the bowel results in a *neurogenic bowel.* In the early period after injury when spinal shock is present and for patients with an injury level of T12 or below, the bowel is *areflexic* and sphincter tone is decreased. As reflexes return, the bowel becomes *reflexic,* sphincter tone is enhanced, and reflex emptying occurs. Both areflexic and reflexic neurogenic bowel can be managed successfully with a regular bowel program coordinated with the gastrocolic reflex to minimize fecal incontinence.

Integumentary System. A major consequence of lack of movement is the potential for skin breakdown over bony prom-
